

HINTS TO MOTHERS FOR THE MANAGEMENT OF THEIR HEALTH DURING THE PERIOD OF PREGNANCY AND IN THE LYING-IN ROOM ;

With an Exposure of Popular Errors in connection with those subjects, and Hints on Nursing. By THOMAS BULL, M.D. New and Cheaper Edition, thoroughly revised and improved. Fcap. 8vo, price 2s. 6d.

THE MATERNAL MANAGEMENT OF CHILDREN IN HEALTH AND DISEASE.

By the same Author. New and cheaper Edition, thoroughly revised and improved. Fcap. 8vo, price 2s. 6d.

THE HANDBOOK FOR MIDWIVES.

By HENRY FLY SMITH, M.B. Oxon., M.R.C.S., late Assistant-Surgeon at the Hospital for Sick Women, Soho Square. With 41 Woodcuts. Crown 8vo, price 5s.

Materia Medica and Therapeutics.

THOMSON'S CONSPECTUS ADAPTED TO THE BRITISH PHARMACOPŒIA.

By EDMUND LLOYD BIRKETT, M.D., &c., Physician to the City of London Hospital for Diseases of the Chest. Latest Edition, with Supplement containing Notices of the Medicines and Preparations added in 1874 to the British Pharmacopœia. 18mo, 6s.

THE ESSENTIALS OF MATERIA MEDICA AND THERAPEUTICS.

By ALFRED BARING GARROD, M.D., F.R.S., Fellow of the Royal College of Physicians; Consulting Physician to King's College Hospital; late Professor of Therapeutics at King's College, London. The Ninth Edition, revised and edited, under the supervision of the Author, by E. B. BAXTER, M.D., F.R.C.P., Professor of Materia Medica and Therapeutics in King's College, London; Senior Physician to the Evelina Hospital for Sick Children; Assistant-Physician to King's College Hospital. Crown 8vo, price 12s. 6d.

DR. PEREIRA'S MATERIA MEDICA AND THERAPEUTICS,

Abridged, and adapted for the use of Medical and Pharmaceutical Practitioners and Students. Edited by Professor R. BENTLEY, M.R.C.S., F.L.S., and by Professor T. REDWOOD, Ph.D., F.C.S. With an Appendix containing the New Medicines included in 1874 by the Medical Council in the British Pharmacopœia, and Commentaries thereon by the Editors. 8vo, with 126 Woodcuts, price 25s.

A DICTIONARY
OF
C H E M I S T R Y
AND THE
ALLIED BRANCHES OF OTHER SCIENCES.

BY
HENRY WATTS, B.A., F.R.S., F.C.S.
EDITOR OF
'THE JOURNAL OF THE CHEMICAL SOCIETY.'

ASSISTED BY EMINENT CONTRIBUTORS.

THIRD SUPPLEMENT.
PART II.

LONDON:
LONGMANS, GREEN, AND CO.
1881.

PREFACE.

THE second and concluding Part of the EIGHTH VOLUME (or Third Supplement) of this Dictionary brings the Record of Chemical Discovery down to the end of the year 1878, including the more important discoveries which have appeared in 1879 and 1880.

The Author has the pleasure of acknowledging the assistance of the following gentlemen who have contributed Articles to this Part.

DICTIONARY OF CHEMISTRY.

THIRD SUPPLEMENT.

(SECOND PART.)

G

GALACTOSE. See SUGARS.

GALENA. See LEAD SULPHIDE.

GALLIC ACID. *Trioxybenzoic acid*, $C^7H^6O^5 = C^6H^2(OH)^3CO^2H$, probably 1 : 2 : 4 : 5 (CO^2H in 1), see p. 292.—This acid is formed by the action of melting potash on di-iodosalicylic, di-iodoparaoxybenzoic, bromoprotocatechuic, and monobromodioxybenzoic acids (Barth a. Senhofer, *Deut. Chem. Ges. Ber.* viii. 754, 1477).

Gallic acid, like salicylic, oxybenzoic, paraoxybenzoic, and protocatechuic acid, is completely oxidised by chromic acid mixture, with rapid evolution of carbon dioxide (Remsen, *Sill. Am. J.* [3], v. 354). Dry gallic acid, triturated in a mortar with dry powder of potassium permanganate, takes fire and gives out sparks (Böttger, *Pogg. Ann. Jubelbd.* 1874, 156),

A mixture of gallic and benzoic acids, treated with sulphuric acid, yields a compound, $C^{14}H^8O^5$, which is also formed by the action of sulphuric acid on a mixture of pyrogallol and phthalic anhydride. This compound is oxidised by nitric acid, yielding phthalic acid. By oxidation with sulphuric acid and manganese dioxide, it is converted into purpurin, and by reduction with sodium-amalgam into alizarin. Hence it appears to be a tri-hydroxyl-anthraquinone (*anthragallol*),

the three hydroxyls being probably in the relative positions 1 : 2 : 3 (Seuberlich, *Deut. Chem. Ges. Ber.* x. 38).

Gallic acid heated with excess of bromine yields tribromopyrogallol, $C^6Br^3(OH)^3$; by potassium chlorate and hydrochloric acid it is converted into is-trichloroglyceric acid, $C^6H^3Cl^3O^4$; and by the action of potassium permanganate, or its solution in cold water acidulated with sulphuric acid, into a condensation-product, $C^{14}H^{10}O^8$ (pp. 292, 293).

On its reaction with *potassium arsenate* in contact with the air, see p. 292.

GALLIUM. Ga. *Atomic Weight*, 69.865 (Lecoq de Boisbaudran, *Compt. rend.* 1875, lxxxi. 493, 1100; 1876, lxxxii. 1036, 1098; lxxxiii. 611, 663, 824, 1044; *Bull. Soc. Chim.* [2], xxv. 521; xxvi. 433; *Ann. Chim. Phys.* [5], x. 100-140; Lecoq de Boisbaudran a. Jungfleisch, *Compt. rend.* lxxxvi. 577; A. Dupré, *ibid.* 720). A metal discovered in August 1875 by De Boisbaudran, in a zinc-blende from the mine of Pierrefitte in the valley of Argelès, Pyrenees; found also in blendes from other localities, especially in the black blende of Bensberg, and the yellow transparent blende from Asturias. To separate it, the mineral, according to its nature, is dissolved in nitrohydrochloric, hydrochloric, or sulphuric acid; plates of zinc are placed in the solution, till the disengagement of hydrogen becomes slow, but is still perceptible, by which means the greater portions of the copper, lead, cadmium, iridium, thallium, silver, mercury, selenium, arsenic, &c., contained in the ore are precipitated; the clear filtered liquid is heated with a large excess of zinc; the resulting gelatinous precipitate, consisting chiefly of alumina, basic salts of zinc, and finally gallium, is redissolved in hydrochloric acid; and the solution is again heated with zinc, whereby a second gelatinous precipitate is obtained, in which the gallium is concentrated in a mass of smaller bulk. This precipitate is redissolved in hydrochloric acid; the solution is treated with hydrogen sulphide; and the filtered liquid, after expulsion of the hydrogen sulphide, is fractionally precipitated with ammonium carbonate, till the solution of the resulting precipitate in hydrochloric acid no longer gives any indication

of the presence of gallium when examined by the spectroscope (*infra*). To complete the separation of the zinc, the precipitated hydroxides and basic salts are dissolved in sulphuric acid, and the solution is cautiously evaporated till the whole or nearly the whole of the free sulphuric acid is expelled; the residue, after cooling, is digested with water till it is dissolved; the nearly neutral solution of the sulphate thus obtained is heated to boiling; the basic gallium sulphate thereby precipitated is filtered off hot, and dissolved in a small quantity of sulphuric acid; the solution is treated with a slight excess of potash, which first precipitates and then redissolves the gallium oxide; and this oxide is precipitated from the alkaline solution by a stream of carbon dioxide. Finally the gallium oxide is redissolved in the smallest possible quantity of sulphuric acid; the solution is mixed with excess of slightly acid ammonium acetate; hydrogen sulphide is passed into the liquid; the filtered acetic solution is diluted with water and heated to boiling, whereby the greater part of the gallium is precipitated as oxide; this precipitate is filtered off hot, washed with boiling water, and redissolved in sulphuric acid; and the solution is mixed with a slight excess of potash, and filtered, whereby a pure alkaline solution of gallium is obtained.

Metallic gallium is prepared by the electrolysis of this alkaline solution, platinum electrodes being used, and the positive electrode being larger than the negative, on which the gallium is precipitated. A Bunsen's battery of five or six ordinary-sized pairs is sufficient for the electrolysis of 20-30 c.c. of the strong alkaline solution. The precipitated gallium is easily detached by dipping the platinum plate into warm water, and bending it backwards and forwards, or pressing it between the fingers; it may be purified by immersing it for half-an-hour at 60°-70° in dilute nitric acid free from chlorine.

Gallium thus precipitated forms a closely adherent layer, somewhat whiter than platinum, hard, and acquiring a good polish by pressure. When the strength of the current is properly regulated, the metal exhibits a fine, dull, silver-white surface, full of shining points consisting of microscopic crystals. It melts at 30.16°, and therefore at the heat of the hand, and may remain for weeks in a state of surfusion even at temperatures near 0°. In the liquid state it has a fine silvery whiteness, but on touching its surface with a small piece of solid gallium, a spot is formed which rapidly extends, the change being due to the crystallisation of the metal, which in solidifying acquires a decided bluish tinge, with diminished lustre. Distinct crystals may be obtained by dipping into the fused metal, cooled 10°-15° below its melting point, a piece of platinum with a particle of solid gallium attached to it. In from 3 to 10 seconds octohedrons form, modified at the summit by traces of the base OP. If these crystals are not directly removed, the metal becomes heated nearly to its melting point, solidification is retarded, and the basal face is so much developed that large tables are formed. The crystals are brilliant, but difficult to measure on account of their faces being slightly rounded. Gallium is hard, but nevertheless leaves a bluish-grey trace on paper. It has but little malleability, spreads under the hammer, and acquires the polish of the anvil, but soon becomes brittle and splits at the edges. In small bars it exhibits a remarkable degree of solidity, even at a temperature approaching its melting point. In thin sheets, which may be formed by fusing the metal between hot glass plates and detaching it under water after cooling, it can be bent several times at a sharp angle without breaking. Melted gallium readily adheres to glass, forming a mirror whiter than that produced by mercury. It preserves its lustre in the air, even of a laboratory, and in water free from air, but slowly tarnishes in ordinary water.

The specific gravity of gallium is 5.935 at 23° and 5.956 at 24.5° referred to water at the same temperatures.

Gallium heated to bright redness in contact with the air, oxidises merely on the surface, and does not volatilise. It dissolves in *hydrochloric acid* at ordinary temperatures, and more rapidly when heated, with disengagement of hydrogen. It is not sensibly attacked by *nitric acid* in the cold; but with the aid of heat it dissolves slowly, with evolution of nitrous vapours. *Aqueous potash* dissolves it slowly, with evolution of hydrogen.

Spectrum of Gallium.—When induction-sparks 1½ to 2 mm. long are passed between a positive external conductor and a negative solution of a gallium salt, a spectrum is produced containing a brilliant violet line (α) at 417 on the scale of wavelengths, and a faint band (β) at 403.1. In a gas-flame gallium shows only the line α , and even this is very faint and fugitive.

Reactions of Gallium Salts.—1. Metallic *zinc* does not precipitate gallium from acid solutions of its chloride or sulphate, but as soon as the solution has become basic, and the evolution of hydrogen very slow, the gallium is thrown down as an oxide, or more probably a basic salt, in white flocks mixed with basic salts of zinc.

It is therefore in reality a basic salt of zinc which precipitates the gallium; and, to render the latter insoluble, it is sufficient to heat the solution of zinc chloride containing gallium till it gives off hydrochloric acid and becomes basic; the highly concentrated solution may then still appear limpid, but on diluting it largely with water, it deposits zinc oxychloride mixed with gallium. The precipitation of gallium by zinc is slow at ordinary temperatures, not being completed for three weeks or a month when large quantities of solution are operated on, but at the boiling heat it is completed in a few hours. 2. *Cadmium* does not precipitate a solution of zinc chloride rich in gallium, even after long boiling.

3. *Ammonia* in excess forms a precipitate in gallium solutions, but a considerable proportion of the gallium is redissolved; and if the precipitate be dissolved in hydrochloric acid and ammonia again added in excess, the whole of the gallium remains in the ammoniacal solution. Gallium oxide appears to be more soluble in ammonia than alumina, for on repeatedly treating a mixed solution of the chlorides of the two metals with excess of ammonia, the first solutions obtained are rich in gallium, while the last precipitates contain nothing but aluminium. On adding ammonia drop by drop to zinc chloride containing a little gallium, the gallium is precipitated before the zinc, and quickly becomes concentrated in the first deposits, only an inappreciable quantity of it remaining in the mother-liquors.

4. *Ammonium Carbonate* appears to act like free ammonia.

5. *Fixed Caustic Alkalis*.—A small quantity of *potash* precipitates gallium oxide, and then acts like ammonia; but the precipitate is extremely soluble in excess of the alkali.

6. *Alkaline Carbonates*.—Carbonic acid precipitates gallium oxide from its solution in potash. Sodium carbonate precipitates gallium from the solutions of its salts, whether cold or warm. At boiling heat, a very small quantity of sodium carbonate forms in gallium salts a thick precipitate, which redissolves on cooling: this effect is due to the decomposition of neutral gallium salts by hot water, and the recombination of their constituents as the liquid cools. When a solution of zinc chloride containing gallium is fractionally precipitated with sodium carbonate, the greater part of the gallium is found in the earlier precipitates. In a mixed solution of gallium and aluminium also, the gallium is found chiefly in the earlier precipitates, but the separation is less complete than in the case of zinc.

7. *Acetic acid*.—Gallium is not precipitated from the slightly acid solutions of its chloride or sulphate by acid acetate of ammonium, but on heating the liquid, gallium oxide is thrown down in white gelatinous flocks, and does not redissolve, even at the boiling heat, except in presence of a considerable quantity of acetic acid. Nevertheless, if a large quantity of acid ammonium acetate or acetic acid be added, the liquid, when heated, will remain limpid. Neutral sulphate of gallium becomes turbid at ordinary temperatures when treated with a small quantity of acid ammonium acetate; but, on adding a large quantity of that reagent, the liquid becomes clear, and is no longer precipitated on boiling unless diluted with water. An ammoniacal solution of gallium chloride or sulphate is precipitated, whether cold or warm, by an excess of acetic acid, unless the liquid is very dilute, or the quantity of acetic acid added is very large.

8. *Hydrogen Sulphide*.—Slightly acid solutions of gallium chloride or sulphate are not precipitated by hydrogen sulphide, even in presence of acid ammonium acetate; but in slightly acid solutions of zinc chloride containing gallium, a considerable proportion of the latter metal is thrown down, together with the zinc sulphide. The precipitation of the gallium takes place more easily, but is by no means complete, if the solution, rich in zinc, be supersaturated with acid ammonium acetate. If the quantity of zinc in the solution is not sufficient to carry down all the gallium at the first precipitation, more zinc-salt must be added by small portions, till the precipitates, when examined by the spectroscope, no longer exhibit the line Ga α .

In a mixture containing a large quantity of zinc chloride, together with the chlorides of indium and gallium, fractional precipitation with hydrogen sulphide in presence of acid ammonium acetate gives successively: (1) A large quantity of indium, a moderate quantity of zinc, and traces of gallium. (2) A moderate quantity of indium, much zinc, and a notable quantity of gallium. (3) Traces of indium, much zinc, and a notable quantity of gallium.

9. *Ammonium Hydrosulphide* precipitates gallium in presence of zinc salts, both from neutral and from ammoniacal solutions, and does not redissolve it when added in excess, unless the quantity of zinc is so small as to be itself redissolved. When a neutral or slightly acid solution of zinc and gallium is treated with ammonium hydrosulphide containing free ammonia, the gallium is concentrated in the first precipitates of zinc sulphide; but, if the solution of zinc and gallium is ammoniacal,

the gallium becomes concentrated in the later precipitates. Ammonium hydrosulphide does not precipitate the ammoniacal solutions of pure chloride or sulphate of gallium.

10. *Barium Carbonate* easily precipitates gallium oxide from cold solutions. If zinc is also present, the separation of the two metals is less complete than that which is effected by fractional precipitation with sodium carbonate, a somewhat considerable quantity of zinc being precipitated together with the gallium.

11. *Potassium Ferrocyanide* gives a yellow precipitate with strongly acid solutions of gallium chloride.

Alloys of Aluminium and Gallium. The alloy obtained when excess of aluminium is heated with gallium to a dull red heat remains quite brilliant, and does not oxidise readily during its preparation. It decomposes water at the ordinary temperature, but more readily at 40°, with formation of a brown powder, which subsequently becomes changed into white flakes of alumina, almost the whole of the gallium being liberated, apparently free from aluminium. The slow evolution of hydrogen from this alloy, is increased by contact with a globule of liquid gallium, an electric couple being formed.

Aluminium and gallium also form liquid and pasty alloys, which oxidise slightly in the air, but decompose water readily. The liquid alloy, when touched with a piece of solid gallium, crystallises in a manner similar to metallic gallium, but it then no longer readily decomposes water (Lecoq de Boisbaudran, *Compt. rend.* lxxxvi. 1204).

Gallium Chloride, GaCl³. Chlorine strongly attacks gallium at ordinary temperatures, forming a nearly colourless crystalline chloride, which is very fusible, easily volatile, and absorbs moisture from the air (Lecoq de Boisbaudran a. Jungfleisch). The same compound is formed by dissolving gallium in hydrochloric acid. It is extremely soluble in water, and deliquescent. The residue left on slowly evaporating its solution absorbs moisture from the air, and liquefies, forming a limpid syrup, which remains clear on addition of a very small quantity of cold water, but yields with a larger quantity a copious white precipitate—doubtless an oxychloride—which collects quickly at the bottom of the vessel, redissolves slowly in cold dilute hydrochloric acid, more quickly when the liquid is heated. If a very small quantity of hydrochloric acid be added to dried gallium chloride, the compound dissolves in cold water, forming a solution which becomes turbid when heated and clear again on cooling. A slightly acid solution of the chloride evaporated at a gentle heat deposits needles and crystalline scales which act strongly on polarised light.

Repeated evaporation of solutions of gallium salts with excess of aqua regia is not attended with any loss of gallium by volatilisation of the chloride (De Boisbaudran).

Bromide. The action of bromine on gallium is less energetic than that of chlorine; nevertheless it commences in the cold, with disengagement of heat. The bromide is white and crystalline; less fusible and volatile than the chloride; deliquescent (De Boisbaudran a. Jungfleisch).

Iodide. The combination of iodine with gallium takes place less quickly than that of chlorine or of bromine, and requires the assistance of a gentle heat. The iodide is crystalline, and would doubtless be colourless if quite pure; but it is apt to retain traces of free iodine, and moreover decomposes partially when somewhat strongly heated. It is fusible and volatile, though less so than the bromide; its boiling point is higher than that of iodine, from which it may be separated by distillation in an inert gas. It is deliquescent (De Boisbaudran a. Jungfleisch).

Oxides. Gallium, when heated to bright redness in contact with the air, oxidises, as already observed, merely on the surface. In pure dry oxygen, no perceptible oxidation takes place at 260°; but at incipient redness, the metal begins to lose its lustre, and becomes covered with a very thin bluish-grey film; at a bright-red heat the coating of oxide becomes more distinct, but it then protects the metal from further action; the oxidation may however be somewhat facilitated by agitation of the liquid metal. A small quantity of the oxide thus formed collects as a sublimate on the cooler parts of the tube.

A more definite product is obtained by ignition of the nitrate (p. 845). This salt, heated to 200° in a current of dry air, decomposes with intumescence, giving off nitrous fumes and leaving a white fritted, very friable mass of oxide. The loss of weight sustained by the nitrate amounts to 63·8 per cent., which is exactly that which should be sustained by a salt having the composition Ga(NO³)³ or Ga²O³·3N²O⁵, when completely resolved into nitric anhydride and sesquioxide, supposing the atomic weight of gallium to be 69·865.

The sesquioxide heated to cherry-redness in a current of pure dry hydrogen, partly sublimes undecomposed, and is partly reduced to a bluish-grey fritted substance exactly

like that which is formed by the direct oxidation of gallium. This lower oxide dissolves in nitric acid without evolution of nitrous fumes, and in dilute sulphuric acid without evolution of hydrogen: it is therefore free from metallic gallium, and probably consists of the monoxide. It reduces potassium permanganate. At a bright red heat the oxide is partly reduced to the metallic state.

Nitrate, $\text{Ga}(\text{NO}_3)_3$. The strongest nitric acid (sp. gr. 1.52) free from nitrous vapours scarcely attacks gallium at ordinary temperatures, but at 40° – 50° the action takes place and goes on regularly, with formation of a grey deposit which takes a long time to dissolve. On evaporating the solution to dryness, and heating the residue to 110° , it partly decomposes; and on dissolving the unaltered portion in water, and evaporating the filtered solution over the water-bath, the nitrate is obtained as a white, compact, very deliquescent mass, which exhales the odour of nitric acid. By evaporation in a dry vacuum or in a stream of dry air at 40° , the water and excess of nitric acid are expelled, and the pure nitrate is obtained. At higher temperatures it is completely decomposed, leaving a residue of sesquioxide (Dupré).

Sulphates. The *sesquisulphate* or *Gallie sulphate*, $\text{Ga}_2(\text{SO}_4)_3$ [mode of preparation not described], is non-deliquescent, but very soluble in water. The concentrated solution is syrupy. A perfectly neutral solution is decomposed by boiling, very little gallium remaining dissolved, provided the solution is sufficiently diluted. On cooling, the precipitate dissolves completely. By slow evaporation, or by the cooling of a strong solution, the sulphate is obtained in soft nacreous scales, sometimes grouped in stellate or radiate masses. It dissolves in alcohol of 60 per cent., but is insoluble in ether. On evaporating an acid solution of the sulphate, and drying the residue till it ceases wholly or nearly to give off white vapours of sulphuric acid, the salt does not lose its solubility in water or in weak alcohol, but it takes some time to dissolve (De Boisbaudran).

The salt obtained by dissolving the lower oxide of gallium in dilute sulphuric acid reduces potassium permanganate (Dupré).

Gallium-ammonium Alum is obtained by slow evaporation of an acid solution of gallie sulphate neutralised with ammonia, or by mixing the solutions of gallie sulphate and ammonium sulphate, and evaporating. It crystallises in cubes with octohedral facets, or in octohedrons with cubic facets, having exactly the appearance of ordinary alum, and capable, like the latter, of forming supersaturated solutions which solidify instantly when touched with a small crystal of the salt. A strong solution of the alum becomes slightly turbid when boiled, but clear again on cooling. Very dilute solutions when boiled yield a copious precipitate, probably a basic salt, and if the liquid be filtered while hot, only a trace of gallium remains dissolved. The precipitation on boiling is prevented by the addition of a drop of sulphuric acid, or of a certain quantity of acetic acid (Lecoq de Boisbaudran).

Atomic Weight and Quantivalence of Gallium. The existence of the alum just described shows that gallium is analogous to aluminium, forming a sesquioxide Ga_2O_3 , a trichloride GaCl_3 , &c. &c. This being established, the atomic weight of the metal may be determined by the analysis of the alum or of the nitrate. Now (a) 3.1044 grams of the alum gave on ignition 0.5885 of sesquioxide, whence may be deduced for gallium the atomic weight 70.032. (b) 0.4481 grams of the metal yielded, by conversion into nitrate and ignition of that salt, 0.6024 grams of oxide, which gives for gallium the number 69.698. The mean of these results, 69.865, may be taken as a near approximation to the true value (Lecoq de Boisbaudran, *Compt. rend.* lxxvii. 941).

The specific heat of gallium between 12° and 23° , as determined by Berthelot (*Compt. rend.* lxxvi. 786), is 0.079, which, multiplied by the atomic weight, gives the product 5.52, a number not differing greatly from the mean value (6.4) of the atomic heats of the metals. The specific heat of liquid gallium, between 106° and 119° , is 5.59, differing therefore but slightly from that of the solid metal; in this respect gallium resembles mercury, bismuth, and some other metals.

Mendelejeff (*Compt. rend.* lxxxi. 969) points out that, according to the periodic relation which has been shown to exist between the chemical functions of the elements and their atomic weights (2nd *Suppl.* 462), there should exist an element intermediate between aluminium (27) and indium (113). This element, which he designates as *ekaluminium*, should have the atomic weight 68, and specific gravity 5.9; should be easily reducible, precipitated by hydrogen sulphide more readily than zinc, precipitated also by barium carbonate, and recognisable by the spectroscope. These properties are regarded by Mendelejeff as sufficiently near to those of gallium to justify the conclusion that the latter is really the suspected ekaluminium.

De Boisbaudran, on the other hand, while admitting the great importance of the relations suggested by Mendelejeff, points out that the properties of gallium are not

in all respects intermediate between those of aluminium and of indium: thus the sesquioxide of gallium is more soluble in ammonia than either indium oxide or alumina, which in fact are nearly insoluble in that reagent. Moreover gallium oxide is precipitated by sodium carbonate before alumina and likewise before indium oxide. The extreme fusibility of gallium also is difficult to reconcile with the degree of fusibility which it should exhibit according to the theory in question (*Ann. Chim. Phys.* [5], x. 138).

GARDENIN. A neutral substance obtained by Stenhouse in 1856 (*Phil. Trans.* cxlvi. 155) from dekamali gum, a resinous exudation from *Gardenia lucida* (p. 627), and further examined by Stenhouse a. Groves (*Chem. Soc. J.* 1877, i. 551). It is extracted from the resin by boiling with alcohol, and separates on cooling in long, light-yellow needles, which must be washed with cold spirit to purify them from an amorphous greenish-yellow resin which forms the greater portion of the dekamali gum, then repeatedly crystallised from alcohol, agitated several times with light petroleum to remove a colourless fatty substance, and finally purified by alternate crystallisation from hot benzene and from alcohol.

Gardenin thus purified forms brilliant deep-yellow crystals, melting at 163° – 164° . When dried at 100° , it gave by analysis 61.91 per cent. carbon and 5.45 hydrogen (mean), agreeing nearly with the empirical formula $C^5H^3O^2$.* It is decomposed by boiling with nitric acid, but does not yield picric acid. Its solution in 30 parts of boiling glacial acetic acid, treated, after cooling, with nitric acid of specific gravity 1.45, yields gardenic acid, a non-azotised crystalline substance, which melts at 236° , is insoluble in water and in dilute acids, but dissolves readily in alkalis, and is reprecipitated therefrom by acids. It is very slightly soluble in boiling spirit, more soluble in glacial acetic acid, from which it separates in the crystalline state.

GARNET. A. v. Lasaulx (*Jahrb. f. Min.* 1875, 149) describes crystals of garnet from Geyer in Saxony, exhibiting, together with ∞O_2 , the form ∞O_3 , hitherto observed only in garnets from Auerbach on the Bergstrasse. According to A. Wichmann (*Pogg. Ann.* clvii. 282; *Jahrb. f. Min.* 1876, 198; *Chem. Soc. J.* 1876, ii. 51, 178), the dark-coloured massive garnet, called *allochroïte*, is partly amorphous and partly possesses double-refracting structure, as formerly observed by Des Cloizeaux in grossularia.

The following are recent analyses of garnets: (1–3) occurring in the eclogites of Upper Franconia (p. 703). 1. Large distinct garnets from Eppeneuth near Hof. 2. Large garnets, seldom crystallised, from Silberbach, near Conradsreuth. 3. Garnet in very numerous grains from Falser Höhe near Markt Schorgast (E. v. Gerichten, *Liebig's Annalen*, clxxi. 183). (4–6) Red garnet from the serpentino of Zöblitz, Greifendorf, and Waldheim in Saxony (Lemberg, *Zeitschr. geol. Ges.* xxvii. 531). 7. Spessartin, from S. Mareel, in Piedmont, where it occurs, together with marcelin, piemontite, red mica, and quartz, in light-yellow, seldom orange-yellow crystals, ∞O_2O_2 , the nucleus of which often consists of marcelin; sp. gr. = 4.01 (Pisani, *Compt. rend.* lxxxiii. 167).

GASES. *Absorption by Metals.*—The solution of gases in iron, steel, and manganese has been investigated by Troost a. Hautefeuille (*Ann. Chim. Phys.* [5], vii. 155) with the following results:

1. Cast-iron kept in fusion in contact with silica or silicates, evolves carbon oxide resulting from the action of iron carbide on silica, the iron, consequently, becoming poorer in carbon and richer in silicon.

2. Melted cast-iron dissolves considerable quantities of hydrogen, the solubility of the gas being diminished by the presence of silicon, and much increased by the presence of manganese.

3. Carbon oxide is much less soluble than hydrogen in the different varieties of

* Flickiger, who also analysed gardenin (*Pharm. J. Trans.* [3], vii. 589), assigned to it the formula $C^{22}H^{10}O^{11}$, but as his product was purified merely by repeated crystallisation from spirit, it was probably still contaminated with the fatty substance above mentioned.

cast-iron. Its solubility is diminished or even annulled by the presence of manganese.

4. Pig-iron, after cooling, retains gases which may be extracted by heating the metal to a temperature not exceeding 800° . Hydrogen is always more abundant than carbon oxide, both in the solid and the fused metal, and is more persistently retained by the metal. Manganiferous iron retains more hydrogen than does ordinary cast-iron.

5. Steel dissolves less gas than cast-iron, hydrogen predominating over carbon oxide, and being more forcibly retained by the metal.

6. Soft iron, on the contrary, dissolves more carbon oxide than hydrogen, and retains it more forcibly.

7. Finely-divided pure iron, deprived of gases, decomposes water slowly at the ordinary temperature, and rapidly at 100° , the decomposition being more rapid the finer the state of division of the iron.

The solubility of carbon oxide in cast-iron, malleable iron, or steel, may be estimated by the action of moist mercuric chloride in a vacuum at ordinary temperatures. By this mode of proceeding it is possible to determine the limit of temperature above which the gases taken up by the iron are partly due to chemical reactions.

Absorption by Saline Solutions.—The absorptive powers of solutions of the chlorides of ammonium, potassium, sodium, barium, strontium, and calcium for carbon dioxide have been determined by J. J. Mackenzie (*Ann. Phys. Chem.* [2], i. 438) with the following general results:

(1). Saline solutions absorb less carbon dioxide than an equal volume of water. (2) The volume of gas absorbed decreases as the concentration of the solution increases. (3). Different solutions possess different absorption-coefficients. The absorption-coefficient for potassium chloride, like its molecular weight, lies between those for sodium and ammonium chlorides, and that of strontium between those for barium and calcium chlorides. (4). The coefficient varies with the temperature almost in the same manner as for pure water.

The absorption of carbon dioxide by sulphuric acid and its mixtures with water, at 17° , has been investigated by J. Setschenow (*Petersb. Acad. Bull.* xxii. 102). The absorption-coefficient of undiluted H^2SO^4 (0.932) is so near to that of water (0.9519 at 17° , according to Bunsen), that there can be no doubt of the actual identity of the two. By dilution the absorption-coefficients are diminished, very rapidly at first, the minimum value 0.666 being attained at $\text{H}^2\text{SO}^4 + \text{H}^2\text{O}$, beyond which the coefficients increase slowly on further dilution.

Diffusion of Gases. J. Clerk Maxwell (*Phil. Mag.* [4], xvi. 453) has studied the phenomena of gaseous diffusion in connection with molecular movement. According to the mechanical theory of gases (iii. 131), this movement of the gaseous molecules goes on in air apparently at rest, as well as in gases which are diffusing one into the other. This movement of the molecules in a stratum of air cannot of course be observed directly, but its existence may be inferred from the following considerations. When a horizontal stratum of air moves onward, the molecules which diffuse out of it into the strata immediately above and below it, endeavour to impart their horizontal velocity to the molecules of these other strata, while the molecules which diffuse from the latter into the moving stratum tend to retard its motion and bring it to rest. This mutual action of contiguous gas-strata is similar to the friction of two rough surfaces, one of which slides over the other, and to the internal friction of liquids called *viscosity*. It is, in fact, only another kind of diffusion, namely, a lateral *diffusion of momentum*, and the relative values of the friction of different gases may be deduced from observations on the so-called transpiration of gases through narrow tubes, while the absolute values are deduced from Meyer's observations on the oscillation of horizontal discs in gases (*Pogg. Ann.* cxliii. 14; *Jahresb. f. Chem.* 1871, 44).

Another method of demonstrating the diffusion of molecules in still air is to warm the upper layer and observe the proportion in which the heat thus imparted is communicated to the lower layers. This is, in fact, a third kind of diffusion—the *diffusion of energy*.

All three kinds of diffusion, viz. *diffusion of matter*, *diffusion of momentum* (friction), and *diffusion of energy* (heat-conduction), are brought about by the movement of the molecules. The greater the velocity of the molecules, and the farther they travel before their course is arrested by collision with other molecules, the more rapid will be the diffusion. As the velocity of the molecules is known, it is possible to calculate, from Loschmidt's experiments on diffusion (*2nd Suppl.* 542), the average distance traversed by a molecule before it strikes against another, or the mean path between two collisions, and thence also the number of collisions which each molecule experiences in a second of time.

Molecular Relations.

	Hydrogen	Oxygen	Carbon Monoxide	Carbon Dioxide
Mass of molecule	1	16	14	22
Mean velocity at 0° per second in meters	1859	465	497	396
Mean path in $\frac{1}{10,000,000}$ mm.	965	560	482	379
Number of collisions in millions per second	17750	7646	9189	9720
Diameter of molecule in $\frac{1}{10,000,000}$ mm.	5.8	7.6	8.3	9.3
Mass in $\frac{1}{25,000,000}$ mgms.	46	736	644	1012

Change of Temperature attending the Diffusion of Gases through Porous Partitions.—

The following observations have been made by Dufour (*N. Arch. ph. nat.* xlv. 9; xlix. 101–33). (1). When a dry stream of air, hydrogen, or coal-gas penetrates the walls of a porous vessel, or passes through a vessel containing fragments of the porous material, a fall of temperature takes place, which gradually becomes smaller and smaller, and at length disappears. (2). When moist streams of these gases circulate under the same conditions, a rise of temperature is produced, which likewise diminishes and finally ceases. (3). The heating is probably due to the absorption of aqueous vapour by the porous substance; the cooling to the evolution of that vapour, these effects being greater or less according to the previous state of the porous vessel. (4). When air on the one side and hydrogen or coal-gas on the other are in contact with a porous partition, and diffusion takes place without alteration of pressure, a rise of temperature is produced on that side of the partition towards which the stream of gas is directed, that is to say on the side in contact with the lighter gas, and a fall of temperature on the other. (5). These changes of temperature appear to occur, not in the entire mass of the gas, but only at the surface of the porous partition, the heating on the one side being due to the condensation of the gas, and the cooling on the other to its expansion. (6). When the diffusion is accompanied by variation of pressure, the effects are complicated by the alterations of temperature directly resulting from increase or diminution of pressure (Dufour).

Thermo-diffusion.—C. Neumann infers, from theoretical considerations, that when a finite portion of a gas enclosed in a tube of infinite length (or returning into itself) has a density greater or less than that of the rest of the gas, a difference of temperature artificially produced at the two extremities of this finite portion must give rise to a continuous movement in the whole of the endless cylinder of gas, directed from the cold to the warm end through the finite portion above mentioned, supposing that the gas in this portion is of greater density than the remainder (*Jahresb. f. Chem.* 1874, 15).

* Graham (*Phil. Trans.* 1849, ii. 349; *Phil. Mag.* [3], xxxv. 511; [4], xxvi. 409); O. E. Meyer, *Pogg. Ann.* cxxv. and cxxvii.; *Jahresb. f. Chem.* 1871, 44).

‡ Voit, *Pogg. Ann.* cxxx. 227, 393; *Jahresb.* 1867, 95.

§ Fick, *Pogg. Ann.* cxxxv. 337.

Experiments made by W. Feddersen (*Phil. Mag.* [4], xlv. 55), in accordance with the requirements of this theory, on a portion of the gas enclosed between diaphragms of platinum or palladium sponge, gypsum, or *magnesia usta*, have shown that it appears to be a universal property of porous bodies, when used as diaphragms, to draw gas through themselves from the colder to the warmer sides. This *thermo-diffusion* differs from ordinary diffusion, inasmuch as it takes place between two portions of the same gas on opposite sides of a diaphragm. It is the correlative of the phenomenon observed by Dufour, in whose experiments a change of temperature results from diffusion, whereas in those of Feddersen, diffusion is produced by change of temperature, and in such a direction that the artificially excited change of temperature is diminished by that which, according to Dufour's law, results from the diffusion itself.

Hygrometric Diffusion.—(1). When a porous partition (the porous cell of a voltaic battery) separates two portions of air of different degrees of moisture, two opposite and unequal streams of air pass through it, the stronger current being directed from the dry to the moist air, and the difference in strength of the two depending chiefly on the difference of vapour-tension on the two sides of the partition. Temperature has little or no direct influence on the result. (2). Hygrometric diffusion takes place also, though less quickly, through dense and very homogeneous plates of marble (5 mm. thick), polished or unpolished; also through plates of gypsum, alabaster, and retort-charcoal. On account of the greater porosity of gypsum, diffusion through it can give rise only to slight differences of pressure on the two surfaces, and even these differences are quickly equalised. Alabaster is much less penetrable by gases than gypsum or marble, and diffusion through it takes place much more slowly. (3). When a limited volume of air is confined in a vessel, part only of which is porous, a difference of hygrometric state between the inner and outer air leads to a difference of pressure, which is independent in amount on the extent of the porous part of the side of the vessel, but is longer in establishing itself as the proportion of porous to compact surface is smaller. (4). The difference of pressure produced by hygrometric diffusion depends, under otherwise similar circumstances, on the thickness of the partition, and in the case of porous clay is nearly in the inverse ratio of the square root of the thickness (limits of observation 3 to 10 mm.) (5). The excess of the diffusion-current of dry air attains its greatest value when the pressure on the two sides of the partition remains equal. This excess, which varies with the nature of the porous partition and the hygrometric conditions of the experiment, is greater in proportion as the thickness of the partition is less. With thicknesses of 3.1 mm., 5.1 mm., and 9.1 mm., it was found to vary as 100 : 72 : 51. (6). When hygrometric diffusion gives rise to a difference of pressure on the two sides of the partition the excess of volume of the stronger current diminishes as the difference of pressure increases. This decrease is quicker as the thickness of the partition is greater (Dufour, *N. Arch. ph. nat.* xlv. 9; liii. 177-210).

Passage of Gases through Liquid Films and Colloid Membranes.—F. Exner (*Pogg. Ann.* clv. 321, 443; *Chem. Soc. J.* 1876, ii. 163) has studied this mode of diffusion by introducing into a diffusion-tube a film of soap formed with a solution of 1 part by weight of dried Marseilles soap in 60-80 parts of distilled water. Experiments were made with air and coal-gas, air and carbon dioxide, air and hydrogen sulphide, air and ammonia, air and oxygen, air and nitrogen, coal-gas and oxygen, coal-gas and hydrogen, nitrogen and hydrogen. A comparison of the velocities with which the gases traversed the film led to the conclusion that the passage of the gases through the film is due, partly to their absorption by the liquid and subsequent elimination from it, partly to simple diffusion through the film, as through a porous partition of extremely small thickness. On this supposition the diffusion-velocity, a , of a gas

must be represented by the expression $\frac{C}{\sqrt{\delta}}$, where C is the absorption-coefficient of the gas for water and δ its density. The following table shows the agreement of the values of a calculated from this formula with those deduced from actual observation :—

Gas	Coefficient of absorption	Density	$\frac{C}{\sqrt{s}}$	α observed	α calculated
Nitrogen	0.015	0.97	0.0153	0.86	0.85
Air	0.017	1.00	0.017	—	1.00
Oxygen	0.030	1.106	0.0285	1.95	1.60
Coal-gas	0.025	0.480	0.036	2.27	2.12
Hydrogen	0.019	0.070	0.072	3.77	3.89
Carbon Dioxide .	1.002	1.52	0.812	47.1	45.1
Hydrogen Sulphide .	3.165	1.17	2.94	165	163.3
Ammonia	700	0.59	903.0	46000	54450

According to Barthélemy (*Compt. rend.* lxxvii. 427), the natural colloidal surfaces of plants exert upon mixed gases a dialytic or separating action similar to that observed in caoutchouc by Graham (*1st Suppl.* 632), transmitting carbon dioxide thirteen times as readily as nitrogen, and six or seven times as readily as oxygen.

Diffusion of Gases through Absorbing Substances (Wroblewski, *Ann. Phys. Chem.* clviii. 539-568, and [2], i. 438-451).—When an absorbable gas is suddenly brought in contact with the surface of a liquid contained in a cylindrical or prismatic open vessel, and not disturbed by currents arising from variations of temperature, the uppermost layer of the liquid will of course be first saturated by the gas; and Wroblewski's experiments show that the diffusion of the gas through the liquid takes place according to Biot's Law of Difference, the gas passing successively from each layer of liquid to the one next below it, and the rate at which this movement takes place being proportional to the difference of saturation of the two layers. When carbon dioxide is brought in contact with an aqueous solution containing in 100 c.c. more than 10 grams of dry sodium chloride, or 26.98 sugar, the gas diffuses itself through the liquid exactly according to the Biot-Fourrier law of heat-conduction, the quantities of gas absorbed being proportional to the square roots of the times of absorption, and the liquid acting, with regard to the diffusion of the carbon dioxide, just like a solid body with regard to the conduction of heat. With weaker solutions and with pure water, the regularity of the diffusion is disturbed by the increase of density of the liquid charged with carbonic acid, which consequently sinks to the bottom, thereby completely altering the conditions of the diffusion. The Biot-Fourrier law of diffusion likewise holds good in glycerin and its aqueous solutions; also in strong solutions of colloid substances, such as gelatin, even when they contain a quantity of the colloid sufficient to render them viscous or semi-solid; a perfectly dry hard plate of gelatin, on the other hand, is impervious to carbon dioxide.

Former experiments by Wroblewski (*Pogg. Ann.* lviii. 539-568) showed that the rate at which carbon dioxide or hydrogen diffuses through a caoutchouc membrane is proportional to the pressure of the gas upon the membrane: this is merely a particular case of the law above stated.

From these results Wroblewski deduces the following law: *When a gas is absorbed by any substance, liquid, solid, or semi-solid, it diffuses itself in the absorbing body according to laws identical with those which regulate the propagation of heat in a solid rod.* The only exceptions to this law are those which are due to the action of gravity.

Aspiration and Migration of Gases.—These terms are applied by F. Bellamy (*Compt. rend.* lxxxiii. 669) to denote the passage of gases enclosed over mercury through the capillary tubes of cotton or linen skeins, hemp, hay, rushes, strips of caoutchouc and many other bodies. When separate portions of the same gas under different pressures are connected by such bodies, the level of the mercury comes to rest only when the pressure on the two sides is equalised. When different gases, such as hydrogen and carbon dioxide, are connected by a skein of cotton-thread, &c., enclosed in a bent glass tube, streams of the two gases pass through the skein in opposite directions till the pressure of each gas on the two sides becomes equal, the hydrogen travelling the faster of the two.

Friction of Gases. O. E. Meyer in 1865 and 1866 (*Pogg. Ann.* cxxv. and cxxvii.) showed, by experiments on circular discs vibrating horizontally round a vertical axis, and by calculation from Graham's experiments on the transpiration of gases through capillary tubes (ii. 820), that the constant of the internal friction of air is independent of pressure, and increases with the temperature. This result was confirmed in a similar manner by Maxwell (*Phil. Trans.* 1866), who had previously deduced it from theoretical considerations (*Phil. Mag.* [4], xix. 31).

Meyer found, from his first experiments, as an approximate result, that the value of the friction-coefficient of air lay between 0·00018 and 0·00027. Subsequently (*Pogg. Ann.* cxliii. 14), by experiments made at various temperatures, he inferred that the temperature-coefficient for the friction is about $\frac{2}{3}$ the coefficient of expansion, so that, representing the coefficient of expansion at the temperature t° by μ_t , and the temperature-coefficient of friction by β , we have,

$$\mu_t = \mu_0(1 + \beta t)$$

where $\beta = \frac{2}{3} \times 0\cdot003665 = 0\cdot002749$.

By a series of experiments made at different temperatures, the value of μ_0 was found to be between 0·000168 and 0·000174.

A. v. Obermayer (*Wien. Acad. Ber.* [2te Abth.], lxxi. 281–308), from a comparison of his own experiments on vibrating discs with those of Meyer and Maxwell, deduces the values $\beta = 0\cdot002723$; $\mu = 0\cdot00016747$, according to which the expression for the friction-coefficient of air becomes:

$$\mu_t = 0\cdot00016747(1 + 0\cdot002723 t).$$

The same methods of investigation have been applied to the determination of the friction-coefficients of a considerable number of gases by Meyer (*Pogg. Ann.* cxliii. 14; *Jahresb. f. Chem.* 1871, 44); by Meyer a. Springmühl (*Pogg. Ann.* cxlviii. 526–549; *Jahresb.* 1873, 16); and by A. v. Obermayer (*Wien. Acad. Ber.* [2te Abth.], lxxiii. 433–474; *Jahresb.* 1876, 42). The results are given in the following table, together with those calculated by Meyer from Graham's transpiration experiments:

Friction-coefficients of Gases.

	Meyer a. Springmühl		Obermayer		Friction-coefficient referred to that of Oxygen = 0·0001873 calculated from Graham's Transpiration experiments
	Transpiration-coefficient	Friction-coefficient at 0°	Transpiration-coefficient	Friction-coefficient at 0°	
Oxygen	1·000	0·000212	1·000	0·0001873	0·0001873
Air	0·899	190	0·896	1678	1683
Nitrogen Dioxide	0·878	186	—	—	1645
Nitrogen	0·873	184	0·885	1659	1635
Carbon Monoxide	0·870	184	0·868	1625	1630
Carbon Dioxide	0·755	160	0·738	1383	1414
Nitrogen Monoxide	0·752	160	0·723	1353	1408
Hydrogen Chloride	0·736	156	—	—	1379
Chlorine	0·687	147	—	—	1287
Sulphur Dioxide	0·654	138	—	—	1225
Hydrogen Sulphide	0·616	130	—	—	1154
Marsh-gas	0·555	120	—	—	1040

Methyl Oxide	0·483	102	—	—	905
Hydrogen	0·439	093	0·459	861	822

The following is a comparison of the transpiration-coefficients of air, oxygen, hydrogen and carbon dioxide, as determined by different observers:

	Air	O ²	H ²	CO ²
Graham *	1	1·113	0·488	0·840
Maxwell †	1	—	0·516	0·859
O. E. Meyer ‡	1	1·095	0·601	0·851
Lang §	1	—	—	0·830
Obermayer	1	1·116	0·513	0·824
Kundt a. Warburg	1	—	0·488	0·804

* This Dictionary, vol. ii. p. 820.

† p. 847 of this volume.

‡ *Pogg. Ann.* cxlviii. 1.

§ *Wien. Acad. Ber.* [2 Abth.], lxxiii. 604.

|| *Deut. Chem. Ges. Ber.* 1876, 160.

With respect to the alteration of their friction-coefficients according to temperature, gases may be arranged nearly in the same order as with reference to their coefficients of expansion:

	Friction-coefficient according to Obermayer	Expansion-coefficient ac- cording to Regnault
Air	$\eta = 0.0001678(1 + 0.003665t)^{0.76}$	0.003671
Hydrogen	$0.861(1 + 0.003665t)^{0.70}$	0.003661
Oxygen	$1.878(1 + 0.003665t)^{0.80}$	—
Carbon Monoxide	$1.625(1 + 0.003665t)^{0.74}$	0.003669
Ethylene	$0.922(1 + 0.003665t)^{0.96}$	—
Nitrogen	$1.559(1 + 0.003665t)^{0.74}$	—
Nitrogen Monoxide	$1.353(1 + 0.003719t)^{0.93}$	0.003719
Carbon Dioxide	$1.383(1 + 0.003701t)^{0.94}$	0.003710
Ethyl Chloride	$0.889(1 + 0.003900t)^{0.98}$	—

From these results it appears that the friction-coefficient of the less easily condensable gases (till lately regarded as uncondensable) is nearly proportioned to the $\frac{3}{2}$ power, and that of the more easily condensable gases to the first power, of the absolute temperature. For temperatures between 150° and 300°, air gave the same values of the exponent as between the lower temperatures—21.5° and 53.5°. Carbon dioxide exhibited a slow decrease of the exponent with the temperature.

Nearly equal values of the exponents for air, carbon dioxide, and hydrogen have been obtained by J. Puluj (*Wien. Acad. Ber.* [2 Abth.], lxxiii, 589), viz. for air 0.722; for carbon dioxide 0.917, and for hydrogen 0.693.

From the friction-coefficients may be deduced the following lengths of the *medium paths* (p. 847) of a molecule:

	Obermayer	Stefan, Loschmidt	Maxwell, Graham
Air	0.0000074 cm.	71	83
Hydrogen	1.44	139	153
Oxygen	79	74	87
Carbon Monoxide	73	65	81
Carbon Dioxide	49	50	56
Nitrogen Monoxide	48	42	56

On the Friction of Rarefied Gases, see Kundt a. Warburg (*Pogg. Ann.* clv. 337-365 and 525-550; *Phil. Mag.* [4], l. 53; *Jahresb. f. Chem.* 1875, 33); A. Kundt (*Pogg. Ann.* clviii. 568-572 and 660; *Jahresb.* 1866, 41).

On the Friction of Air on Glass, see Warburg (*Pogg. Ann.* cliv. 399-415; *Jahresb.* 1876, 41).

E. Wiedemann (*N. Arch. ph. nat.* lvi. 277) has also determined the friction-coefficient of gases at different temperatures, by the velocity of their flow through capillary tubes. The following table gives the results referred to air at 8° = 100.

	8°	100°	184.5°
Air	100	123.1	141.1
Carbon Monoxide	96.87	—	136.1
Carbon Dioxide	80.48	104.8	123.4
Nitrogen Monoxide	80.41	105.6	124.1
Ethylene	56.24	73.89	87.38

For air and carbon monoxide on the one hand, and for carbon dioxide and nitrogen monoxide on the other, which latter have equal molecular weights, the friction increases with rise of temperature in the same ratio. The friction-coefficient μ_t at the temperature t , being equal to $\mu_0 (1 + 0.003665t)^n$, the exponent n is found to have the following values, which are not the same for all gases, and do not all vary with the temperature according to the law laid down by Obermayer:

	0° to 100°	0° to 184.5°	100° to 184.5°
Air	0.7333	—	0.6701
Carbon Monoxide	—	0.6949	—
Carbon Dioxide	0.9296	—	0.8024
Nitrogen Monoxide	0.9602	—	0.7874
Ethylene	0.9645	—	0.8224

**Compressibility of Gases—Deviations from the Boyle-
Mariotte Law** (Buddle, *J. pr. Chem.* [2], ix. 30-47). If this law were true in all cases, the relation between the pressure and volume of a gas at constant temperature would be expressed by the equation $p v = \text{constant}$. But the experiments of Regnault and Natterer have shown that the true relation is

$$p v = \text{const.} + \phi(p),$$

ϕ being the symbol of a hitherto undetermined function, which may be either positive or negative. Regnault,* whose experiments were made at pressures up to 30 atmospheres, and at a temperature near 4° C., found that hydrogen exhibits a positive, whereas all other gases exhibit a negative deviation from Boyle's law. Natterer,† on the other hand, whose observations were extended to much higher pressures, found that the negative deviation of air, nitrogen, and carbon monoxide is converted at very high pressures into a positive deviation, which finally becomes greater than that of hydrogen, and is enormous even for the latter. To a pressure of 2790 atmospheres correspond the following condensations:

Hydrogen	Nitrogen	Air	Carbon Monoxide
$\frac{1}{1008}$	$\frac{1}{705}$	$\frac{1}{726}$	$\frac{1}{727}$

Now, according to the gas-theory of Krönig and Clausius (iii. 131), the conditions for the constitution of a perfect gas are: (1). That the attractive forces between the molecules must be infinitely small. (2). That the radius of the sphere of action of a molecule must be infinitely small as compared with the length of the mean path of the molecules. (3). That the time intervening between two successive collisions must be infinitely small as compared with that of the free movement of a molecule. This last condition implies another, viz. that the portion of its path along which a molecule is exposed to the repulsive action of other molecules must be infinitely small as compared with the length of the path of free movement. In all actually existing gases, however, the attractions between the molecules have a real, though extremely small value, and it is just to these residual attractive forces that the ordinary negative deviations from Boyle's law are generally attributed. If, however, the imperfections in a gas due to attraction are reduced to the smallest perceptible trace, there still remain two causes which may produce a sensible deviation from Boyle's law, viz.: (1). The radius of the sphere within which each molecule exerts an elastic repulsive action must have a certain though very small magnitude ϵ . (2). The interval of time between two successive collisions, and the depth to which the elasticity of the molecules gives way, may have, as compared with the time and the medium length of the path of free motion, a certain magnitude of the order ζ . Now according to the views of Clausius respecting the manner in which the molecules rebound after collision, each molecule may be regarded as fencing off round itself, by repulsive forces, a space of medium radius δ , whose middle point is the centre of gravity of this molecule. A sphere of radius 2δ is called by Clausius the sphere of action of the molecule, and the sphere of radius δ may be called its sphere of elasticity. For convenience of consideration, the molecules may be replaced by elastic spheres of the magnitude of the spheres of elasticity. Moreover, the repelling forces which produce the rebound probably increase very rapidly as the molecules approach one another, so that the spheres of elasticity may be regarded as *hard-elastic*. According to this, ζ should be a small magnitude compared with ϵ , and of the two deviations last-mentioned the first should predominate. At all events it may be supposed that at constant temperatures the elasticity of the molecules is not altered by the number of collisions which take place in the unit of time. So long, therefore, as the paths of the molecules are long enough, the spheres of elasticity at constant temperature may be regarded as incompressible spaces of invariable magnitude.

If, therefore, the pressure on a gas is altered, the change of volume thereby produced affects only the spaces between the spheres of elasticity, which of themselves fill a constant space k . For a gas in which no other cause of deviation from Boyle's law exists, we have therefore, if its volume under the unit of pressure be denoted by v ,

$$v = k + \frac{v_1 - k}{p},$$

or, writing a for $v_1 - k$:

$$vp = a + kp.$$

* 'Relation des expériences entreprises . . . pour déterminer les principales lois physiques et les données numériques qui entrent dans le calcul des machines à vapeur.' Paris, 1847, p. 271.

Supposing now that in hydrogen the attractions between the molecules disappear so completely that, in the discussion of Regnault's observations, they may be left quite out of account, it will then follow that the deviations from Boyle's law exhibited by this gas are due to the circumstance that the spheres of elasticity of its molecules have a not quite imperceptible magnitude as compared with the entire space which it occupies. Accordingly, k is the space occupied by the spheres of elasticity in a given quantity of hydrogen; a the empty space contained between them at 4° and 1 meter pressure. The ratio $\frac{k}{a}$ is found, from Regnault's experiments, to have the mean value 0.0007: consequently,

At 4° and 1 meter pressure, the spheres of elasticity of Hydrogen occupy 0.0007 of the space contained between them,

$$\text{or, since } \frac{0.0007}{1.0007} \text{ is sensibly equal to } 0.0007,$$

at 4° and 1 meter pressure, the spheres of elasticity of Hydrogen occupy 0.0007 of its apparent volume.

As already observed, the radius of Clausius' spheres of action is double that of the spheres of elasticity: consequently the volume of the spheres of action is 8 times that of the spheres of elasticity. Now Clausius has shown that the radius of the spheres of action is to the mean length of path of the molecules as the space occupied by the spheres of action to the total volume of the gas. If then the mean length of the path be denoted by l , we have

$$\frac{2\delta}{l} = \frac{8k}{v}, \text{ or } \frac{\delta}{l} = \frac{4k}{v};$$

and the behaviour of hydrogen under pressure may be expressed thus:

In hydrogen at 4° and 1 meter pressure, the mean length of path of the molecules is equal to 358 times the radius of the spheres of elasticity.

The approximate value of k , determined as above, may perhaps appear to involve a certain amount of improbability, leading as it does by a very simple calculation to the conclusion that, at 4° and 1 atm. pressure, the mean distance between the molecules of hydrogen is about twenty times as great as the radius of the spheres of elasticity.

It is usual, however, for reasons which need not here be discussed, to regard the distances between the molecules as very great in comparison with the dimensions of the molecules themselves. What is meant by 'dimensions of the molecules' it is not very easy to say, unless we understand by it the dimensions of the spheres of elasticity, or something similar; in that case the number twenty may appear rather small. It is, however, large enough to satisfy the necessary conditions of the gaseous state, as shown by the entire calculation above given, and especially by the equation $vp = a + kp$; and moreover it is directly supported by the experiments of Natterer, which show that when hydrogen under a pressure of 1 atmosphere is compressed to $\frac{1}{1000}$ of its volume, it scarcely conforms any more to Boyle's law; whence it follows that, if the mean distances between the hydrogen molecules at one atmosphere are reduced to $\frac{1}{10}$, they become magnitudes of the same order as the dimensions within which the specific forces of the molecules are active.

The volume at the pressure of 1 atmosphere being taken as 1, each pair of numbers given by Natterer for p and $\frac{1}{v}$, yields by calculation a corresponding value

of $\frac{k}{a}$. These are given in the following table:

p	$\frac{1}{v}$	$\frac{k}{a}$	p	$\frac{1}{v}$	$\frac{k}{a}$

Natterer's unit of pressure is that of the atmosphere: the above values of $\frac{k}{a}$ may be reduced to the unit of 1 meter by dividing them by 0.760. The temperature at which his observations were made is not stated, and he appears to have regarded the difference between the actual height of the barometer and 0.760 m. as a quantity which might be neglected; but his results, as they stand, agree remarkably well with those of Regnault. At pressures below 170 atmospheres, the value of $\frac{k}{a}$ comes out less than that deducible from Regnault's observations, viz. 0.0007, a result which may probably be attributed to a want of delicacy in Natterer's apparatus. From 170 atmospheres upwards the values of $\frac{k}{a}$ become nearly constant, the mean value up to 700 atmospheres differing but slightly from 0.007. For the highest pressures the

value of $\frac{k}{a}$ slowly increases, a result quite in accordance with theory: for as the molecules are brought closer and closer together, the time during which they can exert a repellent action on each other increases in proportion to the time of unrestrained movement. The molecules are therefore subject to repulsion during a longer part of their course, behaving indeed as if they exerted a perceptibly repellent action on one another, even beyond their spheres of elasticity; that is, to say, the function $\phi(p)$ ultimately increases faster than the pressure. Its increase, however, in the series above given is so small, that it may perhaps be best to neglect it, at least provisionally, and regard the molecules, even at very high pressures, as hard-elastic.

For these reasons Budde thinks it justifiable to assume that the observations of Natterer and those of Regnault may be represented by the same equation:

$$v = a + kp$$

with the value $\frac{k}{a} = 0.0007$ up to 700 atmospheres; and that above as well as below

700 atmospheres, the behaviour of hydrogen may be explained in second approximation by the assumption that the spheres of elasticity of its molecules have a magnitude which is not quite evanescent.

It has been assumed that the deviations of the gas from Boyle's law are due exclusively to the repulsive forces of its molecules. This is the simplest assumption that can be made, but it is neither necessary nor very probable. A very small residue of attractive forces may also be still present in hydrogen. The magnitude $\phi(p)$ will in that case resolve itself into two summations, one positive, the other negative, and the value kp will represent the difference between the two. It is probable, however, that the negative and positive portions of the deviation increase according to different laws, as indeed is distinctly seen in the case of air and of carbon dioxide.

Since then $\frac{k}{a}$ remains very nearly constant up to a large number of atmospheres, it may be inferred that the negative deviation is not able to disturb the positive to any sensible amount, and that therefore it can be but small in proportion to the latter. The value 0.0007 for the ratio of the magnitude of the elasticity-spheres to the volume of the gas may therefore be somewhat too small, but it is at least approximately correct.

The cause which determines the deviation of hydrogen exists likewise in the case of the other gases, and in them also it must tend to produce a positive deviation. Moreover, it is not improbable that the heavier molecules of the other gases may possess spheres of elasticity larger than those of hydrogen, and that consequently there enters into their deviations a positive element which exceeds the total deviation of the latter. At low pressures, however, this property of the last-named bodies is disguised by the attraction of their molecules.

Under all circumstances the magnitude $\phi(p)$ has to be divided into parts, one of which, ϕ_- , is negative, and arises from the residues of attraction in the gas, while the other, ϕ_+ , is positive. Under different pressures the following combinations occur:—

- | | |
|---------------------------|---|
| (1.) p very small | $\phi_+ = \phi_- = \frac{1}{\infty}$; nearly true for all gases. |
| (2.) p moderately large | $\phi_+ > \phi_-$. Case of hydrogen. |
| | $\phi_- > \phi_+$. Case of other gases. |
| (3.) p very large | $\phi_+ > \phi_-$. Case of the most difficultly condensable gases. |

In the remarks made on p. 853, the elasticity-spheres of the molecules are regarded, in accordance with ordinary usage, as globes. These observations, however, remain equally valid when the elasticity-spheres are supposed to be of any other shape, and δ represents their mean radius, that is to say, the radius of a globe having the same volume as the spheres of elasticity.

Results in accordance with the preceding have been obtained by Hemilian, Mendelejeff, a. Bojuszky (*Deut. Chem. Ges. Ber.* ix. 1312), whose experiments show that, under a diminution of pressure of 2,200 to 20 mm., air, carbon dioxide and sulphur dioxide exhibit both positive and negative deviations from Boyle's law; hydrogen, on the other hand, only positive deviations. Negative deviation, that is to say a compression greater than that which should take place according to Boyle's law, was observed in air, carbon dioxide and sulphur dioxide, under pressures exceeding 1 atmosphere; and positive in air between 20 and 650 mm., in carbon dioxide between 20 and 180 mm., in sulphur dioxide between 20 and 60 mm. Earlier experiments by Mendelejeff a. Kirpitschhoff (*ibid.* vii. 486) also led to the conclusion that air at low pressures deviates considerably from Boyle's law, in the

positive direction, so that the product pv , if supposed = 1 at 250 mm., diminishes at 0.5 mm. to 0.6.

According to Amagat, on the contrary (*Ann. Chim. Phys.* [5], viii. 270), air under low pressures (6.5 to 10.5 mm.) conforms exactly with Boyle's law. The mean of forty-one series of experiments gave for $v' > v$, $\frac{p}{p'} \frac{v}{v'} = 1.0014$; in thirty-six series the deviation from unity did not exceed 0.002.

Liquefaction and Solidification of Gases. Down to the year 1877, six gases, viz. hydrogen, oxygen, nitrogen, nitrogen dioxide, carbon monoxide, and marsh-gas, had resisted all attempts to reduce them to the liquid or solid state; but towards the end of that year they were all liquefied by L. Caillietet (*Compt. rend.* lxxxv. 1016, 1213, 1217, 1270; *Ann. Chim. Phys.* [5], xv. 132-144); oxygen and hydrogen also by R. Pictet (*Compt. rend.* lxxxv. 1214, 1276; lxxxvi. 37, 106; *Chem. News*, xxxvii. 1. 83). The means adopted for the liquefaction of these gases were the same as those previously employed by Faraday in effecting the liquefaction of other gases, namely, cold and pressure, the gases being condensed in thick-walled tubes of fine bore by means of powerful forcing pumps capable of producing a pressure of 300 to 1,000 atmospheres, and at the same time subjected to the intense cold produced by means of liquid sulphur dioxide and solid carbon dioxide.

Oxygen.—Evidence of the liquefaction of this gas was first obtained by Caillietet, and his results were communicated to the Academy of Sciences at Paris on December 2, 1877. Under a pressure of 300 atmospheres, and at a temperature of -29° , produced by the evaporation of liquid sulphur dioxide in a current of dry air, the gas appeared to undergo no alteration, but on allowing it to expand by suddenly removing the pressure, whereby a great fall of temperature is produced, a fog was observed in the tube, indicating the liquefaction, and perhaps solidification of the oxygen.

Nearly at the same time, Pictet, by the use of more powerful apparatus, whereby the gas was subjected to a pressure of 320 atmospheres and cooled to -140° by the combined effects of the evaporation of liquid sulphur dioxide and carbon dioxide, succeeded in liquefying the gas in a long glass tube; and on opening a screw-tap at the end of this tube, a jet of liquid oxygen was seen to spirt out with extreme violence. Pieces of slightly ignited charcoal held in this jet inflamed spontaneously and burned with intense vividness. A ray of electric light thrown upon the jet showed that it was composed chiefly of two parts; a central portion some centimeters long, showing by its whiteness that it consisted of liquid or even of solid oxygen; and an exterior portion, the blue tint of which indicated the presence of oxygen compressed in the gaseous state. In a subsequent experiment, the presence of solid particles in the jet of liquid oxygen was confirmed by illuminating it with polarised light.

Hydrogen.—Dry hydrogen, obtained by decomposing potassium formate with potassium hydroxide, was subjected to a pressure of 650 atmospheres and a cold of about -140° . On opening the tap, liquid hydrogen escaped with violence, making a sharp hissing sound. The jet had a steel-blue colour, and was perfectly opaque for the length of 12 centimeters. At the same moment a rattling was heard like that made by hail when it falls upon the ground, and the hissing became transformed into a peculiar noise, resembling that made by a fragment of sodium thrown upon water. Almost immediately the jet became intermittent, and shocks were felt in the cock at each escape. During the first jet the pressure fell from 650 atmospheres to 370. After closing the tap, the pressure gradually fell for several minutes down to 215 atmospheres, and then slowly rose to 225, where it again became stationary. On re-opening the cock the jet issued in so intermittent a manner as to show that the congelation of hydrogen had taken place in the tube. This was demonstrated by the progressive escape of all the hydrogen when the pumps were stopped, and the production of cold arrested (Pictet). Evidence of the liquefaction of hydrogen was also obtained by Caillietet.

Nitrogen.—This gas, prepared by the action of copper and ammonia on atmospheric air, then washed and dried over melted potash and strong sulphuric acid, was subjected to a pressure of 300 atmospheres at $+13^{\circ}$. On allowing it suddenly to expand, the gas remaining in the tube condensed to a mass of very minute liquid drops, which gradually disappeared from the sides of the tube and collected in the axis in the form of a vertical column, this series of changes taking place in about three seconds. A similar result was obtained with dry air quite free from carbon dioxide (Caillietet).

Nitrogen Dioxide passes to the liquid state under a pressure of 104 atmospheres at -11° ; at $+8^{\circ}$ it remains gaseous under a pressure of 270 atmospheres (Caillietet).

Carbon Monoxide is liquefied under the same circumstances as oxygen, viz. by a pressure of about 300 atmospheres at -29° , and sudden expansion (Caillietet).

Methane, CH_4 , similarly treated (pressure and temperature not stated), likewise exhibited a misty appearance at the moment of expansion.

Acetylene, C_2H_2 , was liquefied and solidified by P. and A. Thénard in 1874, by the action of the silent electric discharge (p. 34 of this Supplement). Caillietet, on submitting it to strong pressure, found that it contracted in volume more rapidly than it should according to Boyle's law, and was ultimately converted into a transparent colourless liquid, the liquefaction taking place :

Under 48 atm. at $+1^{\circ}$	Under 83 atm. at 18°
" 50 " 2.5°	" 94 " 25°
" 63 " 10°	" 103 " 31°

On suddenly removing the pressure, the tube was filled with a white opaque mist.

GAS-LIQUOR. On the utilisation of Gas-liquor in the Ammonia-soda process, see Gerlach (*Dingl. pol. J.* cccxiii. 82; *Chem. Soc. Jour.* 1877 ii. 236).

GAS-WELLS. On the Gas-wells of Pennsylvania, see J. L. Smith (*Ann. Chim. Phys.* [5], viii. 566; *Chem. Soc. Jour.* 1877, i. 287). These wells give out enormous quantities of gas, which issues at very high pressure. The following are analyses of the gases from three of the wells:

	Burns Butler Co.	Lechburg Westmoreland Co.	Harvey Butler Co.
CO_2	0.34	0.35	0.66
CO	trace	0.26	—
H	6.10	4.79	13.50
CH_4	75.44	89.65	80.11
C_2H_4	18.12	4.39	5.72
Hydrocarbon, of composition not stated	—	0.56	—

The gas from the Delameter well, about 30 miles from Pittsburgh, consists chiefly of ethane, C_2H_6 .

GASTALDITE. This name is given by J. Strüver (*Jahrb. f. Min.* 1876, 661) to a mineral which occurs in chloritic slate in the Val d'Aosta, near Brozzo, and in the valley of Lucano, accompanied by copper pyrites, garnet, and apatite. It crystallises in the monoclinic system. Type prismatic, through ∞P and ∞R , the terminal faces being indistinct. It occurs also pulverulent and fibrous. Prismatic cleavage with an angle of $124^{\circ} 25'$. Fracture conchoidal. Hardness 6-7. Sp. gr. 3.044. Colour blackish-blue to sky-blue. Streak greyish-blue. Lustre vitreous to pearly. The plane of the optic axes is the plane of symmetry. Gastaldite exhibits negative double refraction, an inclined dispersion, and strong pleochroism. An analysis showed it to have the following percentage composition:

SiO_2	Al_2O_3	FeO	MgO	CaO	Na_2O	K_2O
58.55	21.40	9.04	3.92	2.03	4.77	trace = 99.71

from which the formula $3\text{RO} \cdot 2\text{Al}_2\text{O}_3 \cdot 9\text{SiO}_2$ is obtained: $\text{RO} = \text{FeO}, \text{Na}_2\text{O}, \text{MgO}, \text{CaO}$.

GASTRIC JUICE. Observations on the composition and physiological action of the gastric juice have been made by Ch. Richet (*Compt. rend.* lxxxiv. 450, 1514) on a patient upon whom, in consequence of the complete closure of the œsophagus, the operation of gastrotomy had been performed. Through the fistulous opening thus established, pure gastric juice, quite free from saliva, was obtained by washing out the stomach with distilled water, and then placing in the mouth some sapid substance which, by its reflex action, provoked a relatively abundant secretion. Pure gastric juice, thus obtained, is a colourless liquid, viscid, but easy to filter, having little odour and not putrefying spontaneously.

The mean acidity of the gastric juice, whether pure or mixed with food, is nearly equivalent to 1.7 gram of hydrochloric acid per 1000 grams of liquid. The acidity never fell below 0.5, nor rose higher than 3.2 grams. The quantity of liquid found in the stomach has no influence on its acidity, which, indeed, is almost invariable, whether the stomach be nearly empty or very full. Wine and alcohol increase the acidity, while cane-sugar diminishes it. If acid or alkaline liquids are injected into the stomach, the gastric juice reassumes its normal acidity in about one hour. The gastric juice is more acid during digestion than when digestion is not proceeding, and the acidity increases towards the end of the operation of digestion.

Berthelot has shown (*Chem. Soc. Jour.* 1872, 783) that when an aqueous solution of organic and inorganic acids is shaken up with ether, the former dissolve in the

ether while the latter remain for the most part undissolved. By following this method, Richet finds that the acids of the gastric juice are almost entirely inorganic, or, more strictly speaking, they are acids insoluble in ether.

Gastric juice, when left to itself, gradually ferments, the amount of organic acid slowly increasing at the same time, until it doubles that of the inorganic acid.

When the gastric juice is separated from the glands of the stomach and mixed with food, its acidity greatly increases during the artificial digestion thus set up, but the inorganic acids always predominate. The ferment producing this acidity is partially soluble.

The time required for digestion varies from three to four hours, for such aliments as starch, fat, or flesh proper; the digestion of milk lasts only about an hour and a half to two hours, while alcohol and water are still more rapidly absorbed, no trace of them being left at the end of thirty-five to forty-five minutes.

GAULTHERIA OIL. *Testing for Adulterations.*—The presence of sassafras oil may be detected by adding 3 or 4 drops of nitric acid (sp. gr. 1·3 to 1·4) to 4 or 5 drops of the oil. Pure gaultheria oil, thus treated, shows no change at first, but solidifies after some hours to a mass of colourless crystals (nitro-methylsalicylic acid); sassafras oil, on the other hand, assumes a blood-red colour, and soon changes to a brown amorphous mass. Chloroform may be detected by its odour when the liquid is warmed (*Chem. Centr.* 1876, 30).

GAULTHERYLENE, C¹⁰H¹⁶. This hydrocarbon boils at 160°, and has a vapour-density = 4·74 (referred to air). By oxidation with chromic acid mixture it is converted into a resinous mass. Hydrochloric acid gas is abundantly absorbed by it, and the product, after repeated rectification, boils at 185°. The distillate is colourless and has a camphorous odour (Biedermann, *Deut. Chem. Ges. Ber.* 1875, 1677).

GEHLENITE. This mineral occurs at Orawicza in the Bannat, in round green lumps, enclosing granules of vesuvianite, and covered with a soft amorphous crust having the composition of samoite in which the alumina is partly replaced by ferric oxide. Analyses 1 and 2: Outer layers of the gehlenite, sp. gr. 2·997 (Janovsky, *Deut. Chem. Ges. Ber.* vi. 1454). 3. Innermost layer of the rounded lumps, consisting of pure gehlenite, sp. gr. 3·01 (Janovsky and v. Zepharovich, *ibid.* vii. 109; *Wien. Akad. Ber.* [1 Abth.] lxxix. 26). 4. Vesuvianite. 5 and 6. Outer crust.

GELSEMIUM. From an examination of the constituents of *Gelsemium semper-virens* by Ch. Robbin, reported by Sonnenschein (*Deut. Chem. Ges. Ber.* ix. 1182), it appears that the substance called *gelsemic acid* by Wormley (2nd Suppl. 552) is identical with *æsculin*.

The alkaloid gelsemine is an amorphous, colourless, or slightly pinkish mass melting below 100° to a colourless liquid. It dissolves but sparingly in water, more readily in alcohol, and freely in ether and chloroform. Its solution has a very bitter taste, and a strongly alkaline reaction. Its *hydrochloride* is amorphous, neutral, readily soluble in water, and the solution is precipitated by tannic acid, solution of iodine in potassium iodide, gold chloride, phosphomolybdic acid, &c. Platinic chloride produces an amorphous, lemon-yellow precipitate, which dissolves on warming, and crystallises on spontaneous evaporation in transparent quadratic octohedrons, which, on the addition of water, are changed into the amorphous compound, while platinic chloride goes into solution.

The composition of gelsemine is C¹¹H¹⁹NO²; that of the hydrochloride (C¹¹H¹⁹NO²)²ClH, and of the amorphous platinum-salt 2[(C¹¹H¹⁹NO²)²ClH] + PtCl⁴. The pure alkaloid dissolves in concentrated nitric acid, with a greenish-yellow, and in sulphuric acid with the same colour, which, however, soon changes into a reddish-brown and dirty red. When potassium dichromate is added to the sulphuric acid solution, the liquid changes first into cherry-red, and then into bluish-green; with ceroseeric oxide a bright cherry-red colour is produced. A large pigeon, to which 0·012 gram of the hydrochloride was administered, died with convulsions in thirty-six minutes, and frogs exhibited the same symptoms.

GENTIAN. According to Hager (*Chem. Centr.* 1876, 823), some kinds of gentian-root contain tannin, whereas others do not. Ville (*Pharm. J. Trans.* [3], viii. 182) finds that cold infusions of *Gentiana Burseri* contain tannin. The colouring principle, gentianin or gentisin, gives the tannin reactions distinctly, for which reason Ville proposes to call it *gentianotannic acid*. The bitter principle, *gentiopicroin*, does not give the reactions of tannin.

GENTISIN, $C^{14}H^{10}O^5$. This substance, the colouring matter of gentian-root—also called *gentianin*, *gentianic acid*, and *gentisic acid* (ii. 830)—has been further examined by Hlasiwetz a. Habermann (*Deut. Chem. Ges. Ber.* vii. 652). According to these chemists, the potassium and sodium-derivatives contain $C^{14}H^9KO^5$ and $C^{14}H^9NaO^5$ respectively, and *acetyl-gentisin*, formed by the action of acetyl chloride on gentisin, has the composition $C^{14}H^8(C^2H^3O)^2O^5$.

By the action of melting potash, gentisin is resolved into acetic acid, phloroglucin, and an acid $C^6H^4O^4$, called *gentisic acid* by Hlasiwetz a. Habermann, who state that it does not agree in its properties with protocatechuic, oxysalicyclic, dioxybenzoic, or hypogallic acid.* The decomposition is represented by the equation:

Gentisic acid melts at 197° [oxysalicyclic acid at 196 – 197°], and when heated above its melting point is resolved into CO^2 and pyrogentisic acid, $C^6H^4O^3$, a compound said to differ from all the known dioxybenzenes, viz. pyrocatechin, resorcin and hydroquinone.

GERANIENE, $C^{16}H^{16}$. This hydrocarbon, obtained from geranium oil by the action of phosphorus pentachloride, is converted, by treatment with half the calculated quantity of iodine, into cymene, $C^{10}H^{14}$ (Oppenheim a. Pfaff, *Deut. Chem. Ges. Ber.* vii. 625).

GILBERTITE. The gilbertite of the Saxon and Bohemian tin mines occurs in two varieties, differing considerably from one another.

(1). One of them is of greenish-white to yellowish-white colour; translucent; occurs in crude lumps of compact to crystallo-granulo-laminar structure, vitreous to fatty lustre, hardness = 1, sp. gr. = 2.65 – 2.72 . It is found on all the veins of tin ore at Altenberg, Ehrenfriedersdorf, Geyer, Pöbershau, Zinnwald, and Schlaggenwald, alternating with tin-stone, wolframite, molybdenite, fluor-spar, &c., and penetrating into all the interstices of the tin-stone and wolframite. It is easily removed from these cavities when the lumps are broken up, and then always exhibits shining contact-faces, sometimes also impressions of the parallel streaks of the wolframite, and is even found imbedded in wolframite. It forms pseudomorphs after topaz, the substance of which has hitherto been designated as 'lithomarge', having indeed considerable resemblance to many kaolins of the tin-stone veins, especially those of Altenberg, which formations have likewise been designated as lithomarge, or even as steatite. Kaolin may, however, be rubbed to dust, whereas gilbertite can only be broken into small laminae.

(2). The second variety, which is found in the same localities, accompanying apatite, iron spar, and nacrite, also tin-stone, wolframite, fluor-spar, &c., occurs in spherical and stellate, concentrically laminated modifications, also in six-sided tabular crystals commonly united in spherical groups. Colour light yellowish-green to sea-green and leek-green. Lustre, vitreous. Hardness = 3. Sp. gr. = 2.82 . This variety is known as pseudomorphs after scheelite and apatite; it has also been found in roundish clusters, enclosed in lumps of siderite (from Schlaggenwald), which seems to suggest its production by transformation of that mineral.

The following are analyses of gilbertite from the localities above mentioned:—*a*, of the first variety from Ehrenfriedersdorf; *b*, of the same from Pöbershau; *c*, of the second variety from Ehrenfriedersdorf:—

	SiO ²	Al ² O ³	FeO	CaO	MgO	K ² O	Na ² O	F	H ² O
<i>a</i> .	48.96	30.96	2.24	0.26	1.97	8.47	1.65	1.04	3.83 = 99.38
<i>b</i> .	48.10	32.30	3.30	0.40	1.12	10.02	—	0.31	4.09 = 100.14
<i>c</i> .	48.10	31.55	3.10	1.30	1.33	8.62	2.14	0.88	3.52 = 100.54

Lehmann found, in gilbertite from St. Austell in Cornwall, 45.15 SiO², 40.11 Al²O³, 2.43 FeO, 4.17 CaO, 1.90 MgO, and 4.25 water, whence Dana regards this Cornish

* The four known modifications of the acid $C^6H^4O^4$, or $C^6H^3(OH)^2CO^2H$, are [CO²H in 1), protocatechuic acid 1 : 3 : 4, oxysalicyclic acid 1 : 2 : 5, and two other dioxybenzoic acids, 1 : 2 : 4 and 1 : 3 : 6 (or 1 : 2 : 3) formed from the two corresponding disulphobenzoic acids (p. 289). The so-called *hypogallic acid* (iii. 239) has lately been shown by Beckett a. Wright to be a mixture, most probably of opianic, hemipinic, and protocatechuic acids (see NARCOTINE).

variety as an impure kaolin. It is more probable, however, that in Lehunt's analysis the alumina was estimated too high and the potash overlooked.

Gilbertite is a distinct mineral species belonging to the mica group. The species 'lithomarge' may be abolished. Aluminic silicates of this class, which have not the composition of gilbertite, are included in the formula, $\text{Al}^{20}\text{O}^3 \cdot 2\text{SiO}^2 + 2\text{H}^2\text{O}$, and consist either of nacrite or of kaolin. Such at least is the case with those which occur in Saxony: thus, the lithomarge of the tinstone veins, of the gangues of Freiberg, Johannegeorgenstadt, &c., of the pelosiderites (argillaceous sphærosiderites) of Zwickau, Wärschnitz, &c., of the topaz-rock of Auerbach, &c., all consist either of nacrite or of kaolin. The amorphous varieties of lithomarge, called myelin and carnat, have also, as previously shown by Frenzel (*J. pr. Chem.* [2], v. 401), the composition of kaolin. Gilbertite and nacrite occur together on the tin veins, the formation of these two minerals appearing indeed to be related to that of the tin-ore gangues (Frenzel, *Jahrbuch f. Mineralogie*, 1873, 794).

GINGER. The extract obtained by boiling ground ginger (*Zingiber officinale*) with alcohol, and evaporating the filtrate, has a strong odour of ginger, and when heated in a current of steam yields a small quantity of essential oil lighter than water. When fused with soda, it yields protocatechuic acid (Stenhouse a. Groves, *Chem. Soc. J.* 1877, i. 553).

GINILSITE. A greyish-yellow mineral from the Ginil Alp, in Graubünden. Sp. gr. = 3.404. Composition:—

SiO^2	Al^{20}O^3	Fe^{20}O^3	CaO	MgO	H^2O
37.83	7.77	15.63	26.67	9.73	3.30 = 100.93

(Rammelsberg, *Jahrb. f. Min.* 1877, 97).

GISMONDIN. The gismondin of Salesl in Bohemia is rhombic, the crystals exhibiting a combination of the prisms with a brachydome and a macrodome. The type is quadrate and the crystals resemble those of bournonite. Axial ratio, $a : b : c = 0.99246 : 1 : 0.94897$. Of the zeolites occurring in the druses of Salesl, analcime is the oldest formation, natrolite the next, and gismondin the last. Gismondin often occurs in the place of apophyllite, which is also a younger formation than natrolite. The succession of the zeolites depends upon the degrees of solubility of their constituents, the more recent formations being the more soluble. The younger zeolite formations exhibit, with but slight variation in the amount of alumina, a decrease of alkalis and silica, and an increase of lime and water. With a constant proportion of silica, they are richer in water, and conversely, with equal proportions of water, they are poorer in silica (Schrauf, *Jahrb. f. Min.* 1877, 944). Gismondin occurs also in the druses of the basalt of the Schifffenberg near Giessen, as a younger formation than phillipsite (A. Streng, *ibid.* 1874, 578).

GLASS. *Constitution.*—From experiments by O. Schott (*Dingl. pol. J.* cccvi. 346) it appears that ordinary glass is a mixture of amorphous alkali-silicate (or borate) with crystallisable calcium silicate. At the high temperature of the glass furnace, the sodium or potassium silicate dissolves the calcium silicate, and by its viscosity prevents the latter from crystallising out during cooling. The composition of glass may be represented by the general formula $\frac{x\text{Na}^2\text{O}}{y\text{CaO}} \left\{ z\text{SiO}^2 \right.$. The proportions of the constituents for each kind of glass must be determined by considerations of utility. If the bases are in the ratio $\text{Na}^2\text{O} : \text{CaO} = 1 : 1$, the proportion of silica in the glass must not be less than 67 per cent.; otherwise devitrification is apt to take place during cooling. Glass thus composed may be represented by the formula $\frac{\text{Na}^2\text{O}}{\text{CaO}} \left\{ 5\text{SiO}^2 \right.$. With a larger proportion of sodium silicate the glass does not easily devitrify, even when the quantity of silica is less than 67 per cent.; for example, a glass having the composition $\frac{2\text{Na}^2\text{O}}{\text{CaO}} \left\{ 4\text{SiO}^2 \right.$ and containing 57.1 per cent. silica, remains amorphous on cooling. For plate-glass, which is exposed to the weather, the proportion of silica should be as high as possible. Crown glass should contain less silica, but more lime. Its composition is usually 71.5 per cent. silica, 13.5 soda, and 15.0 lime.

Chemical Changes which take place during the Fusion of the Glass-mixture.—When the mixture consists simply of sodium carbonate, calcium carbonate and silica, the carbonates first fuse together, and are afterwards decomposed, at a higher temperature, by the silica, with evolution of carbon dioxide. But when, instead of sodium carbonate, a mixture of sodium sulphate and carbon is used, a more complex reaction takes place. When the pot is heated, the conduction of heat is at first so slow that even after exposure to a white heat for three or four hours, only the outer portions of the mass are fused, while the unfused portion in the centre is still sandy and

scarcely red-hot, and the fused glass near the edges of the pot remains turbid from admixture of unfused sand and small gas-bubbles. The zone between the solid centre and the fused outer portion is coloured brown by sodium sulphide, and still contains lumps of unaltered calcium carbonate. It is only in the second stage of the process, the 'refining,' that a rapid evolution of gas takes place.

Carbon and silica may act on sodium sulphate according to either of the three following equations:

In practice, for every molecule of sodium sulphate 0.6 of a molecule of carbon is used; this is too little for equation 2; but carbon from the furnace acts on the glass, and alkali (from 10 to 15 per cent.) volatilises:—0.6 mol. carbon is too much by 0.1 for equation 3; but the coke used contains 10 per cent. of ash, and some of it is burnt on the surface of the pot. The proportions in which the several ingredients enter into the mixture can therefore throw but little light on the reactions which take place.

The only gases actually given off are CO^2 and SO^2 ; nevertheless the source of these gases is not to be sought exclusively in the reaction represented by equation 3: for direct experiment shows that carbon monoxide, which should be evolved according to equation 2, acts upon sodium sulphate, either alone or in presence of silica, as follows:

The sodium sulphide formed according to the first of these equations, acts further on the sulphate as follows:

A similar reducing action is perhaps exerted by the calcium sulphide in the soda-residues sometimes used in the manufacture of glass.

Lastly, the calcium carbonate in the glass mixture acts on the sodium silicate, forming calcio-sodic silicate, which constitutes the glass:

(O. Schott, *Dingl. pol. J.* ccxv. 529; *Chem. Soc. J.* 1876, i. 121).

On the use of Soda-residues in glass-making, see R. Wagner (*Dingl. pol. J.* ccxv. 358; *Jahresb. f. Chem.* 1865, 1085). On the utilisation of manganese-residues in the same manufacture, see *Jahresb. f. Chem.* 1873, 1042.

On the wear of the Melting-pots, and the best means of retarding it, see Platenka (*Dingl. pol. J.* ccxxii. 322; *Jahresb. f. Chem.* 1876, 1117).

Formation of Gold-platinum Mirrors on Glass.—A plate of glass, having been well cleaned and polished, is covered with the following mixture, which is fused upon it at a red heat. A solution of 500 grams of platinum in aqua regia is diluted with 5 litres of water, and mixed with 2 kilograms of ammonia; the washed and dried precipitate is dissolved in 50 grams of hydrochloric and 50 grams of nitric acid; the solution is mixed with 50 grams of water; the whole is evaporated to dryness; and the residue is mixed with 2,000 grams of essence of lavender, 100 grams of turpentine oil, and 2.5 grams of sulphuretted turpentine-balsam. Secondly, 30 grams of gold are dissolved in aqua regia; the solution is evaporated to dryness; the residue shaken up with 500 c.c. water and 500 c.c. ether; the ethereal layer pipetted off and added to the platinum solution; and the ether evaporated. Lastly, to the mixed solution thus prepared is added an intimate mixture of 50 grams litharge, 50 lead borate, and 100 lavender oil; and the whole, after having been rendered homogeneous by shaking, is laid upon the glass (Dodé, *Deut. Chem. Ges. Ber.* vi. 1273).

On the Etching of Glass with Hydrofluoric acid, see Heck (*Dingl. pol. J.* ccxv. 129; Siegwart (*ibid.* ccxx. 479); also *Jahresb. f. Chem.* 1875, 1094; 1876, 1117).

Coloration of Glass by Metals. Copper-ruby Glass. (Ebell, *Dingl. pol. J.* ccxiii. 53, 131, 212, 321, 401, 497; *Chem. Soc. J.* 1875, 485). Many metals, namely noble metals, such as gold and silver, and easily reducible metals like copper and lead, are capable of dissolving as such in melted glass. Gold, silver, and copper can enter as metals into glass in two molecular states, in one of which they do not colour the glass, while in the other they produce a strong coloration. The non-colouring molecular condition of the metals corresponds with the highest temperatures and the nascent state; the colouring molecular condition, with the lower temperatures

and the solid state of the metal. The passage from the former of these molecular states to the latter is called 'tempering' (*Anlaufen*).

Copper-ruby glass is prepared by two methods: 1. By coloration of the ready-made glass (*Lasur*). Copper and iron scales and ochre are rubbed with oil of turpentine to a thin paste, which is applied to the glass by a brush; and after drying, the glass is heated in the furnace, whereupon it absorbs a portion of the copper mixture and acquires a dark-green colour. The development of the ruby colour is effected by heating the copper in a muffle with wood-charcoal for a reducing agent. The coloration succeeds only with potash-glass free from lead, never with crystal or flint-glass.

2. *Fusion Process*.—The glass mixture and copper mixture are fused together and the fused mass is rapidly cooled, whereupon it appears colourless, or with a faint green colour due to iron or other accidental constituents; but on heating it further to the point at which it softens, the deep red colour is suddenly developed throughout the mass (*Anlaufffarbe*). This change exactly resembles that which is observed in the development of the colour in gold-ruby glass (*2nd Suppl.* 555).

Solutions of the above-mentioned metals in glass obtained by fusion, solidify unaltered when quickly cooled; but on leaving them to cool slowly, the metal separates out, always in the metallic state, either as a finely divided precipitate, or in crystals, microscopic or macroscopic according to circumstances.

Gold, silver, and copper, either in the solid state or in solution, exhibit in their optical relations a very close resemblance to colouring matters of mineral or of organic origin, such as Prussian blue, indigo, the aniline-dyes, murexid, &c. Many colouring matters, indeed, have in the solid state a decided metallic lustre, and when finely divided or dissolved, a peculiar rich and bright colour, the two colours thus exhibited being nearly complementary to each other. A similar relation exists between the colours exhibited by gold, silver, and copper in the metallic state, and when dissolved in glass. These metals, indeed, in the state of igneous fusion, are true colouring matters, far exceeding the ordinary dye-stuffs in the solid state in their density, and consequently in their power of reflecting light (Ebell).

Crystallisation of Metallic Oxides from Glass.—Glass at a full white heat dissolves large quantities of metallic oxides, and deposits them on slow cooling in the micro-crystalline state. The oxides in which this effect has been observed are stannic oxide, chromic oxide, manganese dioxide (dissolved as manganoso-manganic oxide), and alumina (Ebell, *Dingl. pol. J.* cxxx. 64, 156, 288).

Bottle-glass. The following table gives the mean results of a number of analyses of bottle-glass by H. Macagno (*Chem. News*, xxxviii. 5). The solubility in water was obtained by weighing the quantity of material dissolved by 5 litres of water in one hour from 100 grams of finely-pulverised glass; the corrosion-degree was ascertained by boiling 100 grams of the same powder for one hour with 5 litres of potassium bitartrate solution of 0.33 per cent., and estimating the quantity of tartaric acid neutralised:—

	Spec. grav.	Chem. comp. per cent.				Solubility in water	Corrosion degree
		K ² O+ Na ² O	CaO	Al ² O ³ + Fe ² O ³	SiO ²		
White glass (five samples)	2.453	14.51	8.22	1.92	75.34	2.617	2.020
Light green glass (three samples)	2.474	15.52	7.73	5.47	71.27	3.177	3.975
Common green glass (eleven samples)	2.570	10.92	15.10	10.34	63.56	2.600	3.202
Dark green glass (two samples)	2.674	3.38	26.58	10.53	58.59	1.270	1.275
Red-brown glass (six samples)	2.516	15.77	9.28	6.88	66.15	3.470	4.888
Yellow-brown glass (seven samples)	2.553	14.62	14.35	8.02	62.84	2.504	3.387

One specimen of red-brown glass contained a trace of manganese. All the samples contained magnesia; in the analyses, when in sufficient quantity to be estimated, it is included with the lime. It would seem from the table that the chemical composition of glass is no criterion for judging of its quality. The amount of base does not indi-

cate the resisting power to water or acids. The deep-green glass seems the best for wine-bottles; the light-green, red-brown, and yellow-brown glasses are the worst, being easily attacked by solution of potassium bitartrate.

Composition of Ancient Glass. By E. Peligot (*Compt. rend.* lxxxiii. 1129; *Ann. Chim. Phys.* [5], xiii. 271). The following results were obtained from various specimens of ancient glass:—

SiO ²	66·7	66·0	67·4	70·9	69·4	69·4
CaO	5·8	7·2	2·7	7·9	6·4	7·1
Al ² O ³ , Fe ² O ³ and MnO ²	2·8	3·0	5·4	4·5	2·9	2·8
K ² O and Na ² O	24·7	23·8	24·5	16·7	21·3	20·7
	100·0	100·0	100·0	100·0	100·0	100·0

Soda and potash generally occurred together, showing that the alkali was obtained from the ash of marine plants. The proportion of lime was only the half or the third of that now in use, in consequence of which the glass generally altered considerably on exposure to the air. Some very old specimens of glass were found to contain lead; one specimen of very heavy glass, weighing 1,000 grains to the cubic inch, contained nearly half its weight of lead oxide.

Decomposition of Glass. Ordinary soda-glass is decomposed by hot water much more easily than the potash-glass used for combustion-tubes. When distilled water is boiled in a flask fitted with two tubes bent downwards a little above the cork, one made of ordinary glass, the other of combustion-tubing, and the condensed water which drops from them is allowed to fall on a piece of delicate red litmus-paper, the water dropping from the soda-glass tube will colour the litmus distinctly blue, whereas that which drops from the tube of potash-glass will produce no effect (*Tollens, Deut. Chem. Ges. Ber.* ix. 1540).

Various pieces of old glass examined by De Luynes (*Compt. rend.* lxxxiv. 303), were found to be covered with scales containing nearly 80 per cent. silica, whereas the glass itself did not contain more than 68 per cent. The transparency of the glass was not diminished by this change.

Glass submitted to influences which decompose it very slowly, such as continued exposure, to moisture, to exhalations from damp earth, or to ammoniacal or acid vapours, often becomes covered with a thin film or scale, which exhibits very remarkable phenomena of iridation. This effect may be imitated, and an adherent coating resembling mother-of-pearl produced, by submitting the glass, under the influence of heat and pressure, to the action of water containing 15 per cent. of hydrochloric acid (*Frémy a. Clémandot, Compt. rend.* lxxxiv. 209).

Devitrification.—From numerous analyses of silicates separated from devitrified glass, Benrath (*Dingl. pol. J.* cciii. 19) infers that ordinary devitrified glass is not formed of tri- or tetra-acid silicates, but that glass in its ordinary state is a solution of silica or other crystallisable bodies in a ground-mass (perhaps R₂O·2SiO₂), and that in this, as in all other solutions, different temperatures correspond with different maximum-contents of dissolved substance. Glass, apparently homogeneous, is like a supersaturated solution suddenly solidified, and when it is softened, or when movements take place in the interior of the mass, the crystallisable constituents, viz. silica and feldspathic silicates, separate out. According to this view, the devitrification of glass is a change analogous to the separation of crystallised chromic oxide (chrom-aventurin), or to the turbidity which shows itself in milk- or alabaster-glass containing calcium phosphate or stannic oxide.

From analyses of three specimens of devitrified glass, and of the amorphous glass from the same samples, H. Schwartz (*Dingl. pol. J.* ccv. 422) infers that amorphous glass may be regarded as the true mother-liquor of the crystals. The sp. gr. of the crystals examined was 2·656 to 2·660, that of the amorphous glass 2·641 to 2·648. These samples, which were from the glass-works of Fr. Siemens at Dresden, contained from 5·22 to 6·87 per cent. of manganous oxide. The property of the manganous oxide to act as a flux, suggests the employment of manganiferous blast-furnace slags in glass-works. The manganese in these slags is usually in the form of sulphide, and the sulphur might easily be removed by the addition of sodium sulphate, according to the reaction:

Soda and manganous oxide would thus be disposable for the formation of silicates, while the sulphur would be got rid of (Schwartz).

The following analyses of devitrified glass, and of the corresponding amorphous glass, are given by H. Wieser (*Dingl. pol. J.* cciv. 390):

	SiO ²	Al ² O ³	FeO	CaO	MgO	MnO	K ² O	Na ² O	S	
Amorphous .	77.08	2.08	0.22	5.77	trace	0.14	1.18	13.88	0.25	= 100.60
Crystallised .	76.73	1.01	0.57	5.37	0.41	0.33	7.15	7.77	0.02	= 99.36

According to these analyses, the crystallised glass contains somewhat less silica than the amorphous, and about the same quantity of lime; the crystallised glass also contains about six times as much potash as the amorphous, whereas the latter contains twice as much soda as the former. Henrivaux (*Bull. Soc. Chim.* [2], xix. 6) points out that these results are contradictory to those obtained by Pelouze, Clémandot, Bontemps, and others, who have shown that the amorphous glass always contains more alkali than the crystals, whereas the latter are richer in silica and in lime (*2nd Suppl.* 556). Bontemps, on the other hand (*Bull. Soc. Chim.* [2], xxi. 166), is more disposed to admit the correctness of Wieser's results, and thinks that the subject requires further investigation.

The crystallisation-products in ordinary glass have also been examined by Schott (*Pogg. Ann.* clv. 422). Previous to the formation of crystals in the glass, a film is produced on the surface by volatilisation of the alkali, exhibiting at first the colours of thin plates, but afterwards becoming white and opaque. Beneath this film bubbles are formed by further volatilisation of the alkali, and it is from these that the crystallisation starts, at first in the form of imperfectly developed crystalline growths, which afterwards unite into compact crystals. The formation of the crystals consists essentially in a separation of the amorphous from the crystalline constituents of the glass. The crystals consist of calcium silicate. Schott also regards glass as analogous in constitution to a saline solution saturated at high temperatures, the alkali-silicate forming the solvent of the calcium silicate. As the temperature rises, the calcium silicate becomes more soluble, and when cooled to a certain point, it separates out. The solution of the calcium silicate in the sodium silicate easily passes, however, into the supersaturated state, and such is its condition in ordinary glass, and it is only when the glass is kept for a considerable time at a red heat that the molecules of the calcium silicate are able to unite together. In many glasses made from impure materials, the rhombic crystals of calcium silicate are accompanied by hexagonal crystals of alumina.

Moulded-Glass. In order that glass may be easily shaped by pressing it into a mould, without the necessity of heating the mould too strongly, it must be easily fusible, must not pass too quickly from the plastic to the solid state, and must be capable of softening quickly when heated before the mouth of the furnace. Formerly lead-crystal glass (ii. 841) was the only kind that fulfilled these conditions; thus a moulded glass analysed by Benrath (*Dingl. pol. J.* ccxviii. 275) contained 50.80 per cent. SiO², 0.14 Al²O³ (with Fe and Mn), 28.11 PbO, and 11.62 K²O. Such glass was, however, too dear for the purpose; and, moreover, the pressed vessels made from it, which are always thick-walled, are too heavy. The first step taken to remedy these defects was the substitution of soda for potash. An English moulded-glass of recent manufacture, and having a density of 2.874, was found by Benrath to contain 61.27 per cent. SiO², 0.68 Al²O³ (with Fe and Mn), 33.36 PbO, 1.05 CaO, 7.55 Na²O, and 7.07 K²O. This composition was obtained by melting together 300 pts. sand, 110 minium, 10 chalk, 70 soda and potash; other manufacturers have attained the same end by using baryta or lime instead of lead oxide. Thus Renault, in Maestricht, by working with a mixture of 300 pts. sand, 80 minium, 40 limestone, 40 witherite, 80 potassium carbonate, and 10 nitre, obtained a glass having the composition:

SiO ²	PbO	CaO	BaO	K ² O	
61.9	16.0	4.5	6.3	11.3	= 100

and a light moulded-glass of recent English manufacture, sp. gr. 2.524, gave by analysis:

SiO ²	SO ³	PbO	Fe ² O ³	BaO	CaO	Na ² O	
74.19	0.28	0.86	0.58	5.16	2.88	17.02	= 100.97

American moulded beer-glasses were found by Caplan (*Dingl. pol. J.* ccxxvii. 509) to have the following composition:

SiO ²	Fe ² O ³	Al ² O ³	MnO	CaO	MgO	Na ² O and residue	
75.00	0.19	0.11	0.38	5.18	0.52	18.62	= 100

According to A. Frank, the American glass is very fusible and has a density of 2.486.

Alabaster-, Milk-, Bone-, Cryolite-, and Opal-Glass. By M. Hodk (*Dingl. pol. J.* ccxxiv. 623-628). The chief constituents of *alabaster-glass* are non-ferruginous sand and potash. The presence of sodium-salts should be avoided, as they tend to produce transparent easily fusible glass. Most recipes include 'burnt bones,' but

good alabaster glass can be produced without them. Borax increases the lustre and fusibility of the glass, but is not absolutely necessary. Powdered tale is also advantageous. Good results are obtained by taking 100 parts sand, 40 parts potash containing at least 95 per cent. of carbonate, 5 borax, and 5 tale. The potash may be reduced to 30 parts if a hot regenerative gas furnace be used.

Coloured glasses are obtained by adding, for turquoise, copper oxide and sulphate, or copper oxide with a little nitre; and for chrysoprase, uranium oxide with a little copper oxide. A grey violet colour is obtained by adding manganese oxide and Ceylonese graphite.

Milk- or Bone-glass is obtained by adding sufficient bone-ash or tin oxide. Of late bone-ash has often been replaced by burnt guano:

(a) 100 parts sand.	(b) 100 parts sand.
30 " bone-ash.	35 " potash.
30 " potash.	30 " burnt guano.
5 " borax.	3 " nitre.
5 " minium.	3 " tin oxide.

Cryolite is now applied in Bohemian works to imitate imperfectly French and Belgian opal-glasses. The effect of cryolite depends mainly on its alumina. The fluorine, however, acts prejudicially, on account of the volatile compound which it forms with silica. Too much cryolite renders the glass too opaque, and the fluorine injures the pots and furnace. The following mixture yields a good glass:—100 parts sand, 20 parts cryolite, 12 parts soda, 4 parts sodium nitrate, 2 parts zinc or lead-oxide.

An analysis of Belgian opal-glass gave:

SiO ₂	PbO	FeO	Al ₂ O ₃	K ₂ O
63·7	16·5	0·3	16·8	2·3 = 99·6.

Here the alumina gives opacity, whilst the large quantity of lead oxide tends to the durability of the finished objects. Experiment shows that 100 parts of finely powdered felspar free from iron, and 22 of minium free from iron and copper, form a completely homogeneous, fusible mass, easily worked without decomposition. This glass in its properties closely approximates to the French and Belgian glass. Metallic oxides yield very rich colours with it. See further Ebell (*Dingl. pol. J.* ccxxv. 70 and 168; *Chem. Soc. Jour.* 1878, xxxiv. 97).

Hard or Toughened Glass. This kind of glass, discovered by De la Bastie in 1875, is prepared by heating ordinary glass to its softening point, then immersing it in a heated bath of oil, fat, wax, paraffin, resinous or bituminous substances, and cooling it quickly. A. Bauer (*Dingl. pol. J.* ccxv. 331) dips the glass into a bath of paraffin heated to 200°, then cools it quickly to a certain point, and afterwards gradually. The best kind of bath is, however, a steam-bath, as it is free from the danger of fire arising from the use of fat or oil baths, and may be regulated to any desired temperature by the use of saturated, unsaturated, or superheated steam.

Glass treated in this manner is so hard that it cannot be cut with a diamond, and has a density of 2·460–2·468, that of ordinary glass being 2·420–2·438. It does not differ in appearance from ordinary glass. Plates of it may be repeatedly thrown on the ground without fracture, and give out a peculiar ring; but if they do break, they crumble into a multitude of small angular fragments; and the same sudden disintegration sometimes takes place without any apparent cause. The tenacity of glass toughened in an oil-bath is said to be equal to 601 kilos., and of glass toughened in a steam-bath 700 to 1000 kilos. per square centimeter, whereas that of ordinary glass is only 220 kilos. Bottles of toughened glass have been found to stand a pressure of 52 atmospheres, whereas ordinary glass bottles of the same thickness stand only 39 atmospheres. De la Bastie (*Dingl. pol. J.* ccxx. 186) found that a plate of hard glass 6 mm. thick was broken into fragments by a weight of 100 grams let fall upon it from a height of 0·8 meter. A plate 3 mm. thick withstood the fall of the same weight from a height of 5 mm., but was broken into very small fragments when the weight fell upon it from a height of 5·75 mm. A strip of hard glass withstood the heat of a flame without cracking, and remained unaltered when dipped into cold water, and heated in the flame while still wet. Pilati (*ibid.* 187) found that blue hard glass had a sp. gr. = 2·522, hardness = 5, and contained 68 per cent. silica, 10 lime, 2 alumina, 17 alkalis, and 3 magnesium, iron, chlorine, and cobalt-compounds.

According to Luyne's a. Feil (*Compt. rend.* lxxxi. 341), hard glass breaks in a similar manner to Rupert's drops. A disc of it may, however, be bored through in the centre without breaking. A square plate of hardened mirror-glass from St. Gobain

showed in polarised light a dark cross, the arms of which were parallel to the sides of the square. The plate could be sawn or cut, without breaking, in the direction of these arms, but not in any other.

The peculiar constitution of toughened glass is not very well understood, but there can be no doubt that its molecules are in a state of tension like those of Rupert's drops and unannealed glass in general. According to Bauer, the effect of the sudden cooling is to preserve the homogeneity of the glass; slow cooling may give occasion to a disintegration of the homogeneous mixture of silicates, which is less liable to take place when the mass is quickly cooled. Pocklington (*Pharm. J. Trans.* [3], vi. 5) infers from optical examination that the physical structure of hard glass is exactly the same as that of glass under strong pressure, and he attributes its peculiar properties to the fact that it consists of a layer of ordinary glass enclosed between two layers of rapidly cooled glass. The slightest disturbance at the surface of contact of the layers in these different states of tension, causes the glass to fall to powder. The glass, if very uniformly hardened, may be worked with a file wetted with oil of turpentine, and with proper precaution it may be polished on a stone. Hydrofluoric acid attacks the soft parts of the glass more strongly than the hard parts, so that wave-lines are produced on the surface, corresponding exactly with those which the glass exhibits in polarised light.

On Soluble Glass, containing Alkaline Bases only, see R. Meyer (*Dingl. pol. J.* cccxxvii. 280; *Chem. Soc. Jour.* [1878], xxxiv. 534); E. Bell (*Dingl.* cccxviii. 47, 160; *Chem. Soc. Jour.* xxxiv. 689, 758).

GLAUBERITE, $\text{SO}^4\text{Ca}.\text{SO}^4\text{Na}^2$ (ii. 845). From measurements of the crystals of Glauberite from Westeregeln, near Magdeburg, v. Zepharovich (*Jahrb. f. Min.* 1874, 543) deduces the axial ratio, $a : b : c = 1.2199 : 1 : 1.0275$; angle, $ac = 67^\circ 49' 10''$. W. Schimper (*ibid.* 1877, 401) describes glauberite crystals from Pendschab, where it occurs attached to cubes of rock-salt, in forms having exactly the habit of the crystals from Westeregeln. The forms observed were 0P, -P predominant; then ∞ P and ∞ P ∞ , with well-developed faces; and sometimes -P, 2P ∞ , and $\frac{3}{2}$ P ∞ , but only very secondary. Laspeyres (*ibid.* 947) describes glauberite from Aranjuez occurring on nodules of grey clay in crystals not more than 20 mm. long, but colourless, not altered by exposure to the air, and with well-developed faces. Axes, $a : b : c = 1.220924 : 1 : 1.0270307$; angle $ac = 67^\circ 49' 33''$, agreeing nearly with the measurements of v. Zepharovich. The most frequent combination is -P, ∞ P. 0P. ∞ P ∞ , with 3P3 and P secondarily.

GLAUCODOTE, or cobalt-arsenical-pyrites, is found at Hakausbö in large twin crystals, whose form fully coincides with the acontite of Breithaupt. The forms observed were ∞ P, ∞ P ∞ , P ∞ , $\frac{1}{2}$ P ∞ , P ∞ , 2P ∞ , P,P2. Twins according to two laws, the first being 'the twin-plane a face of ∞ P'; the second 'the twin-plane a face of P ∞ '. As the angle between two faces of this form is $61^\circ 3'$, a trilling can grow having a hexagonal appearance.

A trilling of this mineral is to be seen at the British Museum (W. J. Lewis, *Jahrb. f. Min.* 1877, 300).

GLAUCOHYDROELLAGIC ACID, $\text{C}^1\text{H}^0\text{O}^7$. An acid formed by the prolonged action of sodium-amalgam on ellagic acid (p. 731).

GLAUCONITE. This iron silicate, which occurs in nodules in the greensand of various localities, is, according to F. Anger (*Min. Mittheil.* 1875, 153), not amorphous, but possessed of double-refracting structure. F. Denalque (*Jahrb. f. Min.* 1875, 422) has analysed glauconite from Belgium, where it occurs widely diffused as glauconitic sand; he finds it to contain

SiO^2	Al^2O^3	Fe^2O^3	FeO	CaO	MgO	K^2O	Na^2O	H^2O
50.42	4.79	19.90	5.96	3.21	2.28	7.87	0.21	5.28 = 99.92

whence the formula $3\text{RO}.2\text{R}^2\text{O}^3.4\text{SiO}^2.3\text{H}^2\text{O}$, in which $\text{RO} = (\text{Fe}, \text{K}^2, \text{Ca}, \text{Mg}, \text{Na}^2)\text{O}$ and $\text{R}^2\text{O}^3 = (\text{Al}, \text{Fe}^2)\text{O}^3$ (compare ii. 846: 1st Suppl. 636; 2nd Suppl. 556).

GLAUCOPHANE (also called *Wichtyn*, v. 1038). This mineral, originally found in Finland, occurs also at Zermatt and in the island of Syra. The glaucophane of Zermatt has been examined by Bodewig (*Jahrb. f. Min.* 1876, 771), that from Syra by Luedecke (*ibid.* 778).

Glaucophane belongs to the hornblende family, and may be classed with arfwedsonite, achmite, and aegyrine. The crystals from Zermatt exhibit only the prismatic zone ∞ P. ∞ P ∞ . ∞ K ∞ , the forms 0P and +P occurring but seldom. Angle ∞ P : ∞ P = $124^\circ 44'$. Cleavage very distinct parallel to ∞ P, the angle being $124^\circ 30'$, which is that of hornblende. Hardness = 6.5, sp. gr. = 3.0907 (Bodewig);

3.101—3.113 (Lüdecke). The chief direction of elasticity (the second bisectrix) lies in the acute angle formed by the crystallographic axes a and c ; 4.24 for red light (lithium), 4.16 for yellow (sodium), 4.13 for green (thallium). The optic axes lie in the plane of symmetry. The optical characters are negative. The mineral is strongly pleochroic, and absorbs light. Before the blowpipe it melts to a greyish-white non-magnetic enamel.

The mean of two analyses by Bodewig of the Zermatt mineral gives the following values:

SiO ²	Al ² O ³	Fe ² O ³	FeO	MgO	CaO	Na ² O	
57.81	12.03	2.17	5.78	13.07	2.20	7.33	= 100.39

whence the formula $\left\{ \begin{smallmatrix} \text{RSiO}^2 \\ \text{RSi}^2\text{O}^3 \end{smallmatrix} \right\}$ in which R = Fe, Mg, Ca, Na², and R = Al, Fe.

An analysis of the glaucophane from Syra gave

SiO ²	Al ² O ³	Fe ² O ³	FeO	MnO	MgO	CaO	Na ² O	
55.64	15.11	3.08	6.85	0.56	7.80	2.40	9.34	= 100.78

whence Lüdecke deduces the formula $3\text{Na}^2\text{SiO}^2.6\text{R}'\text{SiO}^2.3\text{Al}^2\text{Si}^2\text{O}^3.\text{Fe}^2\text{Si}^2\text{O}^3$, in which R = Fe, Mn, Mg, CO.

Strüver's gastaldite (p. 858) is completely isomorphous with glaucophane, but contains a larger proportion of aluminium silicate, $\text{Al}^2\text{Si}^2\text{O}^3$ (Bodewig).

GLAUCOPHANE-ROCKS. Glaucophane occurs, similarly to hornblende, as a constituent of rocks. In the glaucophane eclogites of Syra, the smaragdite, which is an ordinary constituent of eclogites (p. 703), is replaced by glaucophane. Glaucophane-slate also occurs in Syra, together with mica-slate containing glaucophane as an accessory constituent.

Glaucophane-eclogite consists principally of glaucophane, omphacite and garnet, with muscovite and quartz as secondary constituents, and approaching nearly to the eclogites of von Drasche. The *mica-slate* is found in two modifications, one consisting of parallel layers of muscovite and quartz, with numerous glaucophane prisms and small garnets as accessories; the other is quartzose, consisting of many layers of quartz one meter thick, separated by thin films of muscovite, the accessories glaucophane and garnet being isolated. The *eclogite-mica-slate* unites the constituents of glaucophane-eclogite and mica-slate. It consists of thin parallel layers of muscovite enclosing ellipsoidal quartz-masses, together with glaucophane, omphacite and garnet. *Glaucophane-slate* was formerly described as a diathene-rock, but is now found to consist of parallel layers of glaucophane separated by white or greenish muscovite, with epidote and hematite as accessories. Virlet described rocks intermediary between glaucophane-eclogite and glaucophane-slate (poor in mica), to which Lüdecke assigned the names omphacite-zoisite-gabbro and epidote-glaucophane. The first consists of omphacite and zoisite, has a granular structure, with tale, muscovite, epidote, tourmaline and calcite as accessories; the second is a granular mixture of epidote and glaucophane, with omphacite, zoisite and garnet as accessories. *Glaucophane-zoisite-omphacite rock* consists of the three minerals included in its name; there is also a slate having the same composition. *Smaragdite-chlorite rock* is a granular mixture of smaragdite and chlorite with glaucophane, epidote and garnet. The crystalline limestone which covers the mica-slate contains mica and glaucophane (Lüdecke).

GLUCIC ACID. From the experiments of Grote a. Tollens (*Liebig's Annalen*, clxxv. 181) it appears that the acid thus named by Mulder (ii. 848) has no separate existence. His acid calcium glucate is identical with calcium levulinic, $\text{C}^6\text{H}^6\text{CaO}^9$ (see LEVULINIC ACID); and the other salts which he describes as calcium glucates appear to be derivatives of a carbohydrate, $\text{C}^6\text{H}^{10}\text{O}^8$, and to be formed by the action of caustic lime on dextrose.

GLUCINUM or BERYLLIUM. The atomic weight and specific heat of this metal are still under discussion. J. Emerson Reynolds (*Phil. Mag.* [5], iii. 38) has determined, by means of a very delicate alcohol-thermometer, the weight of glucinum which at 100° contains the same quantity of heat as 108 parts (1 atom) of silver. This weight he finds to be 9.2, which therefore, according to the law of Dulong a. Petit—that the atomic weights of all bodies in the solid state contain the same quantities of heat—must be the atomic weight of glucinum; and since the equivalent number of glucinum is 4.6 (ii. 852), it follows that glucinum must be a dyad, its chloride being GCl^2 and oxide GO . This result is in accordance with the periodic law of the atomic weights of the elements (*2nd Suppl.* 462).

On the other hand, Nilson and Pettersson (*Deut. Chem. Ges. Ber.* xi. 381) have determined, by means of Bunsen's ice-calorimeter, the specific heat of glucinum

obtained by reducing the chloride with sodium in an iron cylinder. The metal thus prepared contained 87.09 per cent. of pure glucinum, the rest being made up of glucinum-oxide, iron, and silica. Corrections having been made for these impurities, the specific heat of the pure metal between 0° and 100° was found to be 0.4079, which is about two-thirds of that determined by Reynolds. According to this result, the atomic weight of glucinum should be $3 \times 4.6 = 13.8$, and the metal should be trivalent, the chloride being GCl_3 and the oxide G^2O_3 , as originally supposed by Berzelius.

With this atomic weight, however, it is difficult to assign to glucinum any place in the periodic series, and on this account Lothar-Meyer (*Deut. Chem. Ges. Ber.* xi. 576) considers it most probable that, if glucinum be really trivalent, its equivalent 4.6, determined by Awdewjew (ii. 852) is too high, and that its atomic weight, instead of 13.8, should be between 11 and 11.15, giving it a place in Mendelejeff's table between boron and carbon. With this atomic weight it would form the first member of the aluminium group, separated by the regular difference of 16 from the next member, viz. aluminium (27.3). Boron, hitherto placed in the same column with aluminium (see table, 2nd Suppl. 463), would then form the first member of a special group, so that between the alkaline earth-group and the nitrogen-group there would in future be, not merely two, but at least three groups, headed respectively by boron, aluminium, and carbon.

Another point noticed by Lothar-Meyer as of some importance in deciding the question as to the atomic weight of glucinum is that the atomic heat of oxygen, if calculated from the difference between the atomic heat of trivalent glucinum and the molecular heat of its oxide, G^2O_3 , comes out equal to 2.5 instead of the usual value ranging from 3.5 to 4.8 (Kopp, *Liebig's Annalen*; 3rd Suppl. 290). This anomaly is unfavourable to the view which regards glucinum as a triad.

The glucinum prepared by Nilson a. Pettersson, which, as already observed, was contaminated with silica, iron, and glucinum oxide, formed prismatic crystals, partly microscopic, and having the colour and lustre of steel. Its sp. gr. at 9° was 8.9101, whence, by calculation, that of the pure metal was found to be 1.64. Glucinum is not altered by contact with the air, neither does it decompose water. It dissolves in dilute acids and in caustic alkalis, with evolution of hydrogen. It is not attacked by oxygen or sulphur even at a red heat, but burns when heated in chlorine.

Glucinum iodide, mixed in solution with an equivalent quantity of *bismuth* or *antimony iodide*, forms double salts which, when left to evaporate for a few days over sulphuric acid, are obtained in well-defined crystals having the form of elongated prisms; they are, however, so hygroscopic as to preclude the possibility of exact chemical or crystallographical examination. *Aluminium iodide* yields similar double salts, which, however, form tabular crystals (A. Welkow, *Deut. Chem. Ges. Ber.* vii. 803).

Glucinum Palladiosochloride, $\text{GCl}_2 \cdot \text{PdCl}_2 + 6\text{H}^2\text{O}$, is obtained in deep-brown, very hygroscopic tabular crystals, by leaving a mixture of the concentrated solutions of its constituent chlorides to evaporate over sulphuric acid. It is also formed, with evolution of chlorine, by heating a concentrated solution of glucinum palladiosochloride, $\text{GCl}_2 \cdot \text{PdCl}_4$. It is soluble in water and in alcohol (Werkow).

Glucinum Platinosochloride, $\text{GCl}_2 \cdot \text{PtCl}_4$, crystallises with $8\text{H}^2\text{O}$, according to Marignac (*N. Arch. ph. nat.* 1870, 374), Werkow (*Deut. Chem. Ges. Ber.* 1873, 1288), and Thomsen (*ibid.* 1874, 75), not with $9\text{H}^2\text{O}$, as formerly stated by Thomsen (2nd Suppl. 558). Marignac confirms the observation of Thomsen that the crystals belong to the quadratic system, and finds that the angle of the terminal edges of the octohedral crystals is equal to 115° . The constitution of this salt is regarded by Nilson (*Deut. Chem. Ges. Ber.* ix. 1056, 1142) as tending to show that glucinum is a dyad metal, inasmuch as metals of higher quantivalence do not appear to form normal, but only basic platino-chlorides, and the decidedly trivalent metals, such as bismuth, arsenic, and antimony are not known to form platinochlorides at all.

GLUCONIC ACID, $\text{C}^6\text{H}^{12}\text{O}_7$. This acid, which Hlasiwetz a. Habermann obtained by the action of chlorine-water on glucose- or on cane-sugar (2nd Suppl. 559) may also be produced, together with dextronic acid, by the action of bromine-water and silver oxide on starch. The product of the oxidation, saturated with calcium carbonate, yields calcium dextronate, and with barium carbonate, barium gluconate, which, on evaporation, dries up to a gummy mass, subsequently yielding acicular crystals. *Paramylum* treated in like manner, yields, on neutralisation with baryta, the barium salt of dextronic acid, and, with lime, a salt which, from its composition, solubility, and amount of crystallisation-water, appears to contain an acid isomeric with dextronic and gluconic acids. The free acids are obtained as sour colourless syrups, but gluconic acid may be subsequently crystallised. The acid from paramylum is converted by the action of bases, such as baryta, into dextronic acid, and the latter

by the further action of the base, appears to be transformed into gluconic acid (Habermann, *Liebig's Annalen*, clxxii. 11).

GLUCOSE. See SUGARS.

GLUTAMIC or **AMIDOGlututARIC ACID**, $C^6H^9NO^4 = CH(NH^2) \begin{smallmatrix} CH^2.CO^2H \\ CH^2.CO^2H \end{smallmatrix}$. See GLUTARIC ACID under PYROTARTARIC ACIDS.

GLUTANIC or **OXYGLUTARIC ACID**, $C^6H^8O^5 = CH(OH)(CH^2.CO^2H)^2$. See PYROTARTARIC ACIDS.

GLUTARIC ACID. Syn. with NORMAL PYROTARTARIC ACID (*q.v.*)

GLUTIN. See PROTEIDS.

GLYCERAMINE (TRIMETHYL-), $C^6H^{15}NO^2 = C^3H^6(CH^3)^3NO^2$, is formed by heating monochlorhydrin with trimethylamine till the odour of the latter is no longer perceptible. On adding to the resulting liquid a concentrated solution of platonic chloride, and leaving it at rest, ammonium platinochloride separates out, and the liquid filtered from this precipitate and evaporated, yields a crystalline mass, whilst the mother-liquor retains an uncrystallisable substance which is precipitated by alcohol, and appears to be the platinochloride of monomethyl-glyceramine. The crystalline mass, purified by pressure and recrystallisation, yields the *platinochloride of trimethyl-glyceramine*, $(C^6H^{15}NO^2.HCl)^2PtCl^4$, in orange-coloured tablets apparently belonging to the orthorhombic system. These crystals are soluble in water, either hot or cold, and the aqueous solution is not decomposed by boiling. They are insoluble in alcohol, and give off hydrochloric acid in a vacuum. The *hydrochloride*, obtained by decomposing the platinum-salt with hydrogen sulphide, is a colourless, syrupy liquid, which, when treated with silver oxide, yields the corresponding hydroxide (Hanriot, *Compt. rend.* lxxxvi. 1335).

GLYCERIC ACID, $C^3H^6O^4 = CH^2OH.CHOH.COOH$, or, according to Wislicenus, $CH^2OH-COH-CHOH$ (2nd Suppl. 719). According to E. Mulder (*Deut. Chem.* —O—)

Ges. Ber. ix. 1902), this acid is best prepared by mixing 50 grams of glycerin (commercial) with 50 grams of water in a large glass tube, placing this in a collar, and adding, by means of a funnel reaching to the bottom, 50 grams of fuming nitric acid. After three or four days the contents of three such tubes are slowly evaporated on the water-bath down to about 270 grams, and the syrupy mass thus obtained is preserved in a flask allowing the escape of the gas, which is slowly given off. 1620 grams of the syrupy mass are next mixed with 11 litres of water in a tinned copper vessel, 2400 grams of white lead are gradually added, and the mixture is left to stand for a day. The vessel is then warmed, with constant stirring, to 61°–65°, and kept at this temperature for two hours. The liquid is decanted and allowed to deposit crystals, the mother-liquor added to the solid mass, the water lost by evaporation replaced, and the operation repeated two or three times. The lead salt thus obtained is almost colourless, and, for ordinary purposes, need not be recrystallised.

When glyceric acid is distilled in a retort over an open flame, and the distillate is treated with hydrogen sulphide, an acid is obtained which crystallises in large colourless laminæ, melts at 83°, and agrees in composition with the formula $C^3H^5O^4.2H^2O$. Its *barium salt* has the composition $C^3H^4BaO^4.3H^2O$ (Böttinger, *Deut. Chem. Ges. Ber.* x. 266).

Glycerates.—The *strontium salt*, $(C^3H^5O^4)^2Sr$, obtained by saturating the acid with strontium carbonate, separates after a while, on adding a little alcohol to the solution, in groups of crystals, nearly insoluble in cold, easily soluble in hot water. Alcohol precipitates it as a crystalline powder. The *magnesium salt*, $(C^3H^5O^4)^2Mg + 3H^2O$, separates from very concentrated solutions in stellate groups of small crystals, which quickly effloresce on exposure to the air. It dissolves very easily in cold water and with moderate facility in alcohol; becomes anhydrous at 100°. The *copper salt*, $(C^3H^5O^4)^2Cu$, prepared by boiling the lead salt with cupric sulphate, and purified by repeated crystallisation, has a fine sky-blue colour and brilliant lustre. It dissolves somewhat sparingly in cold, easily in hot water. By prolonged heating in moderately dilute solution, it is decomposed, with separation of cuprous oxide, and the liquid separated therefrom and concentrated over sulphuric acid, yields a verdigris green salt easily soluble in cold water and alcohol. Cupric glycerate is precipitated by alcohol from its concentrated aqueous solution in the form of a pale blue crystalline powder. The copper is not completely precipitated from it by potash. The *manganous salt*, $(C^3H^5O^4)^2Mn + 3H^2O$, prepared like the copper salt, forms small, hard, shining crystals, sometimes united in spherical groups. It dissolves in water and in dilute

alcohol. It gives off water on exposure to the air at ordinary temperatures, and more at 100°, the total loss then amounting to 1 mol. At a higher temperature it gives off $1\frac{1}{2}$ mol. more, and assumes a peach-blossom colour, and at 120° it begins to decompose. The solution of the peach-blossom coloured salt, $(C^3H^5O^4)^2Mn + \frac{1}{2}H^2O$, in a small quantity of water, yields, after a while, the blue crystals of the tri-hydrated salt (K. Garzarolli-Thurniak, *Liebigs Annalen*, clxxxii. 190).

Glyceric Anhydride, $C^3H^4O^3$, separates from an aqueous solution of glyceric acid, evaporated at 100° and left at rest, in microscopic crystals, and on recrystallisation from water, in slender six-sided needles. It is insoluble in cold alcohol and in boiling ether, but dissolves in 647 parts of boiling water, by which, moreover, it is very slowly reconverted into the acid (Sokoloff, *Deut. Chem. Ges. Ber.* xi. 679).

GLYCERIC ALDEHYDE, $C^3H^5O^3 = C^3H^3(OH)^2.CO^H$ (A. Renard, *Compt. rend.* lxxxii. 562). This compound is formed by the action of electrolytic oxygen on glycerin suspended in dilute sulphuric acid. Hydrogen is evolved at the negative pole, and at the positive a mixture containing 3 per cent. CO^2 , 33 per cent. CO and 64 per cent. O; and on adding calcium carbonate to the liquid after forty-eight hours, to remove formic, acetic, and glyceric acids, then filtering, distilling, and leaving the distillate to evaporate over sulphuric acid, and drying, a white amorphous residue is obtained, consisting of hydrated glyceric aldehyde, $4C^3H^5O^3 + H^2O$, slightly soluble in water, nearly insoluble in alcohol and in ether, melting at 71°–72°, boiling and subliming at 130°–135°.

Glyceric aldehyde reduces ammoniacal silver nitrate, yields with oxidising agents (chromic acid, nitric acid, potassium permanganate, silver oxide) formic or acetic acid; by electrolysis, formic acid and a mixture of CO and CO^2 ; and when treated with sodium-amalgam and water is apparently converted into glycerin.

When a solution of glyceric aldehyde is treated with ammonia, the mixture evaporated, and the dry residue repeatedly crystallised, crystals are obtained, very soluble in water, but insoluble in alcohol and in ether, and having the composition $C^3H^5N^2$. This compound sublimes at 120°–130° without previous fusion, is reconverted into glyceric aldehyde by sulphuric or hydrochloric acid, but is not attacked by a boiling solution of sodium carbonate.

Glyceric Thioaldehyde, $C^3H^5S^2O.H^2O$, is formed by the action of hydrogen sulphide on a solution of glyceric aldehyde heated to 60°–80°. It has a waxy appearance, melts at 80°–82°, boils at 180°–185°, dissolves sparingly in cold, very easily in hot water, but is insoluble in alcohol and ether (Renard).

GLYCERIN, $C^3H^5O^3 = C^3H^5(OH)^3$. *Synthesis*. Friedel a. Silva (*Compt. rend.* lxxvi. 1594) have prepared glycerin synthetically from propylene chloride, obtained without the intervention of any allyl-compound or other derivative of glycerin itself. Propylene, C^3H^6 , prepared by converting acetone into pseudopropyl alcohol, and heating the latter with zinc chloride, was passed into a concentrated solution of iodine chloride; the propylene chloriodide thereby produced was suspended in water, and chlorine gas was passed into the liquid, till the iodine at first precipitated was redissolved; and the pure propylene chloride thereby obtained was heated in small quantities with dry iodine chloride to 140° in sealed tubes for eight hours, the tubes being opened after a while to allow the escape of hydrochloric acid, then sealed up, and again heated for eight hours to 140°. To remove the excess of iodine, the contents of the tubes were mixed with water, and chlorine passed into the liquid till the whole of the iodine was dissolved in the water as iodine chloride. The product (145.9 grams) separated from the water and dried, yielded on fractional distillation 18.8 grams of impure trichlorhydrin (boiling point 150–160°), containing about 50 per cent. of tetrachloropropane. The formation of the trichlorhydrin may be represented by the equation:

The impure trichlorhydrin heated with water to 180° yielded a small quantity of glycerin, which was recognised by conversion into acrolein and allyl iodide.

Properties.—The crystallisation of glycerin at low temperatures has already been mentioned (1st *Suppl.* 638). According to F. Nitzsche (*Dingl. pol. J.* ccix. 146), a method of obtaining glycerin in crystals was discovered by Kraut in 1870. This method (which is not described) is applied in the works of Sarg and Co. at Liesing, near Vienna, to the purification of glycerin, the crystals being freed from adhering mother-liquor in a centrifugal machine, then dried and melted. These crystals are described as monoclinic, absolutely colourless, having a pure sweet taste, very highly refractive, and melting at 20° to glycerin having a density of $30\frac{1}{2}$ Bm. According to V. von Lang, on the other hand (*Pogg. Ann.* clii. 637), these crystals are orthorhombic, with the axial ratio $a : b : c = 0.70 : 1 : 0.66$. They are very deliquescent.

P. van Hamel Roos (*Chem. Soc. J.* 1876, i. 651) describes crystallised glycerin (58 lbs.) which appeared to have been solidified by the agitation of railway transport during the low temperature of January 1876. The crystals were monoclinic, colourless and had a pure sweet taste. On putting some of them into ordinary good glycerin, splendid crystals began to form, most of the impurities remaining in the mother-liquor. The crystals melted at 60° F., and the density of the liquid at this temperature was 1.261. According to A. Winkelmann (*Pogg. Ann.* cliii. 481), the density of glycerin is 1.220, and its specific heat 0.612. According to Oppenheim a. Salymann (*Deut. Chem. Ges. Ber.* vii. 1622), the corrected boiling point of glycerin under 755.55 mm. pressure is 200.08°.

Moderately concentrated glycerin heated to 150° burns with a blue flame, and may be burnt from a wick, without odour or residue (R. Godeffroy, *ibid.* 1566). E. Schering (*Dingl. pol. J.* ccxv. 287) observes that glycerin does not rise high in a wick. Its flame is colourless, and therefore well adapted for experiments on flame-coloration.

Reactions.—1. Glycerin heated with *zinc-dust* yields, together with an oil, a mixture of hydrogen and propylene, the bromide of which boils at 142° (Kerstein, *Deut. Chem. Ges. Ber.* ix. 695).

2. When glycerin is somewhat strongly heated for several hours with *sodium sulphide*, a liquid passes over, which, on fractional distillation, yields, together with products of higher boiling point, an ethereal liquid having an alliaceous odour, a density of 0.825 at 15°, and boiling at 58°. The alcoholic solution of this liquid is precipitated white by auric chloride and mercuric chloride, light yellow by silver nitrate, orange-yellow by lead acetate. It is violently attacked by nitric acid. Mercuric oxide dissolves in it, and on adding the oxide to saturation, the liquid separates into two layers, the lower of which solidifies to a crystalline mass. The crystals thus obtained dissolve easily in ether and in carbon bisulphide, and the compound crystallises from it in silky needles melting at 35° (Schlagdenhaufen, *Compt. rend.* lxxvi. 1021).

3. When glycerin is heated in a retort with *aluminium-foil* and *iodine*, the latter being gradually added, an oily liquid containing iodine passes over at 200°, and on washing this liquid with water, dissolving it in alcohol, and shaking the solution with mercury, a yellow mercury-allyl iodide, $C^3H^5Hg.I$, is formed, which dissolves in warm alcohol, and separates therefrom, on cooling, in shining nearly white scales which quickly turn yellow. The alcohol from which the mercury-compound had separated gave no precipitate with water, thereby showing the absence of pseudopropyl iodide. The end-reaction of aluminium iodide with glycerin may therefore be represented by the equation:

analogous to that which represents the reaction of glycerin with phosphorus iodide (Hodgkinson, *Chem. News.* xxxv. 237).

4. Glycerin heated with *formic acid* is reduced to allyl-alcohol:

(Henninger, *Bull. Soc. Chim.* [2], xxi. 242).

5. When glycerin (2 pts.) is heated for some time to 120°–130° with *phenol* (2 pts.) and *sulphuric acid* (3 pts.), the mixture assumes first a yellow, then a yellowish-red, and finally a dark red colour; and on dissolving the thick mass after cooling, in water, a brownish-yellow liquid is obtained from which hydrochloric acid throws down a colouring matter easily soluble in water and in alcohol, sparingly soluble in ether; it does not crystallise from these solutions. It is coloured a fine red by alkalis and by salts having an alkaline reaction, and forms lakes with baryta, alumina, lead oxide and other oxides. Heated with *aniline*, it is converted into a red colouring matter which acquires a violet-red tint when treated with ammonia. Similar bodies are obtained with *pyrogallol* and *thymol* (C. Reichl, *Deut. Chem. Ges. Ber.* ix. 1429).

6. *Conversion of Glycerin into Acetone.*—When dichlorodibromacetone, obtained by the action of bromine on dichlorhydrin (2nd Suppl. 14), is digested for several weeks at a temperature not exceeding 40° with water and granulated zinc, the action being assisted at first by addition of a little sulphuric acid and gentle heating, a liquid is obtained which, when distilled and dehydrated with calcium chloride, yields a acetone, together with a brominated compound. The acetone may be separated from the latter, by combination with sodium bisulphite. The reduction of the dichlorodibromacetone to acetone may also be effected by hydriodic acid (O. Lange, *Deut. Chem. Ges. Ber.* vi. 98).

7. *Conversion into Glucose.*—Glycerin is oxidised to glucose by the action of potassium permanganate in sunshine, or by chromic acid mixture:

Glycerin is also converted into glucose when placed in contact with iron which* is undergoing oxidation by the action of air and water, the oxidising action being as it were transferred to the glycerin; and hog's lard similarly treated is resolved into fatty acid and glycerin, which is then oxidised to glucose (Kasman, *Bull. Soc. Chim.* [2], xxvii. 246).

8. *Fermentation*.—On the fermentation of glycerin induced by the action of schizomycetes, see p. 776.

Detection and Estimation of Glycerin.—When certain acid borates, common borax, for example, are dissolved in glycerin, the glycerin does not merely act as a solvent, but decomposes the borate, setting free a portion of the boric acid, which is then capable of imparting the well-known green colour to flame. This reaction may be used as a test for glycerin in water, wine, beer, milk, &c. The liquid is first made neutral or slightly alkaline (the presence of free acids would of course vitiate the test), and a borax bead is dipped into it, left at rest for a few minutes so as to allow solution to take place on its surface, and then held in the Bunsen flame in the usual way. Another and more delicate method is to place a little pounded borax on a watch-glass, pour on it some of the faintly alkaline solution, stir with a glass rod, and introduce some of the mixture into the flame by means of a looped platinum wire. In either case the green colour will appear more or less distinctly, if glycerin be present in sufficient quantity. The same reaction is produced by *erythrite*, and apparently also by *glycol*, but these compounds are not likely to be present in any liquid which is to be tested for glycerin. *Ammoniacal salts* have also the power of decomposing borax (*2nd Suppl.* 208), and must therefore be eliminated previous to the application of the test (Senier & Lowe, *Chem. Soc. J.* [1878], xxxiii. 438).

Estimation.—The amount of pure glycerin in commercial samples contaminated with ethers, fatty acids, &c., may be determined by treatment with a mixture of nitric and sulphuric acids, whereby the foreign substances are converted into soluble nitro-compounds, while the glycerin is converted into insoluble nitroglycerin, which may be washed with water, dried over the water-bath, and weighed. To facilitate the drying, the nitroglycerin is previously mixed with an equal weight of methyl-alcohol, the vapour of which easily carries off the water. 100 parts of pure glycerin dried in a vacuum at 120°–150° yield 190 parts of nitro-glycerin (Champion & Pellet, *Bull. Soc. Chim.* [2], xix. 493).

For the estimation of glycerin in *wine*, Macagno (*Dingl. pol. J.* ccxvi. 95) digests a litre of the wine with recently precipitated lead hydroxide; evaporates the liquid on the water-bath, then adds a further quantity of lead hydroxide; exhausts the mass with absolute alcohol; and precipitates the dissolved lead by a stream of carbon dioxide. The filtered liquid when evaporated leaves nearly pure glycerin.

Metallic Glycerides (J. Puls, *J. pr. Chem.* xv. 83). Various metallic salts are dissolved by mixtures of glycerin and caustic alkali. When glycerin is mixed with *ferric chloride* and potash in certain proportions, a clear solution is formed, which, after a time, depending on the proportions of the mixture, suddenly begins to deposit ferric hydroxide, the precipitation going on till no more iron is left in the liquid. Strong solutions of this kind are of a cherry-red colour, and are only partially precipitated on heating; in dilute solutions, on the contrary, the precipitation is complete. Carbonic acid, in all cases, precipitates the iron completely; potassium sulphide also precipitates it, except in presence of a large excess of glycerin. These reactions are exhibited by all ferric salts, including the phosphate. When solutions from which the ferric oxide has been precipitated by heating, are evaporated to dryness, the residue dissolves completely in water, and the solution still retains the property of 'coagulating,' that is, depositing the iron as ferric hydroxide.

The facility with which this so-called coagulation takes place depends upon the proportions of the mixture. With glycerin, ferric oxide, and potash, in the molecular proportion $C^3H^5O^3 : Fe^2O^3 : KHO = 1 : 1 : 1$, no action takes place. With $3 : 1 : 1$ a solution is formed from which all the iron is precipitated by carbonic acid, or on dilution with water. The larger the proportion of glycerin, the more slowly does precipitation take place; with the proportion $6 : 1 : 1$ it takes place after two months only; and with $12 : 1 : 1$ no alteration is apparent even after five months. The proportion $3 : 2 : 1$ yielded a perfect solution, which, however, soon became gelatinous, and solidified so completely that it could be cut in pieces. With $3 : 2 : 2$ the solution remained complete for six hours; hence potash appears to retard the coagulation. With $3 : 3 : 1$ no iron is dissolved; $3 : 3 : 2$ gives a clear solution which immediately solidifies; so likewise with $3 : 3 : 4$ and $3 : 3 : 5$. With $3 : 4 : 3$ and $3 : 5 : 3$ no alteration was perceptible.

From these results Puls infers that the ferric hydroxide in these solutions is in

the so-called colloidal state. He finds, indeed, that solutions containing glycerin, ferric oxide, and potash in the proportion 3 : 1 : 1, and 79 per cent. water, which coagulated spontaneously after some time, behaved towards reagents, as carbonate or chloride of potassium, &c., in the same manner as colloid substances, being, in fact, suddenly brought by these reagents to the state of coagulation. The coagulation of the solutions employed in the experiments above described may therefore be attributed to the action of the potassium chloride which was present in all of them. The coagulation is also very quickly induced by sulphate, chlorate, nitrate, acetate, and tartrate of potassium, either in solution or in crystals; also by certain insoluble substances, as calc-spar, fluor-spar, witherite, and heavy-spar.

Uranium solutions and *copper* solutions react with glycerin and potash in the same manner as iron solutions. Experiments with *cupric chloride* showed that the solvent power of glycerin varies with the dilution of the liquid, as well as with the proportion of alkali. This is seen from the following tables:

TABLE I.

1 mol. glycerin and 1 mol. KOH	
When 100 pts. of the solution contain of glycerin :	92 pts. (1 mol.) glycerin dissolve :
0.19 pts.	7 pts. CuO
0.49 "	51.4 "
0.96 "	67.9 "
1.85 "	73.7 "
5.80 "	73.4 "

TABLE II.

1 mol. glycerin and 2 mol. KOH	
When 100 pts. of the solution contain of glycerin :	92 pts. (1 mol.) glycerin dissolve :
0.20 pts.	29.4 pts. CuO
0.51 "	65.4 "
0.72 "	71.6 "
0.96 "	71.4 "
1.80 "	73.6 "
2.56 "	74.7 "
4.47 "	75.8 "

TABLE III.

1 mol. glycerin and 3 mol. KOH	
When 100 pts. of the solution contain of glycerin :	92 pts. (1 mol.) glycerin dissolve :
0.20 pts.	47.7 pts. CuO
0.48 "	72.2 "
0.72 "	72.7 "
0.94 "	73.4 "
1.70 "	73.2 "
2.58 "	74.5 "
4.15 "	75.0 "
4.15 "	75.1 "

TABLE IV.

When 100 pts. of the solution contain of glycerin :	92 pts. (1 mol.) glycerin dissolve of CuO :	In presence of the following molecules of KHO :
0.19 pts.	7.0 pts.	1
0.20 "	29.4 "	2
0.20 "	47.7 "	3
0.20 "	53.9 "	4
0.20 "	59.9 "	6
0.20 "	64.6 "	8

In no case is the proportion of 79.3 pts. CuO (1 mol.) to 92 pts. glycerin (1 mol.) attained. It appears, however, from the first set of experiments (Table I.) that in a solution containing not less than 5.8 per cent. glycerin, 73 pts. CuO are dissolved for every 92 pts. glycerin present, so that the amount of glycerin contained in a liquid may be inferred from that of the cupric oxide dissolved by it; and this relation may be made available for the quantitative estimation of glycerin.

Bismuth solutions, mixed with glycerin and potash, exhibited reactions similar to the above, excepting that the quantity of bismuth held in solution was relatively much less.

Baryta, *strontia*, and *lime*, dissolved in proportions indicating the formulae of the following compounds: $\text{BaO} \cdot 5\text{C}^2\text{H}^5\text{O}^3$ to $\text{BaO} \cdot 6\text{C}^2\text{H}^5\text{O}^3$; $\text{SrO} \cdot 10\text{C}^2\text{H}^5\text{O}^3$ to $\text{SrO} \cdot 20\text{C}^2\text{H}^5\text{O}^3$; $\text{CaO} \cdot 3\text{C}^2\text{H}^5\text{O}^3$ to $\text{CaO} \cdot 34\text{C}^2\text{H}^5\text{O}^3$.

Sodium-glyceride, $\text{C}^2\text{H}^5(\text{ONa})(\text{OH})^2$, which Letts obtained by the action of sodium on glycerin (2nd. Suppl. 564), crystallises from methyl alcohol in scales and nodules.

Its solution, mixed with cupric chloride, also dissolved in methyl alcohol, yields a green precipitate of a copper-glyceride containing cupric chloride.

Nitroglycerin, $C^3H^5(NO^2)_3O^3$. According to S. Kern (*Chem. News*, xxxi. 253), this substance explodes with maximum violence at 262° . At 187° it merely gives off red fumes, and at 294° a very slight explosion takes place.

The blasting oils of commerce are usually mixtures of trinitro-glycerin with the mono- and the dinitro-derivatives. For the analysis of these products, Ph. Hesse (*Zeitschr. anal. Chem.* 1874, 257) employs a modification of Dumas' combustion process, the mixture of the oil with cupric oxide being placed in a long combustion tube, and protected by a screen of tin plate during the expulsion of the air of the tube by the stream of carbon dioxide, and the combustion regulated as far as possible, so that the successive portions of the finely-divided blasting oil may be brought to the temperature required for combustion, only by the action of radiant heat. A simpler, and at the same time very exact method is to treat the blasting oil with alcoholic potash, whereby it is exactly decomposed into glycerin and potassium nitrate, in which the nitrogen may be estimated by the usual methods (Hesse). According to Sauer a. Ador, on the other hand (*Deut. Chem. Ges. Ber.* x. 1882), the amount of nitrogen obtained by this latter method is always too low. By Dumas' method they obtained from dynamite cartridges 18.35 to 18.52 per cent. nitrogen, answering to pure dinitro-glycerin, whereas by decomposition with alcoholic potash they obtained only 12.3, 12.5, and 13–14 per cent. nitrogen.

Chlorhydrins. 1. *Monochlorhydrin*, $C^3H^7ClO^2 = C^3H^5(OH)_2Cl$.—Of this compound there are two modifications, viz.:

Both these bodies are formed by heating glycerin with hydrochloric acid. The first, discovered by Berthelot in 1854 (i. 813), boils at 227° under ordinary pressure, at 139° under a pressure of 10 mm. of mercury, and is converted by nascent hydrogen into ordinary propyl glycol, $CH^2=CHOH-CH^2OH$. By treatment with potassium cyanide (exchange of Cl for CN) and subsequent saponification (O.OH for N), it is converted into an acid, $C^4H^8O^4$, having the constitution $CH^2OH-CHOH-CH^2-COOH$. This acid is a yellowish liquid which, when evaporated, appears to yield an anhydride analogous to lactide. Its salts crystallise with difficulty.

The second chlorhydrin occurs in small quantity amongst the higher-boiling portions of the product, and passes over on distillation in a vacuum between 145° and 160° . After rectification it boils at 146° under a pressure of 10 mm. It is probably identical with the compound which Henry obtained (*Deut. Chem. Ges. Ber.* vii. 409) by the action of hypochlorous acid on allyl alcohol, $CH^2=CH-CH^2OH + HOCl = CH^2OH-CHCl-CH^2OH$, and should be converted by nascent hydrogen into normal propyl glycol; but in all the reactions to which it has been subjected it yields a large quantity of polyglycerins (Hanriot, *Compt. rend.* lxxvi. 1139; *Bull. Soc. Chim.* [2], xxvii. 256).

Monochlorethylin, $CH^2OH-CHCl-CH^2-OC^2H^5$, produced in like manner by the action of hypochlorous acid on ethyl allylate, is a thickish colourless liquid, of fruity odour and sharp taste, having a density of 1.117 at 11° , boiling at 183° .

Monochloracetin, $CH^2OH-CHCl-CH^2OC^2H^3O$, from ethyl acetate and hypochlorous acid, is a thick colourless liquid having a refreshing odour and bitter taste, a density of 1.27 at 9° and boiling at 230° .

Chlorobromhydrin, $CH^2OH-CHCl-CH^2Br$, from allyl bromide and hypochlorous acid, is a colourless liquid which turns brown on exposure to light, has a density of 1.764 at 9° , and boils at 197° ; and the isomeric compound, $CH^2OH-CHBr-CH^2Cl$, from allyl chloride and hypobromous acid, has a density of 1.759 at 11° , and likewise boils at 197° . When treated with nitric acid, it is converted, first into nitrochlorobromhydrin, $C^3H^5ClBrNO^3 = CH^2O(NO^2)-CHBr-CH^2Cl$, and then into a chlorobromopropionic acid, $CH^2Cl-CHBr-CO^2H$, which melts at 37° and boils at 215° . A third compound, isomeric with these chloro-bromhydrins, is the secondary alcohol, $CH^2Cl-CHOH-CH^2Br$, which Reboul obtained by the action of hydrobromic acid on epichlorhydrin (ii. 808), (*L. Henry, Deut. Chem. Ges. Ber.* vii. 409, 757).

Dichlorhydrin, $C^3H^5Cl^2(OH)$, likewise admits of two modifications, one unsymmetrical and having the constitution of dichlorinated normal propyl alcohol,

$\text{CH}^2\text{Cl}-\text{CHCl}-\text{CH}^2\text{OH}$; the other symmetrical, and having the constitution of dichlorinated pseudopropyl alcohol, $\text{CH}^2\text{Cl}-\text{CHOH}-\text{CH}^2\text{Cl}$. The latter is the ordinary dichlorhydrin, which Berthelot obtained by heating glycerin with hydrochloric acid (i. 893); the former is produced by the action of hypochlorous acid on allyl chloride:

and appears also to be formed in small quantity in the preparation of ordinary dichlorhydrin (2nd Suppl. 317). The unsymmetrical modification is converted by oxidation into dichloropropionic acid, the symmetrical into dichloroacetone (Henry, *loc. cit.*)

Epichlorhydrin and *Epicyanhydrin*, see pp. 734, 735.

Trinitrin or **Trinitropropane**, $\text{C}^3\text{H}^3(\text{NO}^2)^3$, is formed by distilling tribromhydrin (from allyl iodide) with silver nitrite. Treated with sodium, it yields a brownish product, which has not been obtained pure. Alcoholic potash converts trinitrin into a tripotassic salt which separates as a white powder, and may be purified by washing with alcohol or by recrystallisation from water. Trinitrin, treated with iron and acetic acid, is converted into glyceryl-triamine, $\text{C}^3\text{H}^3(\text{NH}^2)^3$ (Brackebusch, *Deut. Chem. Ges. Ber.* vi. 1289).

GLYCERYL OXIDE or **GLYCERYL ETHER**, $(\text{C}^3\text{H}^5)^2\text{O}^2$. This compound, which Linnemann a. von Zotta obtained by heating glycerin with calcium chloride (2nd Suppl. 565), has been further examined by v. Zotta (*Liebig's Annalen*, clxxiv. 87). To prepare it, glycerin (300 pts.) is distilled in a capacious retort with calcium chloride (45 pts.), previously dried by heating at 190° till the mixture becomes viscid and begins to froth over. The distillate is then cautiously heated over an open flame to remove volatile products, the residue is exhausted with ether, and the ether left to evaporate. The extract, subjected to fractional distillation, yields a liquid boiling between 160° and 210° , which, when shaken with strong potash-ley to remove phenol, leaves an oil which floats on the surface, and may be dried over potassium carbonate. The caustic potash solution also yields to ether a certain quantity of this oil, which, after evaporation of the ether, may be united to the first portion and rectified, whereby impure glyceryl oxide is obtained boiling between 168° and 175° . A further quantity may be obtained by similar treatment from the fractions of the crude product boiling between 150° and 280° . The whole may be purified by a few rectifications.

Glyceryl oxide is a colourless liquid, oily and nearly inodorous at ordinary temperatures, miscible in all proportions with ether, alcohol, and water, having a density of 1.16 and boiling at 171° – 173° . Heated with water in a sealed tube to 100° , it is converted into glycerin, and at 140° a brown substance is produced. With bromine it yields dibromhydrin, $\text{C}^3\text{H}^5\text{Br}^2(\text{OH})$. It is not attacked by sodium-amalgam. Heated with chromic acid mixture, it yields a distillate containing formic acid and acetaldehyde.

GLYCERYL-PHOSPHORIC ACID, $\text{C}^3\text{H}^5\text{PO}^6$. This acid, which was extracted by Gobley from brain and from yolk of eggs, and prepared by Pelouze by the action of phosphoric acid or anhydride on glycerin (ii. 891), has been further examined by Thudichum a. Kingzett (*Chem. Soc. J.* 1876, ii. 20), who prepare it by the action of boiling baryta-water on the brain-constituent, $\text{C}^{12}\text{H}^{20}\text{NPO}^3$, called by Thudichum *cephalin* or *kephalin*. On precipitating the resulting solution with alcohol, dissolving this precipitate in water, and evaporating on the water-bath, a barium salt was obtained having the composition $\text{C}^3\text{H}^5\text{BaPO}^6$. The precipitate formed by alcohol in the aqueous solution appears to contain both water and alcohol in combination; after washing with alcohol, it has the composition $\text{C}^3\text{H}^5\text{BaPO}^6 + \text{H}^2\text{O}$. The aqueous solution of the barium salt gives with lead acetate a precipitate of lead *glycerophosphate*, which, after drying, forms a hard, friable, faintly-coloured mass. The acid separated from it by hydrogen sulphide yields, on neutralisation with calcium carbonate and evaporation, a white calcium salt, $\text{C}^3\text{H}^5\text{CaPO}^6$; and on precipitating the mother-liquor of this salt with alcohol, an acid salt is obtained having the composition $\text{C}^6\text{H}^{10}\text{CaP}^2\text{O}^{12}$.

of the glycidic series (ii. 895), is prepared by heating epichlorhydrin, $\text{C}^3\text{H}^4\text{OCl}$, with potassium acetate, whereby glycidic acetate, $\text{C}^3\text{H}^4\text{O}(\text{OC}^2\text{H}^3\text{O})$, is obtained, as a mobile liquid having an ethereal odour and boiling at 168° – 169° , and treating this compound in ethereal solution with sodium hydroxide, whereby it is resolved into sodium acetate and glycide. This latter, when purified by fractional distillation, is a liquid boiling at 161° – 163° , and miscible in all proportions with water, alcohol, and ether. It unites with hydrochloric acid, and when heated with water is converted

into glycerin. Acid potassium sulphide converts it, by dehydration, into acrolein (H. v. Gegerfelt, *Bull. Soc. Chim.* [2], xxiii. 160).

GLYCOCHOLIC ACID. G. Hufner (*J. pr. Chem.* [2], x. 267) prepares this acid by covering fresh bile in a tall glass cylinder with a layer of ether, and adding 2 c.c. strong hydrochloric acid for every 50 c.c. of the bile. The whole then solidifies after a while to a crystalline pulp, which is drained on a filter, and the impure crystals of glycocholic acid which remain are crystallised from hot water.

GLYCOCINE. See GLYCOLLIC ACID, AMIDO- (p. 879).

GLYCODYSLYSIN, $C^{20}H^{39}NO^4$, is formed by heating glycocine with cholic acid to 190° – 200° , also by heating glycocholic acid to the same temperature. The product dissolves in alcohol, and separates therefrom as a white amorphous, chemically indifferent powder, easily soluble in alcohol, ether, and chloroform (J. Lang, *Bull. Soc. Chim.* [2], xxv. 180).

GLYCOGEN, $C^6H^{10}O^5$. *Occurrence and Formation in the Animal Organism.*—Experiments have been made by v. Mering (*Pflüger's Archiv. f. Physiologie*, xiv. 274) to decide the question whether (as supposed by Pavy, Dock, and others) glycogen is formed by direct transformation of bodies introduced into the system, or whether (as supposed by Tiffenbäch and Weiss), these bodies merely contribute to the accumulation of glycogen in the liver by undergoing oxidation, and thus to a certain extent protecting and sparing the glycogen. The mode of experimenting consisted in introducing various substances into the system of rabbits and dogs, whose livers had been rendered as far as possible free from glycogen by previous starvation. The results showed that a considerable accumulation of glycogen in the liver is induced by the assimilation of grape-sugar, cane-sugar, milk-sugar, fruit-sugar, inulin, lichenin, glycerin, arbutin, gelatin, and proteids (egg-albumin, fibrin, casein), whereas after the introduction of inositol, mannite, quercite, erythrite, and fats, no appreciable quantities of glycogen are found. These results seem to show that the formation of glycogen is a direct consequence of the transformation of certain substances introduced into the organism. The glycogen obtained after feeding with carbohydrates, meat and albuminoids was in all cases the same. J. Forster (*N. Rep. Pharm.* xxv. 733) found that in dogs which had been starved for several days, the quantity of glycogen in the liver was increased by the injection of sugar into the circulation, but by no means in proportion to the quantity of sugar thus introduced. He thence infers that the glycogen is produced, not directly from the sugar, but by the decomposition of albumin, and accumulates in the liver after the introduction of a considerable quantity of sugar into the circulation. The increase of glycogen produced by injection of sugar after prolonged fasting is a consequence of the accelerated decomposition of albumin thereby induced; and in accordance with this view it is found that the excretion of urea is at the same time considerably increased. S. Wolfberg (*Zeitschr. f. Biologie*, xii. 266; *Chem. Soc. J.* 1877, i. 484) also infers from his own experiments and those of Claude Bernard, Voit, Pettenkofer, Valentin, and others, that glycogen is an intermediate decomposition-product of albumin in the animal organism, the amount formed in any case being dependent on the quantity of albuminoids thus altered, and on the presence of various other substances, especially carbohydrates, which influence—by their greater or lesser power of resisting the decomposing actions of the organism—the rate at which the glycogen thus formed becomes further changed.

Glycogen occurs, together with glycocine, in the muscular tissue of the American scallop (*Pecten irradians*) (p. 879).

Transformation into Glucose.—It is commonly stated that glycogen is quickly and completely converted into glucose by the action of saliva and of pancreatic ferment. Siegen, however (*Chem. Centr.* 1877, 8), finds that, when the fermentation is completed, the glycogen-solution appears, from its power of reducing cupric oxide, to contain only a fraction of the quantity of glucose which it should contain, if the whole of the glycogen had been converted into that compound, viz. 34–41 per cent. under the influence of saliva, and 45–48 per cent. under that of pancreas extract. This shows either that the glycogen is converted, not into glucose, but into a substance which reduces cupric oxide in a different proportion, or that in the reaction above mentioned another product is formed besides glucose. Further experiments are required to decide which of these views is the correct one.

On the Estimation of Glycogen in the Liver, see Salomon (*Zeitschr. anal. Chem.* 1874, 470; *Jahresb. f. Chem.* 1874, 1051).

GLYCOGENIC ACID, $C^6H^{10}O^7$. An acid produced by treating an aqueous solution of glycogen at 100° with bromine, and then adding silver oxide: $C^6H^{10}O^5 + H^2O + Br^2 = C^6H^{10}O^6Br^2$; and $C^6H^{10}O^6Br^2 + Ag^2O = 2AgBr + C^6H^{10}O^7$. It is an intensely sour syrupy liquid, the aqueous solution of which dissolves carbonates, forming salts

most of which are crystalline. The lead salt has the composition $C^6H^4O^7$. In all the others the acid appears to be monobasic (Chittenden, *Liebig's Annalen*, clxxxii. 206).

GLYCOLINIC ACID. This name was given by Friedländer to an acid, $C^2H^4O^4$, which he supposed to be formed by the action of sodium-amalgam on an alcoholic solution of ethyl oxalate (1st *Suppl.* 640). According to Dobus, however, the only products of this reaction are glycollic, glyoxylic, and tartaric acids (2nd *Suppl.* 569).

GLYCOLIGNOSE. This substance, which J. Erdmann obtained as a residue from the wood of the spruce fir, after exhaustion with dilute acetic acid, alcohol and ether, and to which he assigned the formula $C^{30}H^{46}O^{21}$ (1st *Suppl.* 640), has been further examined by F. Bente (*Deut. Chem. Ges. Ber.* viii. 476), who obtains by analysis numbers agreeing with Erdmann's formula, but finds that when the glycolignose is boiled with hydrochloric acid, whereby, according to Erdmann, it is resolved into glucose and lignose, $C^{18}H^{26}O^{11}$, as shown by the equation, $C^{30}H^{46}O^{21} + 2H^2O = 2C^6H^{12}O^6 + C^{18}H^{26}O^{11}$, the insoluble residue of lignose which remains after washing successively with water, warm dilute ammonia, water and alcohol, amounts, not to 56.33 per cent. as required by the equation, or to 60–65 per cent. as actually found by Erdmann, but to 70.025 per cent. This residue also contains 0.54 per cent. carbon more than the amount required by theory, and the solution, which is turbid from separation of flocks, contains, not the required 48.51 per cent. of glucose, but only on the average 25.01 per cent. Pure grape-sugar similarly treated does not deposit any flocks. The lignose obtained as above gives, when fused with potash, oxalic and succinic acids, together with bodies resembling pyrocatechin, and probably containing protocatechuic acid, a result confirming Erdmann's statement that fir-wood contains aromatic compounds or residues. Bente doubts, however, whether glycolignose is a distinct chemical individual, inasmuch as it yields lignose in variable proportions, but not to the amount required by Erdmann's formula, even when subjected to the prolonged action of hydrochloric acid. *Poplar-wood* purified by Erdmann's method exhibited the same composition as fir-wood, and likewise yielded a quantity of lignose greater than that required by theory.

GLYCOLLIC ACID, $C^2H^4O^3 = CH^2OH.CO^2OH$. *Formation.*—1. From dichlorethoxyl-ethylene by the action of water at 100° (p. 755). 2. By boiling monochloroacetonitril $C^2HCl(NO^2)N$, with milk of lime or caustic potash (Beckurts u. Otto, *Deut. Chem. Ges. Ber.* ix. 1591). 3. As ethylic ether, together with glyoxylic and tartaric ethers, by the action of sodium-amalgam on an alcoholic solution of ethyl oxalate (2nd *Suppl.* 569).

Preparation.—Fittig (*Ber.* ix. 1198) prepares glycollic acid by boiling a moderately strong aqueous solution of chloroacetic acid for a few hours, whereby it is completely resolved into hydrochloric and glycollic acids. On distilling the product and evaporating the residue on the water-bath, there remains a syrupy liquid containing only a trace of chlorine, from which it may be freed by again evaporating with water. The calcium salt obtained from the residue is pure glycollate.

Glycollic acid may also be easily prepared by heating aqueous oxalic acid with granulated zinc at 100° for a week, then filtering and adding excess of lime. The solution thus prepared contains calcium glycollate, together with a little glyoxylate, and the glycollate may be separated by removing the excess of lime with oxalic acid, boiling the liquid until the glyoxylate is destroyed, and concentrating by evaporation (Crommydis, *Bull. Soc. Chim.* [2], xxvii. 3).

Metallic Glycollates. The crystals of *calcium glycollate*, obtained in the manner just described, contain 5 mols. H^2O , one of which they lose on exposure to the air, and the other four at 100° , or over sulphuric acid in a vacuum (Crommydis). The existence of an anhydrous crystalline calcium glycollate observed by Fahlberg (2nd *Suppl.* 570) is confirmed by Carius (*J. pr. Chem.* [2], ix. 303). On evaporating the solution at a temperature as near as possible to 100° , this anhydrous salt separates on the surface in small crystalline groups, which sink to the bottom and form a hard crust. To obtain it pure, the supernatant liquid must be decanted while hot, and the crystals washed with a little water and dried. It is distinguished from the hydrated salt by its sparing solubility. If, on the other hand, the crystalline crust be left to cool in the liquid, the anhydrous salt becomes mixed with needles of the hydrated salt; and, lastly, if the solution be completely evaporated to dryness at 100° over the crystalline crust, there remains, together with the latter, a small portion of the salt in the form of an amorphous fissured mass, easily soluble in water. In Fahlberg's paper, above quoted, it is stated that hydrated calcium glycollate contains 2 mols. of water. Fittig, however, points out (*J. pr. Chem.* [2], x. 271) that this statement is incorrect, the error arising from a confusion between the old and new atomic weights

of calcium (20 and 40). The crystals contain 27–28 per cent. water, and this agrees with the formula $(C^2H^3O^2)^2Ca + 4H^2O$.

The following glycollates have been examined by G. Schreiber (*J. pr. Chem.* [2], xiii. 436). The *magnesium salt*, $C^4H^6MgO^6 + 2H^2O$, crystallises in extremely thin microscopic needles, and appears almost pulverulent when dry. 1 pt. of it dissolves in 12·6 pts. water at 18°; in boiling water it is much more soluble. The *strontium salt*, $C^4H^6SrO^6 + 5H^2O$, crystallises in slender microscopic needles; dissolves in 29·9 pts. water at 19°; is nearly insoluble in absolute alcohol; gives off the whole of its crystallisation-water at 180°. The *aluminium salt* is very soluble in water, and does not crystallise. The *silver salt*, contrary to the usual statements, was obtained in the anhydrous state, containing only 1·6 per cent. of hygroscopic water.

Chologlycollic acid, $C^2H^4O^7$, is formed by the action of nitrous acid on glycocholic acid (p. 456).

Diphenylene-glycollic acid, $C^{14}H^{10}O^3 = (C^6H^4)^2COH-COOH$, is formed by the action of alkalis on phenanthrene-quinone (p. 676).

AMIDO-DERIVATIVES OF GLYCOLLIC ACID.

Amidoglycollic Acid, Glycicine, or Glycine, $C^2H^5NO^2 = \begin{array}{c} CH^2.NH^2 \\ | \\ CO.OH \end{array}$.

Amidacetic acid.—This compound occurs to the amount of about 0·5 per cent., together with glycogen (2 to 2·4 per cent.) in the muscular tissue of the American scollop (*Eecten irradians*), found on the eastern coasts of the United States.

Formation.—1. From Cyanogen. When cyanogen gas is treated with concentrated hydriodic acid (sp. gr. 1·96) at the boiling heat, one of the cyanogen-atoms is converted, by assumption of hydrogen, into the methylamine-residue, CH^2NH^2 , whilst the second cyanogen-atom, by exchange of nitrogen for the elements of water, is transformed into carboxyl, the result being the formation of glycicine, as shown by the following equation:

(Emmerling, *Deut. Chem. Ges. Ber.* vi. 1351).

2. By reduction of ethyl cyanocarbonate (p. 617).

3. Together with methylamine, ammonia, and carbon dioxide, when methyl-uric acid is heated for some time to 170° with hydrochloric acid saturated at 0° (H. Hill, *Sill. Am. J.* [3], xii. 428).

4. Together with tyrosine, ammonia, leucine, indol, and a viscid yellowish body, called gelatin-peptone—all, as well as the glycicine, in small quantity only—by the pancreatic digestion of gelatin. The formation of glycicine in the alimentary canal may explain, by its reaction with benzoic acid, the production of hippuric acid in the organism of vegetable-feeders; in carnivorous animals the glycicine thus formed is converted into urea (Nencki, *ibid.* vii. 1593).

Reactions.—1. Glycicine gives with *ferric chloride* a deep red colour, which disappears on addition of acids, and is regenerated by ammonia. On mixing a solution of glycicine with a drop of *phenol* and a little *hypochlorous acid*, a fine blue colour is produced.

2. By oxidation with *ammonium permanganate* in presence of free ammonia, glycicine yields oxalic, carbamic, and oxamic acids, and water; the formation of urea has not been observed (Drechsel, *J. pr. Chem.* [2], xii. 417).

3. Glycicine, dissolved in nitric acid, is converted by *nitrous acid* into chologlycollic acid, $C^2H^4O^7$ (p. 436).

4. By *cyanic acid*, glycicine is converted into hydantoic acid, thus:

5. Hydantoic acid is also formed by boiling a solution of glycicine and urea with excess of *barryta-water* as long as ammonia continues to be given off:

Sarcosine or *methyl-glycicine*, treated in like manner, is converted into methyl-hydantoic acid.

Ethyl-glycocine, $C^2H^4(C^2H^5)NO^2$, is produced by treating glycocine with ethyl iodide and absolute alcohol. On agitating the product with silver chloride, the hydrochloride of ethyl-glycocine is obtained in needle-shaped crystals melting at 137° . Ethyl-glycocine is likewise found amongst the products of the reaction of 4 pts. alcohol, 2 pts. methyl iodide, and 1 pt. glycocine (Kraut, *Liebig's Annalen*, clxxvii. 267).

Trimethyl-glycocine or Betaine, $\begin{array}{c} CH^2-N(CH^3)^2 \\ | \\ CO-OCH^3 \end{array}$, or perhaps $\begin{array}{c} CH^2-N(CH^3)^3 \\ | \\ CO-O \end{array}$,

is formed by the action of methyl iodide (3 mol.) on glycocine (1 mol.); and the analogous compound, triethyl-glycocine, by heating triethylamine with ethylic chloracetate (p. 323).

Iodotriethyl-glycocine Ethylate or Ethylic Iodotriethylamidoglycollate, $\begin{array}{c} CH^2-N(C^2H^5)^3I \\ | \\ CO.OC^2H^5 \end{array}$ (Kraut, *Liebig's Annalen*, clxxxii. 172). This ether is formed by the action of ethyl iodide (4 mol.) on silver glycocine (3 mol.) at ordinary temperatures:

The hard crystalline crust which forms after a few days is to be washed, first with cold alcohol, then with cold water. The ethylic iodotriethylamidoglycollate is found in the alcoholic extract. The corresponding platinumchloride, $[Cl(C^2H^5)^3N.CH^2.COO(C^2H^5)]^2PtCl_4$, crystallises in thick orange-coloured anhydrous crystals which are soluble in water. The mother-liquor of this salt contains glycocine and diethyl-glycocine. The aqueous extract contains two-thirds of the glycocine employed in the reaction. The residue insoluble in alcohol and in ether still contains, together with ethyl iodide, a portion of the ethylic iodotriethylamidoglycollate, which, when boiled with an alkaline hydroxide, passes into solution, with separation of alcohol.

Chlorotriethylglycocinammonium platinumchloride, $[Cl(C^2H^5)^3N.CH^2.COOH]^2PtCl_4 + 2H^2O$, crystallises in roseate, well-defined monoclinic crystals, which are nearly insoluble in alcohol, and give off their water at 100° .

Diethylglycocine Ethylate or Ethylic Diethylamidoglycollate, $C^6H^{11}NO^2 - CH^2.N(C^2H^5)^2$, is obtained by distilling silver-glycocine with ethyl iodide, not in excess, $\begin{array}{c} CH^2.NH(C^2H^5)^2 \\ | \\ CO.OC^2H^5 \end{array}$,

after the two substances have been left in contact at the temperature of the air for several days. It is a colourless alkaline liquid having a density of 0.919 at 15° and boiling at 174° . The corresponding platinumchloride is at first oily, but solidifies after a while in short monoclinic anhydrous crystals. This ether, heated for some hours with ethyl iodide, is converted into iodotriethylglycocinammonium ethylate.

Silver-glycocine, treated in like manner with methyl iodide in excess, yields the methylic ether of trimethyl-glycocine or oxynourine, and oxynourine or betaine itself, both of which are found in the alcoholic extract of the product (Kraut).

Phenylamidoglycollic Ethers. 1. *Ethyl Phenylamidoglycollate*,

$C^6H^5NO^2 = \begin{array}{c} CH^2.NHC^6H^5 \\ | \\ COOC^2H^5 \end{array}$, *Phenylglycocollylülther*.—This ether is prepared by

heating 1 mol. ethyl monochloracetate with exactly 2 mol. aniline over an open flame till reaction begins, then removing the source of heat, and allowing the reaction to go on quietly to the end. The whole then solidifies to a crystalline mass, which may be freed from aniline hydrochloride by boiling with water. On dissolving the residual oil in alcohol, and adding water by drops to the cooled solution, a solid body is precipitated; and after these operations have been several times repeated, ethyl phenylamidoglycollate is obtained in colourless nacreous laminae, melting at $57^\circ-58^\circ$, only slightly soluble in water even when hot, but dissolving with moderate facility in cold alcohol and ether, very easily in the same liquids when hot, also in hydrochloric acid. It is therefore advisable, in preparing this body, to use a slight excess of the chloracetic ether, in order to avoid the presence of free aniline, and the necessity of removing it with hydrochloric acid (F. J. Meyer, *Deut. Chem. Ges. Ber.* viii. 1156).

Methyl Phenylamidoglycollate, $C^6H^5NO^2 = \begin{array}{c} CH^2.NHC^6H^5 \\ | \\ COOCH^3 \end{array}$. Prepared like the pre-

ceding. The viscid oil obtained by heating 1 mol. methyl chloracetate with 2 mol. aniline at once yields crystals of aniline hydrochloride, which may be removed by

agitation with water. By distilling the residual oil in a current of steam, a turbid distillate is obtained, which soon deposits the methylic phenylamidoglycollate in splendidly iridescent needles and prisms which may be purified by redistillation. They melt at 48° , are nearly insoluble in water, but dissolve easily in alcohol, ether, and hydrochloric acid (Meyer, *ibid.* 1157).

Tolyamidoglycollic acid or **Tolyglycocine**, $C^6H^{11}NO^2 = \begin{matrix} CH^2.NH(C^6H^7) \\ | \\ COOH \end{matrix}$.

This compound is formed by heating monochloroacetic acid with solid toluidine. At ordinary temperatures, the two bodies simply unite to form a salt, but when 1 mol. chloroacetic acid and 2 mols. toluidine are heated together on the water bath, a reaction takes place, attended with a rise of temperature to 130° , and formation of a large quantity of hydrochloric acid:

To separate the tolyglycocine, the liquid is rendered slightly alkaline with ammonia; this toluidine thereby separated is removed by agitation with ether; the aqueous solution is evaporated to dryness on the water-bath to remove excess of ammonia; the residue redissolved in water; and the greater part of the hydrochloric acid removed by means of recently precipitated silver oxide. The solution is then again made alkaline with ammonia; the dissolved chloride, together with a small quantity of oxide of silver, is decomposed by hydrogen sulphide; the filtrate repeatedly evaporated to dryness and redissolved in water; and the solution, after renewed addition of silver oxide, again treated in the same manner. The rather dark-coloured liquid thus obtained, which no longer contains a trace of chlorine, is then boiled with charcoal and evaporated to dryness; and the residue, after washing with ether, is several times alternately dissolved in alcohol and in water. On evaporating the water or alcohol from these solutions, the tolylamidoglycollic acid remains as a viscid oil which solidifies in beautiful microscopic needles; and by slow evaporation of the alcoholic solution it may be obtained in larger crystals having a yellowish tinge. It is nearly insoluble in ether, melts at about 145° , and decomposes at about 170° . Its solutions have an acid reaction; the silver salt blackens quickly on exposure to the air, and almost instantly when heated; the lead salt appears to be more stable.

Tolyamidoglycollic acid has not yet been obtained quite pure, but its mode of formation and that of its derivatives, and the properties of these bodies, leave no doubt as to its composition: it might perhaps be obtained pure by decomposition of the lead salt (P. J. Meyer, *Deut. Chem. Ges. Ber.* viii. 1158).

Ethyl Tolyamidoglycollate, $CH^2.NH(C^6H^7)-COOC^2H^5$, is prepared like the corresponding phenyl-compound (p. 880) by heating 1 mol. ethyl monochloroacetate with 2 mols. toluidine over an open fire, till the mass, after a somewhat violent reaction, suddenly solidifies to a crystalline pulp. The product, which no longer smells of chloroacetic ether, is then removed from the fire and dissolved in alcohol, and the solution is mixed with water, which throws down an oil solidifying at ordinary temperatures. After repeated solution in alcohol, and careful treatment of the cooled solution with water, the tolylamidoglycollic ether is obtained in white nacreous laminae which melt at 48° – 49° , dissolve but sparingly even in hot water, with moderate facility in cold alcohol, very easily in hot alcohol and in ether, also in hydrochloric ether. Hence it is advisable in preparing this body—as in the case of the corresponding phenyl-compound—to use a slight excess of chloroacetic ether (Meyer, *ibid.* 1159).

Glycollamides (P. J. Meyer, *Deut. Chem. Ges. Ber.* viii. 1154–1164).

1. Phenylamidoglycollamide, $C^6H^{10}N^2O = \begin{matrix} CH^2.NH(C^6H^5) \\ | \\ CONH^2 \end{matrix}$. *Phenylglycocinamide*.

Phenyl-oxyethylene carbamide.—This compound is formed by the action of aniline on chloroacetamide:

When 1 mol. chloroacetamide is cautiously heated with 1 mol. aniline till the whole is fused, and the temperature is kept at the same degree till the liquid exhibits a strong reaction of hydrochloric acid, a product is obtained which dissolves in hot water, and separates on cooling as a white crystalline body purifiable by recrystallisation. This substance is phenylamidoglycollamide. It crystallises in microscopic

needles, melts at 133° , dissolves very easily in ether, alcohol and hot water, and with moderate facility in cold water.

If the group or radicle $\text{CH}^2\text{—CO}$ or $\text{C}^2\text{H}^2\text{O}$ be called *oxethylene*, this compound may be regarded as *phenyloxethylene-carbamide* or *phenyloxethylene-urea*

anilide.—When chloracetanilide is boiled with a slight excess of aniline till the whole is dissolved, the excess of aniline then removed by hydrochloric acid, and the residual oil boiled with a large quantity of water, phenylamidoglycollanilide is obtained as a body melting at 110° – 111° , slightly soluble in cold, more freely in hot water, also in alcohol and in ether, and forming a well-crystallised hydrochloride (Meyer). Wilm. a. Wischin obtained the same compound by the action of aniline on phenylamidoglycollic acid (phenyl-glycocine) and its ethers; also by that of aniline hydrochloride on phenyl-glycollamide, and directly by boiling chloracetyl chloride with excess of aniline.

When chloracetanilide is digested for several hours in a sealed tube with moderately concentrated alcoholic ammonia, the product evaporated till it no longer smells of ammonia, and the resulting liquid mixed with water, a white crystalline precipitate is obtained, which dissolves in hot water, and separates from the solution in dazzling white needles often several inches long, having the composition of phenylamidodiglycollamide.

This compound melts at 140.5° , dissolves easily in ether and in alcohol, with moderate facility in hot water, sparingly in cold water. When boiled with soda-ley it gives off aniline. Its *hydrochloride* crystallises from hot hydrochloric acid in silvery needles and laminae; the *nitrate* in splendid white needles which melt at 172° and decompose at a higher temperature.

Tolyl-oxethylene-carbamide.—Prepared by heating 1 mol. chloracetamide with 1 mol. toluidine at the temperature of the water-bath till a clear liquid is obtained, leaving this liquid to cool, and repeating the operation. The product is dissolved in hydrochloric acid, from which it separates by rapid cooling in small shining laminae, by slow cooling in needles and prisms. If contaminated with undecomposed chloracetamide, it may be purified by recrystallisation from hot water. If more than 1 mol. of toluidine has been used, the product also contains tolyl-amidacetoluide and sal-ammoniac, which may also be removed by solution in a moderately large quantity of hot water.

Tolylamidoglycollamide melts at 162° – 163° , turning brown at the same time. It is sparingly soluble in cold water, moderately in ether, very easily in hot water and alcohol. When heated above its boiling point it gives off toluidine (Meyer. *ibid.* 1160).

Prepared by heating 1 mol. chloracetanilide with rather more than 2 mols. toluidine over an open fire till large quantities of hydrochloric acid are given off, and pouring the product into water, whereby an oil is separated, which quickly solidifies after the excess of toluidine has been removed by hydrochloric acid. After several recrystallisations from hot water, the compound is obtained in slender white needles, insoluble in cold water, sparingly soluble in hot water, easily in alcohol and ether, melting at 82° – 83° .

toluide.—This compound may be obtained: 1. By fusing 1 mol. chloracetamide with 2 mols. toluidine, and recrystallising the product from alcohol. 2. By fusing chloracetyl chloride or chloracetoluide with excess of toluidine, and crystallising from alcohol after addition of hydrochloric acid. 3. It is best prepared by heating a mixture of 1 mol. monochloroacetic acid and 3 mols. toluidine over an open fire till a

violent reaction sets in, indicated by the rapid formation of bubbles within the liquid. The vessel is then to be removed from the fire, the action allowed to go on quietly to the end, and the solidified mass boiled with water to remove toluidine hydrochloride. By repeatedly crystallising the residue from alcohol, till the mother-liquor appears quite colourless, the tolylamidoglycollotoluide is obtained in white silvery laminae very slightly soluble in hot water, rather sparingly in cold alcohol, easily in hot alcohol and in ether. It melts at 136° , and when heated above this temperature, turns dark brown and gives off toluidine. It is not altered by heating with water to 200° , but when boiled with baryta-water it gives off toluidine. The hydrochloride, formed by passing hydrochloric acid over the compound heated to 100° , is decomposed by boiling with water.

Tolyl-amido-diglycollamides, or Tolyl-oxethylene-biurets. 1. The monotolyl-compound, $C^{11}H^{15}N^3O^2 = N(C^7H^7) \begin{matrix} CH^2-CO-NH^2 \\ CH^2-CO-NH^2 \end{matrix}$ is produced by heating tolylamidoglycollamide for some time in an open vessel. Toluidine is then given off, and on cooling, a crystalline residue is obtained which is somewhat difficult to dissolve in alcohol, whereas tolylamidoglycollamide is easily soluble therein. On washing this residue with alcohol to remove the unaltered amide, and repeatedly crystallising it from hot alcohol, the monotolyl-oxethylene-biuret is obtained in beautiful iridescent laminae and short thick prisms.

This compound may, however, be more easily prepared by heating monochloracetamide with an equivalent quantity of toluidine. It is also one of the bodies formed, as above mentioned, as secondary products in the preparation of tolylamidoglycollamide, in greater or smaller quantity, according as the mixture of 1 mol. chloracetamide and 1 mol. toluidine is kept in the state of fusion on the water-bath for a shorter or longer time. In this case, therefore, the biuret is formed at a temperature much below the melting point of the tolylamidoglycollamide, perhaps in consequence of the presence of free hydrochloric acid which abstracts toluidine. On treating the product with a small quantity of cold alcohol, the tolyl-oxethylene-biuret remains as a sparingly soluble body, which, when recrystallised from hot alcohol, likewise separates in iridescent laminae and prisms. It melts without decomposition at 250° , dissolves very sparingly in water, slightly in cold, more easily in hot alcohol and ether.

By due attention to the course of the reaction, it is possible to prevent the formation either of this body or of the tolylamido-glycollamide. If the former is produced, it is almost always accompanied by a third body, which may be separated from the biuret by treating the mass with a small quantity of alcohol, filtering, and mixing the filtrate with water; this third body then separates in very slender needles, and may be purified by redissolution in alcohol and precipitation with water. If all the three bodies are formed at once, the amide is first removed by treatment with a small quantity of boiling water, and the residue is treated as above.

This third body is the nitril of tolyl-glycocine, or tolylamidacetonitril, $CH^2.NH(C^7H^7)-CN$, and is formed by abstraction of water from tolylamidoglycollamide, $CH^2.NH(C^7H^7)-CONH^2$, in the same way as acetonitril from acetamide (Meyer, *Deut. Chem. Ges. Ber.* viii. 1163).

Ditolylamido-diglycollamide, or Ditolyl-oxethylene-biuret, $NH \begin{matrix} CH^2-CO-NH(C^7H^7) \\ CH^2-CO-NH(C^7H^7) \end{matrix}$ (*Diglycollamidsäureditoluidid*). This compound is prepared, like the corresponding phenyl-compound, by heating chloracetoluide with moderately concentrated alcoholic ammonia in sealed tubes to 100° for several hours, concentrating the product, and precipitating with water. A crystalline precipitate is thereby obtained, which may be purified by repeated solution in alcohol, precipitation with water, and final recrystallisation from very dilute alcohol.

Tolylamido-diglycollamide crystallises in rosettes of long soft silky needles, melts at 149.5° , dissolves easily in ether and hot alcohol, with moderate facility in cold alcohol, sparingly in water even at the boiling heat. With acids and bases it behaves like the analogous phenyl-compound (Meyer, *ibid.* 1155).

Tritolylamido-diglycollamide, or Tritolyl-oxethylene-biuret, $C^{25}H^{27}N^3O^2 = N(C^7H^7) \begin{matrix} CH^2-CO-NH(C^7H^7) \\ CH^2-CO-NH(C^7H^7) \end{matrix}$ (*Diglycollotoluididsäureditoluidid*), is formed by heating tolylamidoglycollotoluide in an open vessel to about 160° – 170° . Large quantities of toluidine are then given off, and the product on cooling solidifies to well-defined needles. In sealed tubes the reaction does not take place below 235° . The product is repeatedly crystallised from alcohol—in the latter case with addition of hydrochloric acid—and finally separates in very beautiful long

white needles, which melt at 251° . It is nearly insoluble in water, slightly soluble in cold alcohol and ether, freely soluble in the same liquids at higher temperatures.

By further heating of the oxethylene-biurets formed as above, it might be possible—by elimination of a second molecule of an amine—to obtain a homologue of isocyanic acid or carbimide, CONH . One of these homologues, producible from tritolyl-

oxethylene-biuret, would have the composition $\text{N}(\text{C}^7\text{H}^7) \begin{smallmatrix} \text{CH}^2 \\ | \\ \text{CO} \end{smallmatrix}$; and monotolyl-oxethylene-biuret might yield in like manner the next homologue of carbimide, viz.

Thioglycollic acid, $\text{C}^2\text{H}^4\text{O}^2\text{S} = \text{HS}-\text{CH}^2-\text{COOH}$ (Classen, *Liebig's Annalen*, clxxxvii. 113). This acid is formed, together with thiodiglycollic acid, $\text{C}^4\text{H}^6\text{SO}^4 = \text{COOH}-\text{CH}^2-\text{S}-\text{CH}^2-\text{COOH}$ (v. 776), by the action of monochloroacetic acid on potassium hydrosulphide:

To prepare it, crystallised chloroacetic acid (1 mol.) is added to a concentrated solution of potassium hydrosulphide (2 mols.); the product, at the end of the reaction, is concentrated on a water-bath, and filtered; the filtrate is treated with excess of absolute alcohol; the filtered alcoholic solution is evaporated; the residual salt dissolved in water and decomposed by sulphuric acid; the thioglycollic acid thereby separated is extracted by ether; and the ether evaporated.

Thioglycollic acid thus obtained is a colourless uncrystallisable oil, soluble in all proportions in water, alcohol, and ether. It has a faint odour, which becomes suffocating when the acid is warmed. It appears to be capable of volatilising without decomposition when slowly heated, but decomposes when quickly heated, giving off a very unpleasant odour.

Thioglycollic acid forms three classes of salts, represented by the following formulæ:

α . Thioglycollic acid is a strong acid, and forms salts of this type with the alkalis, alkaline earths, and some of the metals of the iron group, generally with those metals which have a greater affinity for oxygen than for sulphur. They are obtained by dissolving the oxides or carbonates in the acid. They are very soluble, and for the most part do not crystallise well.

The *normal potassium salt*, $\text{HS.CH}^2.\text{CO.OK}$, is very soluble in water and crystallises therefrom in spherical groups of small needles containing 1 mol. H^2O . It dissolves very readily in alcohol, but the solution gradually absorbs water, and the salt is then for the most part deposited in the anhydrous state. It is not deliquescent. The anhydrous salt dissolves in small quantity in boiling alcohol, and crystallises on cooling in capillary needles. It oxidises in contact with the air. On treating it with excess of potassium carbonate, carbon dioxide is given off, and the dipotassium salt $\text{KS.CH}^2.\text{CO.OK}$ is produced.

Barium salt, $(\text{HS.CH}^2.\text{CO.O})^2\text{Ba}$.—This salt dries up on spontaneous evaporation to a gummy mass. It is insoluble in alcohol, and is precipitated thereby from its aqueous solution in the amorphous state.

The *ethylic ether*, $\text{HS.CH}^2.\text{CO.O}^c\text{H}^3$, is easily obtained by boiling the acid with absolute alcohol, and adding a few drops of strong hydrochloric acid. It is a colourless, very fetid oil, heavier than water and somewhat soluble therein. It begins to boil at about 155° , but the boiling point slowly rises to 250° , and the ether partly decomposes, giving off hydrogen sulphide and forming ethylic thiodiglycollate, which passes over with the undecomposed portion. If the boiling be somewhat prolonged, this decomposition is nearly complete. The two ethers may be easily distinguished by the fact that the thiodiglycollic ether, when treated with alcoholic potash, immediately forms a crystallisable potassium salt, which is not the case with the thioglycollic ether.

β . The basic thioglycollates containing univalent metals are distinguished from the acid salts (p. 885) by the circumstance that the atom of metal which is attached to the sulphur may be removed by the weakest acids, whereas in the metallothioglycollic acids this removal can be effected only by hydrogen sulphide. The only basic thioglycollates known are those of the alkalis and alkaline earths. The former are uncrystallisable and difficult to obtain pure.

The barium salt, $\left. \begin{array}{l} \text{CH}^2.\text{S} \\ | \\ \text{CO}_2\text{O} \end{array} \right\} \text{Ba} + 3\text{H}^2\text{O}$, may be prepared by mixing the normal potassium salt with ammonia and barium chloride; by mixing the potassium salt or the free acid with barium hydrate; or by mixing the normal barium salt with ammonia. It is crystalline, nearly insoluble in cold water, and is but slowly dissolved by warm water. Carbonic acid decomposes it readily into carbonate and normal thioglycollate of barium.

γ. Metallo-thioglycollic acids, $\left. \begin{array}{l} \text{CH}^2.\text{S.M}' \\ | \\ \text{CO}_2\text{OH} \end{array} \right\}$. Thioglycollates having the metal

in immediate connection with the sulphur are formed only by those metals which have a great affinity for sulphur. Each of these compounds is a true acid capable of forming salts with other metals. On account of their tendency to pass into compounds in which the hydroxylic hydrogen is also replaced by a metal, only the three following have been obtained in a state somewhat approaching to purity.

Mercuriothioglycollic acid, $\text{C}^4\text{H}^2\text{O}^4\text{S}^2\text{Hg} = \text{CO}^2\text{H}.\text{CH}^2\text{S}.\text{Hg}.\text{CH}^2\text{S}.\text{CO}^2\text{H}$, is prepared either by mixing free thioglycollic acid with mercuric oxide, whereupon a brisk reaction takes place,—or, better, by mixing a cold solution of the potassium salt with mercuric chloride, the mercuriothioglycollic acid then immediately separating as a felted mass of long slender needles:

Mercuriothioglycollic acid is nearly insoluble in cold water, but dissolves easily in boiling water and in alcohol, and crystallises in long slender needles resembling cotton-wool when dry, or in short flat prisms. It has an acid reaction, and unites with nearly all metals except the alkali-metals, forming sparingly soluble and for the most part crystallised salts. It decomposes metallic salts, taking the metal to itself, and forming acid salts with barium, aluminium, and manganese, neutral salts with lead, mercury, and silver. These salts decompose only at very high temperatures, leaving pure or nearly pure metallic oxides.

The barium salt, $\text{BaH}^2(\text{O.CO.CH}^2.\text{S})^2\text{Hg}^2$, formed on mixing hot solutions of the acid and barium chloride, separates in ramified groups of microscopic crystals. The aluminium salt, $\text{Al}^3\text{H}^3(\text{O.CO.CH}^2.\text{S})^2\text{Hg}^2$, formed from alum and the free acid, resembles the barium salt. The manganese salt, $\text{MnH}^2(\text{O.CO.CH}^2.\text{S})^2\text{Hg}^2$, resembles the two preceding in its mode of formation and its external characters. The lead salt, $\text{Pb}(\text{O.CO.CH}^2.\text{S})^2\text{Hg}$, is formed as an amorphous precipitate, on mixing a solution of the acid with lead acetate. The mercuric salt, $\text{Hg}(\text{O.CO.CH}^2.\text{S})^2\text{Hg}$, is produced in like manner from mercuric chloride and the free acid; also on adding mercuric chloride to potassium thioglycollate. It is amorphous or indistinctly crystalline. The silver salt, $\text{Ag}^2(\text{O.CO.CH}^2.\text{S})^2\text{Hg}$, is a white amorphous precipitate formed from the free acid and silver nitrate. Its analysis gave 33.49 per cent. silver instead of the calculated quantity 36.18, showing that the hydrogen in the acid had not been completely replaced by silver.

Cuprosothioglycollic acid, $(\text{HO.CO.CH}^2.\text{S})^2\text{Cu}^2$.—Potassium thioglycollate gives with cupric salts a bluish-black precipitate, which, on further addition of potassium salt, becomes nearly white, in consequence of the reduction of the cupric salt formed in the first instance to a cuprous salt. In this respect the behaviour of thioglycollic acid to cupric salts is similar to that of xanthic acid and analogous compounds, and of mercaptan. The white compound has the composition above given, and reacts altogether like a cuprous compound, dissolving readily in potassium cyanide and sodium thiosulphate, and without colour in ammonia. In the moist state it blackens, being resolved into the cuprous salt, $\text{Cu}^2(\text{O.CO.CH}^2.\text{S})^2\text{Cu}^2$, and free thioglycollic acid, but this change may be prevented by addition of acetic acid. The compound dissolves readily in hydrochloric acid and in alkalis, forming salts. By addition of other metallic salts to the alkaline solution, amorphous precipitates are produced, and the metallic hydroxide formed at the same time may be extracted by acetic acid. The barium salt, $\text{Ba}(\text{O.CO.CH}^2.\text{S})^2\text{Cu}^2$, is a greyish amorphous precipitate.

Bismuthothioglycollic acid, $(\text{HO.CO.CH}^2.\text{S})^2\text{Bi}$, is formed, on mixing potassium thioglycollate with a solution of bismuth nitrate, as a yellow precipitate which redissolves on agitation, but becomes constant on further addition of the bismuth salt. This precipitate is a white soft mass which soon becomes hard and brittle; it melts at 30° – 35° . On continued addition of bismuth nitrate it yields amorphous yellow precipitates which do not melt, and the easily fusible compound itself, when heated on the water-bath, loses weight and becomes infusible.

Argento-, Plumbo-, and Cadmiothioglycollic acids.—These acids have

not been obtained in a state even approaching to purity, the precipitates which are formed by metallic salts in a solution of potassium thioglycollate, consisting of salts of these acids containing the same metal that enters into the acid itself (p. 884).

Argentothioglycollate of Silver, $\text{Ag.O.CO.CH}^2\text{S.Ag}$, is formed on adding silver nitrate to free thioglycollic acid or the potassium salt, as a white, perfectly amorphous mass, which is not altered by light; is quite insoluble in acetic acid and in cold nitric acid; shrinks up on drying to a hard dark-coloured mass; and requires a somewhat high temperature to decompose it.

Cadmiothioglycollate of Cadmium, $\text{Cd(O.CO.CH}^2\text{S)}^2\text{Cd}$, is obtained as an amorphous or indistinctly crystalline mass on adding potassium thioglycollate to a solution of cadmium sulphate, the latter being kept in excess. It dissolves readily in the potassium salt and in hydrochloric acid.

Plumbothioglycollate of Lead, $\text{Pb(O.CO.CH}^2\text{S)}^2\text{Pb}$, obtained like the silver-compound, is a white or slightly yellowish precipitate, amorphous at first, but crystallising after some time in distinct flat prisms. It is quite insoluble in acetic acid, but is dissolved by a large excess of nitric acid. If the potassium thioglycollate is added in excess, the precipitate is yellow and contains a much smaller proportion of lead.

Platinic chloride does not form a precipitate with thioglycollic acid, probably because the resulting platinothioglycollic acid is soluble in hydrochloric acid.

Thioglycollic Ethers, $\text{RS.CH}^2\text{CO.OM}$ (R denoting an alcohol-radicle and M a metal or hydrogen); also called *Sulphacetic Ethers*. These compounds, first prepared by Blomstrand (*Deut. Chem. Ges. Ber.* iv. 717), have been further examined by Glaesson (*ibid.* viii. 120).

Ethyl-thioglycollic acid, $\text{C}^2\text{H}^5\text{S.CH}^2\text{COOH}$.—The ethylic ether of this acid is formed, with great rise of temperature, on mixing the alcoholic solutions of ethylic monochloracetate and sodium mercaptide, and, after filtration from the separated sodium chloride, may be precipitated by water. By heating the ether with baryta-water in sealed tubes, and decomposing the resulting barium salt with sulphuric acid, the ethyl-thioglycollic acid is obtained as an uncrystallisable oil. It is easily soluble in alcohol and ether, moderately soluble in water. It does not volatilise without decomposition, but may be distilled with vapour of water. Its salts dissolve readily in water and in alcohol; they do not bear so high a temperature as the phenyl-thioglycollates (p. 887). They are oxidised by nitric acid, and form a viscid brown precipitate with iron salts. The *potassium salt*, $\text{C}^2\text{H}^5\text{S.CH}^2\text{COOK}$, forms deliquescent crystalline crusts, slightly soluble in alcohol. The *silver salt*, $\text{C}^2\text{H}^5\text{S.CH}^2\text{COOAg} + \text{H}^2\text{O}$, is a crystalline precipitate which does not give off its water over sulphuric acid. The *barium salt*, $(\text{C}^2\text{H}^5\text{S.CH}^2\text{COO})^2\text{Ba}$, and the *calcium salt*, $(\text{C}^2\text{H}^5\text{S.CH}^2\text{COO})^2\text{Ca}$, crystallise in radiate groups of needles. The *lead salt* is a viscid mass, the *magnesium salt*, $(\text{C}^2\text{H}^5\text{S.CH}^2\text{COO})^2\text{Mg} + 3\text{H}^2\text{O}$, and the *zinc salt*, $(\text{C}^2\text{H}^5\text{S.CH}^2\text{COO})^2\text{Zn} + 2\text{H}^2\text{O}$, are crystalline masses. The *cadmium salt*, $(\text{C}^2\text{H}^5\text{S.CH}^2\text{COO})^2\text{Cd} + \text{H}^2\text{O}$, forms prisms which melt and give off their water at 100° ; it is less soluble than the preceding salts. The *manganese salt* is of similar character. The *cobalt salt*, $(\text{C}^2\text{H}^5\text{S.CH}^2\text{COO})^2\text{Co} + 2\text{H}^2\text{O}$, forms small violet-red very soluble prisms; the *nickel salt*, $(\text{C}^2\text{H}^5\text{S.CH}^2\text{COO})^2\text{Ni} + 2\text{H}^2\text{O}$, is greenish, but in other respects like the cobalt salt. The *copper salt*, $(\text{C}^2\text{H}^5\text{S.CH}^2\text{COO})^2\text{Cu} + 2\text{H}^2\text{O}$, forms small shining rhombic plates which melt at 90° , and decompose with great facility.

The *ethylic ether*, $\text{C}^2\text{H}^5\text{S.CH}^2\text{COO.C}^2\text{H}^5$, prepared as above described, is a strongly refractive oil, which has a strong odour, a density of 1.0469 at 4° , and melts at 187° – 189° .* It is not attacked by iodine, but bromine acts upon it strongly. Ammonia converts it into ethyl-thioglycollamide, $\text{C}^2\text{H}^5\text{S.CH}^2\text{CO.NH}^2$, which crystallises in long thin prisms, melts at 44° , dissolves easily in water and in alcohol, and cannot be volatilised without decomposition.

Ethylic Diethylsulphiniodacetate, $\text{C}^2\text{H}^5\text{S} \begin{array}{c} \diagup \text{CH}^2 \\ \diagdown \text{COOC}^2\text{H}^5 \end{array}$, is formed by heating ethylic

ethylthioglycollate and methyl iodide in equal numbers of mols. to 120° in a sealed tube, and separates, on leaving the product to evaporate in a vacuum, in yellowish crystals. When agitated with silver oxide it yields a strongly alkaline solution.

Amylthioglycollic acid is a viscid liquid. Its ethylic ether boils at 230° , and has a density of 0.9797 at 4° . Its salts, except those of the alkali-metals, are but slightly soluble. The *zinc* and *cadmium salts* are white precipitates; the *copper salt* crystallises in slender needles; the *lead salt* is very easily fusible.

* Erlenmeyer a. Lisenko (*Zeitschr. Chem. Pharm.* 1862, 134) describe this ether as a liquid boiling at about 100° . The cause of this discrepancy appears to be that they prepared it with sodium mercaptide which had been somewhat altered by heat, as indeed appears from the fact that they were obliged to heat it with the chloracetic ether in sealed tubes, whereas with unaltered sodium mercaptide a strong reaction takes place at ordinary temperatures.

Phenyl-thioglycollic acid, $C^6H^5.S.CH^2.COOH$.—The ethylic ether of this acid, prepared by the action of sodium phenyl-mercaptide on ethylic chloracetate in alcoholic solution, is decomposed by alcoholic potash like the corresponding ethyl-compound, yielding potassium phenyl-thioglycollate, which separates in crystalline spangles; and by decomposing this salt with hydrochloric acid, the free acid is obtained in the form of an oil which soon becomes crystalline. From a hot dilute solution it separates on cooling in thin brittle plates. It melts at 43.5° , and resolidifies at 28° . It dissolves in all proportions in alcohol and ether, slightly in cold, more readily in warm water, forming strongly acid solutions. It cannot be volatilised alone, but distils even with vapour of water. It is not decomposed by boiling with dilute acids. Its salts are, for the most part, slightly soluble in water, insoluble in alcohol; they may all, except the copper salt, be heated to 100° without alteration, but begin to blacken and decompose at 200° .

The potassium salt, $C^6H^5.S.CH^2.CO.OK$, crystallises in thin silky needles, moderately soluble in hot water; it is not decomposed either by boiling its solution or by fusing it with potash. The sodium salt, $C^6H^5.S.CH^2.CO.ONa$, may be produced directly by decomposing sodium monochloracetate with an alcoholic solution of sodium phenyl-mercaptide; it forms crusts composed of nodules. The ammonium salt forms crystalline crusts which melt with decomposition above 100° . The silver salt, $C^6H^5.S.CH^2.COOAg + H^2O$, is a white precipitate.

The following are represented by the general formula $(C^6H^5.S.CH^2.COO)^nM^n$.

Barium salt.—Anhydrous crystalline mass composed of slender needles; moderately soluble in hot water.—*Calcium salt*. Anhydrous; groups of oblique tablets.—*Lead salt*. Anhydrous; ammonium precipitate which soon hardens, and melts at 60° .—*Magnesium salt*, $+ 3H^2O$. Shining scales containing $3H^2O$.—*Zinc salt*, $+ 2H^2O$. Radiate groups of long needles having a silky lustre.—*Cadmium salt*, $+ H^2O$. Shining scales.—*Manganese salt*, $+ 5H^2O$. Bulky mass composed of oblique plates.—*Cupric salt*. Anhydrous; amorphous precipitate of fine green colour. Easily alterable; becomes viscid when exposed in the moist state to the air; heated with water it yields tarry masses consisting of a basic salt. The normal salt dissolves easily in ammonia, and the solution when evaporated in a vacuum leaves blue prisms.

The cobalt, nickel, aluminium, ferric, and chromic salts are amorphous precipitates.

The ethylic ether, $C^6H^5.S.CH^2.CO.OCH^3$, is a liquid which in the pure state has a sweetish, aromatic, and not unpleasant odour, a specific gravity of 1.136 at 4° , and 1.1269 at 15° , and boils with partial decomposition at 276° – 278° . The amide, $C^6H^5.S.CH^2.CONH^2$, prepared from it crystallises from alcohol in small plates melting at 104° , easily soluble in alcohol, less soluble in water, very slightly soluble in ether.

Bromophenyl-thioglycollic acid, $C^6H^4Br.S.CH^2.COOH$.—The ethylic ether of this acid is formed, with brisk reaction, on adding bromine to a solution of ethylic phenyl-thioglycollate in carbon disulphide. Treated with alcoholic potash, it yields the corresponding potassium salt, and this, when decomposed by hydrochloric acid, yields the free acid in shining slightly soluble needles melting at 112° .

Oxidation-products of Ethyl- and Phenyl-thioglycollic acid (Claesson, *loc. cit.*) By subjecting a salt of either of these acids to the action of a solution of potassium permanganate (not of nitric acid, or of chromic acid mixture), the sulphur contained in it may be oxidised, without further decomposition of the molecule, to SO^2 or SO^3 . In this manner the following acids have been obtained:—

Ethyl-sulphoglycollic acid, $C^2H^5.SO^2.CH^2.COOH$.—This acid, separated from its zinc salt by hydrogen sulphide, forms a thick uncrystallisable liquid, which dissolves very easily in water, as also do most of its salts. The potassium salt, $C^2H^5.SO^2.CH^2.CO^2K$, crystallises from alcohol in small, colourless, very hygroscopic plates. The barium salt, $(C^2H^5.SO^2.CH^2.CO^2)^2Ba$, forms small nodules; the copper salt, $(C^2H^5.SO^2.CH^2.CO^2)^2Cu + 2H^2O$, rather large bluish plates, becoming anhydrous at 240° . The zinc salt and the silver salt are moderately soluble; the latter forms small needles. The lead salt forms small, very soluble plates.

Phenyl-sulphoglycollic acid, $C^6H^5.SO^2.CH^2.COOH$, is separated by hydrochloric acid from the concentrated solution of its potassium salt, as an oil; it dissolves in ether and is left on evaporation in the form of an oil which soon solidifies. By crystallisation from water, it is obtained in small monoclinic crystals which melt at 109° , have a very sour taste, and dissolve easily in alcohol and in ether. Its salts are more soluble than those of phenyl-thioglycollic acid, the potassium and zinc salts being even deliquescent. The silver salt, $C^6H^5.SO^2.CH^2.COOAg$, crystallises from boiling water in slender needles. The copper salt, $(C^6H^5.SO^2.CH^2.COO)^2Cu + 2H^2O$, forms small green moderately soluble tablets.

Phenyl-sulphiglycollic acid, $C^6H^5.SO.CH^2.COOH$, is produced when a salt of phenyl-thioglycollic acid is treated with half the quantity of permanganate required

to convert it into the sulpho-acid. It forms colourless crystals melting at 74° . The copper salt is a greenish amorphous precipitate.

GLYCOLS. *Action of Water.*—Carius found that ethylene bromide heated with water in a sealed tube to 150° – 180° is resolved into acetaldehyde and hydrogen bromide (1st Suppl. 602):

This conversion of a glycollic ether into an aldehyde might be supposed to take place either through the medium of the brominated hydrocarbon or through that of the corresponding glycol. Thus the conversion of isobutylene bromide into isobutyric aldehyde might be represented by either of the two following sets of equations:

Experiment shows, however, that bromisobutylene, $(\text{CH}^3)^2\text{C}=\text{CHBr}$, is not acted upon by water at 150° – 200° , whereas isobutylene glycol, $(\text{CH}^3)^2\text{COH}-\text{CH}^2\text{OH}$, heated with water in sealed tubes to 180° – 200° , is transformed, by elimination of H^2O into the corresponding aldehyde. The reaction must therefore be represented by the second pair of equations above given (Nevolé, *Compt. rend.* lxxxiii. 228).

Action of Oxalic acid on Ethylene-glycol.—The reaction begins at 80° with evolution of pure carbon dioxide, while formic acid distils over, the distillate containing successively from 6.7 to 56.7 per cent. of that acid. The portions which distil over between 172° and 175° consist of pure ethylene diformate, $\text{C}^2\text{H}^4(\text{OCHO})^2$, and those obtained between 120° and 172° perhaps contain ethylene monoformate. The same bodies are produced, together with glycol and small quantities of free formic acid and methyl formate, by the action of potassium formate at 85° on a mixture of ethylene bromide and ethyl alcohol (Lorin, *Compt. rend.* lxxix. 387; *Bull. Soc. Chim.* [2], xxi. 409; xxii. 104).

Glycolic Diformin or Ethylene Diformate is also produced by heating ethylene glycol for some time to boiling in a reflux apparatus with 3 to 4 parts of 75–80 per cent. formic acid. On distilling the product, a mixture of the mono- and di-formins passes over between 170° and 180° ; and the diformin may be easily isolated by again treating the mixture with about 1 part of crystallisable formic acid and rectifying the product. Glycolic diformin is a colourless, very mobile liquid having a peculiar odour and boiling without decomposition at 174° . When heated in sealed tubes it is decomposed in the manner shown by the equation

At the same time the water thus produced saponifies a portion of the formin, so that the residue contains small quantities of glycol and formic acid (Henninger, *Bull. Soc. Chim.* [2], xxi. 242).

On Glycolic Ethers, see ETHYLENE COMPOUNDS, pp. 752–755.

Glycolic Chlorosulphonic acid or Ethylene-chlorosulphonic acid, $\text{C}^2\text{H}^4\text{Cl}(\text{SO}^3\text{H})$, is formed, together with chloral, by the action of sulphuric acid on the compound $\text{CCl}^2-\text{CH}-\text{CH}^2\text{Cl}$, produced by the union of glycolic monochlorhydrin with chloral (L. Henry).

GLYCOLYL-THIOCARBAMIDE, $\text{CS} \begin{smallmatrix} \text{NH}.\text{CH}^2 \\ \text{NH}.\text{CO} \end{smallmatrix}$. See CARBAMIDES (THIO-), p. 400.

GLYCOPROTEIN. See PROTEIDS.

GLYCOSAMINE, $\text{C}^6\text{H}^{13}\text{NO}^5 = \text{COH}(\text{CHOH})^4.\text{CH}^2.\text{NH}^2$ (G. Ledderhose, *Deut. Chem. Ges. Ber.* ix. 1260). The hydrochloride of this base, $\text{C}^6\text{H}^{13}\text{NO}^5.\text{HCl}$, is formed by boiling chitin for half-an-hour with strong hydrochloric acid. The chitin then dissolves, forming a blackish-brown solution, which when evaporated leaves the hydrochloride in the form of shining crystals mixed with a black amorphous mass. If chitin be similarly treated, with addition of metallic tin, the solution formed has only a slight yellowish-brown colour, and the formation of the amorphous substance is entirely avoided. The crystals amount to about 40 per cent. of the chitin employed. They have a decidedly sweet taste, dissolve freely in water, sparingly in alcohol, forming acid solutions. They give with soda ley and copper sulphate a dark-blue solution, which deposits cuprous oxide on warming.

Glycosamine hydrochloride is dextrogyrate, having a specific rotatory power, $[\alpha]_D =$

70·6. It appears to ferment with yeast. The solution of the free base has an alkaline reaction, and decomposes with brown coloration when evaporated.

The constitution of glycosamine is that of a carbohydrate in which HO is replaced by NH².

GLYCYRRHIZIN and **GLYCYRRETIN**. Z. Roussin (*Arch. Pharm.* [3], viii. 156) observes that glycyrrhizin is a tasteless substance, and ascribes the sweet taste of liquorice-root to an ammonia-compound of glycyrrhizin, which, like the compounds formed by that substance with potash and soda, has a very sweet taste. According to Habermann (*Deut. Chem. Ges. Ber.* x. 870), amorphous commercial glycyrrhizin yields to glacial acetic acid a body which crystallises from alcohol in hemispherical groups of needles. It dissolves readily in water and in aqueous alcohol, less freely in absolute alcohol, scarcely at all in ether. In its reactions it resembles the amorphous compound described by Gorup-Besanez (ii. 920), but has a different composition, and when boiled with dilute sulphuric acid yields a resinous body having the sweet and acid taste of the original substance.

Griessmeyer finds that glycyrrhizin is resolved into glycyrretin and fermentable sugar by boiling, not only with dilute acids, but also with saline solutions, and even with water (*Dingl. pol. J.* cxix. 228).

According to Weselsky a. Benedikt (*Deut. Chem. Ges. Ber.* x. 1158), glycyrretin fused with potassium hydroxide yields nothing but paraoxybenzoic acid.

GLYOXAL, C²H²O² = HOC—COH. Debus obtained this compound, together with glyoxalic acid and other products, by the action of nitric acid on alcohol (ii. 920). According to Lubawin (*Deut. Chem. Ges. Ber.* viii. 768), it is better to use a 50 per cent. aqueous solution of aldehyde. In cylinders holding a quarter of a litre, the oxidation is completed in a week; and the evaporated product consists mainly of glyoxal. 100 grams of aldehyde yield from 45 to 100 of the recrystallised compound of glyoxal and acid sodium sulphite. Lubawin has detected formic acid amongst the products of the action of ammonia on glyoxal, and explains the reaction in the same manner as Debus.

GLYOXALINE, C³H⁴N². This base, which Debus obtained, together with glycosine, C⁶H⁶N⁴, by the action of ammonia on glyoxal (ii. 921), has been further examined by G. Wyss (*Deut. Chem. Ges. Ber.* ix. 1543; x. 1365). To prepare it, the evaporated residue of glyoxal obtained by Lubawin's process is treated very gradually with ammonia in slight excess, the temperature being kept down. Glycosine then separates as a brown powder, and the filtered solution contains the glyoxaline together with ammonia, chiefly as acetate. This liquid is boiled with milk of lime to expel the ammonia, then evaporated to a syrup, treated with absolute alcohol to separate mineral salts, and filtered; the residue is strongly pressed to separate as much as possible of the liquid; and the whole of this liquid is distilled from a wide-necked retort. After one rectification the glyoxaline is perfectly pure, and solidifies to a radiate, dazzling-white crystalline mass. It dissolves easily in water, alcohol, and ether, but is not deliquescent, and crystallises in thick nacreous prisms. It has an alkaline reaction, and emits a slight fishy odour when warmed. Its vapour-density, determined in sulphur-vapour (it suffers scarcely any decomposition at 447°), is 2·35: hence its molecular formula is C³H⁴N² (not C⁶H⁸N⁴, as supposed by Lubawin).

Reactions.—1. Acetic anhydride and the chlorides of acetyl and benzoyl are without action on glyoxaline, even when heated with it, or, at least, form only addition-products. From this it might be inferred that glyoxaline is a tertiary base. But if it be boiled for some hours with *ethyl bromide*, the syrup remaining after evaporation on the water-bath taken up with water, the bromine removed by freshly precipitated silver chloride, and platonic chloride added to the concentrated solution, there gradually separates a salt having the composition [C³H³N²(C²H³)(C²H⁵)Cl]²PtCl⁴ + $\frac{1}{2}$ H²O. Hence the reaction between glyoxaline and ethyl bromide takes place as represented by the equation:

By treating the bromethylate with moist silver oxide, the hydroxide may be obtained as a strongly alkaline liquid, which, when dried in a vacuum over sulphuric acid, changes to a deliquescent crystalline solid. *Benzyl chloride* acts on glyoxaline in a perfectly similar way.

Glyoxaline is quite unaffected by chromic acid, and by reducing agents of all kinds, but *potassium permanganate* oxidises it completely, yielding formic acid and carbon dioxide.

When concentrated solutions of glyoxaline sulphate and *potassium nitrite*, or of

the hydrochloride and *silver nitrite*, are heated for a long time, the mixture evaporated, and the residue exhausted with absolute alcohol, a nitroso-derivative possessed of acid properties is obtained. The alkaline salts of this body are reddish-brown, and give with solutions of metallic salts, amorphous variously-coloured precipitates.

Tribromoglyoxalinic acid, $\text{C}^3\text{HBr}^3\text{N}^2$, is produced, together with glyoxaline hydrobromide, by the action of bromine on an ethereal or (better) aqueous solution of glyoxaline. In the latter way a bright brown precipitate is formed, which may be crystallised from a large quantity of boiling water. It is readily soluble in alcohol, almost insoluble in cold water, and sparingly soluble in ether, chloroform, and carbon disulphide; soluble in alkalis, and precipitated by acids. With the exception of hydrocyanic acid, it is the only known organic acid not containing oxygen. Most of its salts are insoluble. The silver-compound, when boiled with ethereal solutions of *methyl* or *ethyl iodide*, gives methyl- and ethyl-tribromoglyoxalates, well-crystallised bodies, insoluble in water and alkalis, soluble in alcohol and in ether. On treating them for some time in warm alcoholic solution with *sodium-amalgam*, the bromine contained in them is displaced by hydrogen, yielding methyl- and ethyl-glyoxaline, $\text{C}^3\text{H}^2(\text{OH})\text{N}^2$ and $\text{C}^3\text{H}^3(\text{C}^2\text{H}^3)\text{N}^2$, which are oily bases forming deliquescent hydrochlorides and crystalline platinochlorides, that of the methyl-derivative crystallising in slender yellow needles, and that of the ethyl-derivative in yellowish prisms.

Silver-glyoxaline is obtained as a granular insoluble precipitate when silver nitrate is added to a solution of glyoxaline—

or better by adding caustic soda to a mixture of glyoxaline and silver nitrate. The reaction of acetyl chloride on this body gives unsatisfactory results; the iodides of methyl and ethyl, however, act upon it in the cold, giving, besides small quantities of the above-mentioned homologues, insoluble doughy compounds, not yet investigated.

Constitution of Glyoxaline.—The facility with which one of the atoms of this base can be replaced by metals and alcohol-radicles makes it probable that glyoxaline is an imide-base, and its reaction with the alcoholic iodides points to the conclusion that it is also a nitril-base. Such a constitution may be represented by the formula

acetyl chloride is no proof of the absence of an imidogen-group, since the phenylated guanidines, as well as some other bases, exhibit the same peculiarity. Assuming this constitution, some of the above bodies may be thus formulated:—

Glycosine, the base formed simultaneously with glyoxaline, has been but little studied. It forms, however, with silver nitrate, a double salt, $\text{C}^3\text{H}^4\text{N}^4.\text{AgNO}^3$, and exhibits the remarkable property of dissolving easily not only in acids but likewise in soda-ley at the boiling heat.

GLYOXYL-CARBAMIDE or **GLYOXYL-UREA**, $\text{C}^3\text{H}^4\text{N}^2\text{O}^3 = \text{CH}^3(\text{C}^2\text{HO}^2)\text{N}^2\text{O}$. (L. Medicus, *Liebig's Annalen*, clxxv. 230; *Deut. Chem. Ges. Ber.* ix. 1162; x. 544.) This appears to be the constitution of an acid, isomeric with lantanuric acid, the potassium salt of which was obtained by Strecker, with brisk evolution of carbon dioxide, on adding acetic acid to a solution of the potassium salt of the acid $\text{C}^4\text{H}^3\text{N}^3\text{O}^4$, called by Strecker *oxonic acid* (*q.v.*)

It is also formed, together with urea and carbon dioxide, by boiling uroxanic acid with water:

The resulting solution concentrated and left to evaporate leaves a syrupy liquid, and on neutralising this with barium carbonate, dissolving in water, and adding alcohol, a precipitate is obtained consisting of the *barium salt of glyoxyl-urea*, $(\text{C}^3\text{N}^2\text{H}^3\text{O}^3)^2\text{Ba}$.

The *potassium salt* is a crystalline powder; the *silver salt* an amorphous powder. Glyoxyl-urea itself crystallises in thick shining needles, slightly soluble in cold, easily in hot water.

Glyoxyl-urea breaks up, under the action of potassium hydroxide, in the manner indicated by the following equations:—

the ultimate products being ammonia, acetic acid, and oxalic acid.

GLYOXYL-DICARBAMIDE or -DIUREIDE,

This is the constitution of allantoïn, which may in fact be formed by heating glyoxylic acid with urea (p. 57).

GLYOXYLIC ACID, $\text{C}^2\text{H}^2\text{O}^3$ (Debus); $\text{C}^2\text{H}^4\text{O}^4 = \text{CH}(\text{OH})^2 - \text{CO} \cdot \text{OH}$ (Perkin). See ii. 922 and 1st *Suppl.* 650. The constitution of this acid has been further examined by Perkin (*Chem. Soc. Jour.* 1877, ii. 88). The glyoxylic acid was prepared by decomposition of dibromacetic acid, which is readily obtained by treating acetic anhydride with bromine, and subjecting the resulting monobromacetic acid to the further action of bromine at the boiling heat and in sunshine. The silver salt of this acid, when boiled with water, is resolved, with rise of temperature and formation of silver bromide, into dibromacetic and glyoxylic acids:

The same salt, boiled with alcohol, yields a mixture of (probably) ethylic dibromacetate and ethylic diethylglyoxylate, $\text{CH}(\text{OC}^2\text{H}^3)^2 - \text{COOC}^2\text{H}^3$. Heated to 100° with dry ethyl oxide, silver dibromacetate yields an oily product which, when purified by agitation with ether and sodium carbonate, has the composition $\text{C}^4\text{H}^2\text{Br}^2\text{O}^4$, its formation being represented by the equation $2\text{C}^2\text{HBr}^2\text{AgO}^2 = 2\text{AgBr} + \text{C}^4\text{H}^2\text{Br}^2\text{O}^4$; and this oil, when treated with water, is decomposed into dibromacetic and glyoxylic acids:

It appears to possess the properties of an anhydride, and may be regarded either as a

The aqueous solution of glyoxylic acid, if quickly evaporated over sulphuric acid in a vacuum, leaves merely a gummy mass; but by slower evaporation over sulphuric acid under the ordinary atmospheric pressure, the acid is obtained in crystals which are apparently oblique rhombic prisms, but it is not easy to make out their form, as they are small and rather confused; moreover, they are produced in a very thick liquid and deliquesce rapidly when taken out. The acid is very soluble in water and in alcohol, tastes very much like tartaric acid, melts to a syrupy liquid when heated, and cannot be distilled without decomposition.

When heated to $120^\circ - 130^\circ$ for five hours with absolute alcohol, it yields a colourless liquid consisting of the ethylic ether of diethyl-glyoxylic acid, $\text{CH}(\text{OC}^2\text{H}^3)^2 - \text{COOC}^2\text{H}^3$.

The *ammonium salt*, obtained by decomposing calcium glyoxylate with ammonium oxalate, or by neutralising glyoxylic acid with ammonia, has, after evaporation in a vacuum, the composition $\text{C}^2\text{H}^3\text{N}^3\text{O}^3$ or $\text{C}^2\text{H}(\text{NH}^4)\text{O}^3$, and is the compound which most favours the formula $\text{C}^2\text{H}^2\text{O}^3$ proposed for glyoxylic acid by Debus. This salt, however, though quite neutral to test-paper, when freshly prepared, like the glyoxylates of potassium and sodium, becomes acid when its solution is evaporated in a vacuum, even after having been rendered slightly alkaline with ammonia, which dissolves it with great facility. From these properties Perkin infers that the compound in question is not a true ammonium salt, but an *amido-acid* formed from the ammonium glyoxylate

(produced in the first instance) by elimination of H^2O , and interchange between the group NH^2 and an OH -group; thus:

Amidoglyoxylic acid is similar in constitution to aldehyde-ammonia, $\text{CH(NH}^2\text{)OH}-\text{CH}^3$, the CH^3 being replaced by carboxyl.

This view of the constitution of the compound obtained by neutralising glyoxylic acid with ammonia receives some support from the fact that a compound exhibiting both acid and basic properties is obtained in like manner by decomposing calcium glyoxylate with oxalate of aniline. The substance thus produced is non-crystalline, dissolves easily in ammonia, and is likewise soluble in hydrochloric acid; and the solution, when evaporated, leaves a soluble hydrochloride from which a platinochloride may be prepared.

Debus, on the other hand (ii. 922), maintains that the ammonia-derivative of glyoxylic acid is a true ammonium salt, inasmuch as it is formed from calcium glyoxylate by the ordinary process of double decomposition, and yields silver glyoxalate by decomposition with silver nitrate.* The acidity of the evaporated salt he attributes to the partial loss of ammonia, which is constantly observed in the evaporation of solutions of ammonium salts (p. 75). He therefore still considers that glyoxylic acid is correctly represented by the formula $\text{C}^2\text{H}^2\text{O}^3$, which is likewise most in accordance with the fact that glyoxylic acid is formed by direct oxidation from glyoxal, $\text{C}^2\text{H}^2\text{O}^2$.

Reactions.—1. When hydrochloric acid is added to a mixture of syrupy glyoxylic acid and hydrocyanic acid, and the mixture is set aside for some weeks, crystals of sal-ammoniac separate, and the solution, if then agitated with ether, yields a small quantity of oxalic acid; and on evaporating it to dryness at 100° and extracting the residue with absolute alcohol and ether, a solution is formed containing glycollic acid. 2. When a dilute aqueous solution of glyoxylic acid is agitated with silver oxide, and hydrogen sulphide is passed into the liquid, there is obtained, together with oxalic acid, a syrupy sulphuretted acid which is but partially precipitated by lead acetate, and may thus be separated from the oxalic acid. The solution of its potassium salt forms precipitates with lead acetate, mercuric chloride, and barium chloride. The acid is easily etherified. It probably consists of 'mercaptan-glycollic acid' [? thioglycollic acid]. 3. Glyoxylic acid is strongly acted upon by acetic anhydride, and sodium acetate (Perkin's reaction), but neither fumaric nor maleic acid could be discovered in the dark-coloured product, the only substances present, besides glycollic and oxalic acids, being a dark-coloured syrupy compound having an odour of burnt sugar (Böttinger, *Deut. Chem. Ges. Ber.* x. 1084).

GMELINITE. This mineral occurs in Nova Scotia in two distinct types, the first of which, occurring at Two Islands and Cape Blomidon, exhibits +R and -R almost in equilibrium, together with ∞R , 0P, and $\infty\text{P}2$. The prism ∞R is horizontally striated; $\infty\text{P}2$ has somewhat rounded edges, and the colour is light flesh-red to milk-white. The second type occurs on the Five Islands, eight miles distant from Two Islands. In this type there is an entire absence of 0P; -R is scarcely discernible, ∞R exhibits a strong lustre on its faces without a trace of striation. The characteristic form of this locality is -2R, which is distinctly striated parallel to its combination-edges with R, the crystals being complete rhombohedrons, some faces being well developed, whereas other crystals, when small, exhibit drusy faces. Colour darker than in the crystals of the first type. Gmelinite from Bergen Hill occurs in a type intermediate between the two already described, as R and -R are unequally developed, and 0R and $\infty\text{P}2$ are not present. Chemical composition as follows:

	SiO^2	Al^2O^3	Fe^2O^3	CaO	Na^2O	K^2O	H^2O	
Two Islands	51.36	17.81	0.15	5.68	3.92	0.23	20.96	= 100.11
Five Islands	50.45	18.27	0.17	1.12	9.79	0.20	20.71	= 100.71
Bergen Hill	48.67	18.72	0.10	2.60	9.14	—	21.35	= 100.58

From the above analyses it is evident that the chemical composition exerts a considerable influence upon the crystallographical type. Gmelinite from Five Islands contains a large amount of soda, and has a rhombohedral type, R predominating; that from Bergen Hill exhibits no particular characteristics, whilst that from Two Islands,

* It must be observed, however, that Perkin does not deny the formation of ammonium glyoxylate in the first instance, or its existence in solution, but considers that this salt is converted into an amido-compound by loss of H^2O , on evaporation in the manner above described.

in which there is a large proportion of lime, is remarkable for its pyramidal character (Howe, *Sill. Am. J.* [3], xii. 270).

GNEISS. The sp. gr. and amount of silica in a series of varieties of gneiss in the Black Forest of Baden have been determined by Vogelgesang (*Jahrb. f. Min.* 1873, 431):

1-6. Gneiss from the neighbourhood of Zindelstein, 9 kilom. W.N.W. of Donau-echingen: 1. Ordinary gneiss. 2. Porphyritic. 3. Fine-veined, resembling mica-slate. 4. Brown porphyritic. 5. Red granular-veined. 6. Thin, scaly gneiss, resembling hornblende. 7 and 8. Gneiss from Unterkirnach, 6 kilom. W.N.W. of Villengen. 7. Coarse-veined gneiss. 8. Granular-veined, imbedded in the preceding in layers from 1.5 to 2 meters thick:

Sp. gr.	1	2	3	4	5	6	7	8
SiO ² per cent.	2.708	2.724	2.712	2.685	2.617	2.769	2.725	2.650
	55	56	59	63	65	53	56	75.3

The first three varieties, after several days' treatment with cold dilute sulphuric acid, yielded, in solution, the following quantities of substance:

1. = 23.64 2. = 14.84 3. = 23.48 per cent.

The last acid extract contained 6 per cent. SiO², 6 per cent. Fe²O³, 5 per cent. Al²O³, together with the greater part of the CaO, MgO, and alkalis present in the rock, therefore nearly half its amount of bases, but only about $\frac{1}{10}$ of the amount of the silica present. The analysis of rock No. 4 gave:

SiO ²	Al ² O ³	Fe ² O ³	CaO	MgO	Alkalis	Loss by ignition
63.34	15.44	11.89	2.93	1.76	3.36	1.29 = 100.01.

A petrographic description of the gneiss of Sweden has been given by A. E. Törnebohm (*Jahrb. f. Min.* 1874, 131). P. Schweitzer (*Am. Chem.* iv. 443) has analysed the quartz, felspar, and mica of the granitic gneiss on which New York is built. (See also *Jahresb. f. Chem.* 1874, 1244, 1250, 1258.)

On the Heat-conductivity of Gneiss, see HEAT.

On Gneiss-granulite, see GRANULITE.

GOETHITE. This variety of ferric oxide is found in Adair County, Missouri, in cavities of calcite concretions, forming crystals from $\frac{1}{8}$ to $\frac{3}{4}$ inch long, aggregated in bundles at the base of the calcite from which they radiate. Sometimes a single crystal shoots directly through a calcite crystal. Sometimes also a quartz crystal is seen penetrated in various directions by goethite. Minute, velvety balls of goethite, not larger than $\frac{1}{32}$ of an inch, are also found resting on the calcite (Broadhead, *Sill. Am. J.* xiii. 419).

GOLD. *Occurrence.*—Gold in a state of fine crystallisation is found at Vöröspatak. The predominating forms are O and $\infty O \infty$, often in equilibrium, with occasionally 303 and ∞O and $\infty O 2$ in combination, but the cube generally predominates. A twinning-formation appears to be general, occurring even with gold in the form of 'plate' and 'foil.' The faces of $\infty O \infty$ are also often characterised by a fine double striation parallel to the cubical edges, also the combination-edges of $\infty O \infty$ with O. The octohedral faces generally exhibit an equilateral striation, and depressions are sometimes observed on the cubical faces. The largest crystals found in this locality measured from 12 to 15 mm. Twins of the 'middle crystal' are characterised by an abnormal development parallel to the combination-edge between O and $\infty O \infty$, whilst twins of the form $\infty O 2$ are curtailed in the direction of a trigonal axis, and have the appearance of a very regular obtuse hexagonal pyramid. Gold occurs also at Vöröspatak acicular, and as 'wire,' and crystals which at first sight appeared to be prisms, were found in reality to be peculiar 'penetration-twin' cubes, with $\infty O 2$ in combination. The plate and foil formations are produced by twinning with an abnormal development parallel to a face of the octohedron (G. vom Rath, *Jahrb. f. Min.* 1876, 866).

In Idaho (U.S.), gold occurs in scheelite, intimately associated with small quantities of pyrites, chalcopyrite, and leucopyrite. In the Golden Queen Mine, Lake Co. Colorado, gold occurs in scheelite in small crystalline granules, filling what appears to have been a geode of scheelite crystals (B. Silliman, *Sill. Am. J.* xiii. 451).

E. Cohen (*Jahrb. f. Min.* 1873, 511) describes the occurrence of gold at Marabastad and Eersteling in South Africa. The gold is diffused through quartz-veins in metamorphic slate, whereas the quartz-veins in the granite appear to be free from it. In the secondary beds the gold is very widely diffused, but seldom occurs in large quantities in any one place. In Mindano, one of the Philippine Islands also, gold is rarely found in quartz-veins, but mostly in secondary strata, accompanied by platinum, lead (?), magnetic iron ore, specular iron ore and zircon (Minard, *Bull. Soc. Chim.* [3], ii. 403).

* Specimens of native gold have been analysed by A. H. Church (*Chem. News*, xxix. 199, 209; xxxi. 153): *a*. From Ladock in Cornwall; *b*. Ashantee gold; *c*. Gold from Wanlockhead in Scotland; *d*. From Sutherlandshire:

Au	Ag	Cu	Fe	SiO ² and loss	Sp. gr. at 16°
92.34	6.06	—	trace	1.60 = 100	—
90.055	9.940	trace	trace	— = 99.995	17.55
86.60	12.39	—	0.35	— = 99.34	16.50
79.22	20.78	—	—	— = 100	16.62

Analyses by R. Smith of gold from Queensland: (*a*) from Gilbert River, (*b*) from Paddy's County, have been published by R. Daintree (*Geol. Soc. Qu. J.* xxviii. 297):

Au	Ag	Cu	Pb	Bi	Fe
89.920	9.688	0.128	0.026	—	0.070 = 99.832
92.800	6.774	0.048	0.048	trace	0.014 = 99.684

The following samples obtained by melting gold direct from the mines have been analysed by S. Kern (*Chem. News*, xxxvii. 23).

	1	2	3	4	5
Gold	99.46	99.280	98.50	94.20	96.75
Silver	0.52	0.640	1.48	5.76	3.17
Lead	traces	0.005	traces	0.01	0.01
Copper	0.01	0.070	0.01	0.01	0.06
Bismuth	0.01	0.005	0.02	—	—
Iron	—	—	—	traces	none

No. 2 could be hammered in the cold, but fell to pieces when being forged in a heated condition. Specimen plates from these alloys tore easily, and were very brittle. Ingots prepared from them after they had been worked with nitric acid and refined by cupellation, showed no brittleness, forged well, and were free from lead, bismuth, and iron. These results confirm the experiments of Roberts as to the effect of lead, antimony, and bismuth, in imparting brittleness to gold. Gold containing notable traces of arsenic showed no brittleness; but .05 to .08 per cent. of arsenic was found to prevent gold being readily worked under the hammer.

Preparation.—On the separation of the gold (about 18 per cent.) contained in the silver chloride formed in the purification of argentiferous gold by means of chlorine gas (*1st Suppl.* 652), see *2nd Suppl.* 575.

On the separation of gold from silver, and the preparation of *fine gold*, as practised in the Assay Office at Frankfort-on-the-Maine, see H. Rössler (*Liebig's Annalen*, clxxx. 240; *Jahresb. f. Chem.* 1876, 285).

For recovering the small quantities of gold remaining in baths which have been used for electro-gilding, Böttger boils the liquid with a strongly alkaline solution of sodium stannite, whereby a velvet-black precipitate is formed containing gold and tin. This precipitate is washed and dissolved in the smallest possible quantity of aqua regia, and from this solution the gold is precipitated in the metallic state by acid sodium tartrate (*Deut. Chem. Ges. Ber.* 1876, 285).

W. Skej finds, contrary to the statement of Daintree (*2nd Suppl.* 574), that when a piece of gold is immersed in a solution of auric chloride, and an organic substance, such as wood or cork, is likewise introduced into the liquid, only a small quantity of gold is precipitated on the immersed metal (*Chem. News*, xxx. 162).

For the preparation of precipitated gold (for gilding on porcelain, &c.), P. Weisskopf (*Dingl. pol. J.* cxx. 65) recommends the following process. To 750 c.c. of a slightly acid solution of auric chloride are added 12 grams of commercial caustic soda dissolved in 200 c.c. water, 0.5 gram starch or milk sugar dissolved in 6 c.c. water, and then 6 c.c. alcohol of 80 per cent. and 6 c.c. aldehyde. The gold is thereby precipitated in the form of a black powder, becoming cinnamon-brown when washed, and finer and softer than that which is obtained when ferrous sulphate is used as the precipitant.

On the Electrodeposition of Gold, see ELECTROLYSIS (p. 711).

Detection and Estimation.—According to S. Kern (*Chem. News*, xxxii. 171), *potassium thiocyanate* is an extremely delicate test for gold. The gold is first separated from foreign metals, and then converted by addition of sodium chloride into NaAuCl⁴. On adding this solution to the thiocyanate, an orange-red turbidity is produced, and soon afterwards a precipitate of the same colour. On slightly warming the liquid, however, this precipitate disappears, and the liquid becomes quite colourless.

To detect gold in iron pyrites, H. Schwarz (*Dingl. pol. J.* cxxviii. 212) fuses 100 grams of the powdered mineral with 46.6 grams of iron filings under a layer of common salt. When cold the fused mass is broken up, and the resulting ferrous sulphide

dissolved in dilute sulphuric acid. The solution being filtered off, the residue containing the sulphide of gold is washed, dried, and roasted on a tile; some borax and 2 grams of pure lead are then added, and the mixture fluxed in a muffle furnace; a small button of lead is thus obtained, in which, after dissolving in aqua regia, the presence of gold can be easily recognised by the usual tests.

For the gold-assay of pyrites in Australia, a kilogram of the mineral is roasted dead, and stirred up with water to a stiff paste; a spoonful of mercury is then added, and the whole triturated in an iron mortar; and after a while another equal quantity of mercury is added. The mixture is then treated with hot water, sodium carbonate, and 5 or 6 spoonfuls of mercury, again triturated for some time, and the amalgam is levigated, collected, and distilled. This process yields from 80 to 90 per cent. of the quantity of gold that is obtainable by assaying in the dry way (G. Ullrich, *Dingl. pol. J.* cccvii. 517).

Gold-amalgams. The liquid amalgams obtained by squeezing alloys of gold and mercury through chamois-leather always contain (at the ordinary temperature) 0.126 per cent. of gold. At 0° the proportion is .110 per cent. gold; at 20°, .126 per cent.; and at 100°, .650 per cent.: these amalgams, therefore, behave like aqueous solutions. When glass capillary tubes are used instead of chamois-leather for the separation of the liquid amalgam, no relation can be discovered between the diameter of the tube and the percentage of gold.

The residues left after the action of nitric acid on solid or liquid gold amalgams are not homogeneous, which proves that there probably exist definite compounds of gold and mercury dissolved in excess of mercury, just as in aqueous solutions definite hydrates are mixed with excess of water (Kasantseff, *Bull. Soc. Chim.* [2], xxx. 20). A mixture of gold and mercury heated to a temperature a little above the boiling point of mercury till its weight became constant, left an amalgam containing 10.02 to 10.5 per cent. mercury, which is the composition of the compound Au^3Hg (Schnauss, *Arch. Pharm.* [3], vi. 411).

Bromides (J. Thomsen, *J. pr. Chem.* [2], xiii. 337). The *monobromide*, or *Aurous Bromide*, AuBr , may be prepared by heating hydro-auric bromide, AuHBr^4 , in a porcelain dish, in such a manner that the heat may affect the bottom and not the sides. Water and hydrogen bromide then escape, and a solid mass is left consisting chiefly of the tribromide; and this, when heated for some hours at about 115°, with occasional stirring, gives off bromine and a little hydrogen bromide, and finally leaves a yellowish-grey greasy mass having the composition AuBr . This bromide is a yellowish-grey, friable, greasy substance, permanent in the air, resolved at a temperature a little above 115° into bromine and gold, and converted by hydrobromic acid into gold and hydro-auric bromide: $3\text{AuBr} + \text{HBr} = \text{Au}^2 + \text{AuHBr}^4$.

The *tribromide*, or *Auric Bromide*, AuBr^3 , is best prepared by acting on hydro-auric bromide with ether in a flask in which the liquid may be cooled by exhausting the air. A drop exposed on a glass plate till the ether has evaporated shows under the microscope a dark, very fine layer of regular crystals. In preparing large quantities of the bromide, the concentrated solution must be evaporated at a very low temperature. Auric bromide forms a dark-brown powder which is anhydrous and not deliquescent. It is perfectly soluble in water and ether, and the solutions are almost black when concentrated. An aqueous solution of auric bromide is easily prepared by shaking auroso-auric bromide for some time with warm water. A solution of auric bromide is reduced by sulphurous acid, first to aurous bromide, and then to metallic gold, the strongly coloured solution being first completely decolorised without formation of a precipitate, and the colourless solution yielding with potassium iodide a precipitate of aurous iodide having a fine yellow colour. The second stage of the decomposition takes place after a few minutes only, gold being separated and the liquid again becoming coloured dark brown by reproduction of the tribromide.

Hydro-auric Bromide, $\text{AuHBr}^4 + 5\text{H}^2\text{O}$, is prepared by pouring bromine on pulverulent gold, and when the reaction is over, adding a quantity of hydrobromic acid (sp. gr. 1.38) equal in weight to the gold employed, and then as much bromine as is required to dissolve the gold completely. The solution left to itself at ordinary temperature soon deposits large, flat, needle-shaped crystals, having a dark cinnabar-red colour; they melt in their water of crystallisation at 27°, but may be preserved without alteration at ordinary temperatures, either in the air or over lime or sulphuric acid.

The *dibromide*, or *Auroso-auric Bromide*, Au^2Br^4 , or $\text{AuBr}.\text{AuBr}^3$, formed by the action of bromine on finely divided gold, is a nearly black, brittle, non-deliquescent mass, which decomposes at 115° into the monobromide and free bromine. It dissolves slowly in water, with absorption of heat, and formation of aurous and auric bromides. It is more quickly decomposed by acids, and partially by anhydrous ether, auric

bremide being dissolved, while the residue, probably consisting chiefly of aurous bromide, decomposes slowly, leaving metallic gold.

Chlorides (Thomsen, *loc. cit.*) The *monochloride*, or *Aurous Chloride*, AuCl , is formed by heating the trichloride to 185° , the completion of the change being indicated by the yellow colour of the product.

The *trichloride*, or *Auric Chloride*, AuCl_3 , is rapidly and easily prepared by decomposing auroso-auric chloride with a small quantity of water, the complete decomposition of the separated aurous chloride into auric chloride and gold being promoted by heating. On decanting the solution from the separated gold, evaporating it slowly, and finally drying the residue at 150° , the trichloride remains in the form of a dark brown crystalline mass. As dilute solutions of auric chloride are apt to decompose during evaporation, care must be taken to have the solution sufficiently concentrated; also to protect the sides of the basin from overheating. Auric chloride is also obtained as a bye-product, during the preparation of auroso-auric chloride, in the form of large, reddish brown, laminar crystals. It is very deliquescent in damp air, and very soluble in water, forming a dark red solution.

Hydrated Auric Chloride, $\text{AuCl}_3 + 2\text{H}_2\text{O}$, is formed when the solution of auric chloride, prepared as above, is concentrated by evaporation till a pellicle forms on the surface, and separates in large dark orange-coloured brittle crystals often grouped in tufts; they are very hygroscopic and deliquescent, but give off their water of crystallisation in dry air, even at ordinary temperatures.

The *dichloride*, AuCl_2 , or Au^2Cl^4 , or *Auroso-auric Chloride*, $\text{AuCl}.\text{AuCl}_3$, is easily obtained by the action of dry chlorine gas on spongy gold (best prepared by precipitation with sulphurous acid, boiling with nitric acid, washing, and drying at 170°). It is a dark-red, hard body, easily reduced to a fine powder, very hygroscopic, and decomposed by water into aurous and auric chlorides, which may be separated from each other by rapid filtration; the aurous chloride, however, is decomposed by washing into chloride and metallic gold. The dichloride is decomposed at 250° , into chlorine and auric chloride, part of which volatilises in the rapid current of gas.

By acting on auric chloride with *silver fluoride*, F. W. Clarke (*Sill. Am. J.* [3], xiii. 291) has obtained a brown mixture of auric oxide and silver chloride, the gold fluoride probably formed in the first instance being decomposed by the water present into auric oxide and hydrofluoric acid.

Auric Hydroxide, AuHO^2 , or $\text{Au}^2\text{O}^3.\text{H}^2\text{O}$, is best obtained, according to Thomsen, by heating a very dilute solution of auric chloride (about 1 mol. AuCl_3 to 800 mol. water) with 3 mol. sodium hydroxide—whereupon the liquid becomes first bright yellow and then dark brown—and adding a solution of sodium sulphate, which throws down the auric hydroxide in the form of a dark brown precipitate. It is insoluble in water, but dissolves easily in very dilute hydrobromic acid, less easily in very dilute hydrochloric acid (Thomsen).

Sulphides. According to A. v. Schrötter and E. Privoznik (*Dingl. pol. J.* cccxiii. 360), it is not possible, with the materials and processes commonly used, to obtain definite compounds of gold and sulphur by precipitating gold-solutions with hydrogen sulphide, whether these solutions are acid or neutral, cold or hot, dilute or concentrated, the precipitates formed being almost always mixtures of a sulphide of gold with free gold or free sulphur. Neither can a definite sulphide of gold be obtained by dissolving the precipitated sulphide in a solution of the sulphide of an alkali-metal, because, when the solution thus formed is decomposed by an acid, the resulting precipitate is always mixed with free sulphur, which cannot be removed without decomposing the gold sulphide.

According to W. Skey (*Chem. News*, xxx. 36), gold sulphide is dissolved at ordinary temperatures by potassium cyanide, and is slowly attacked by mercury, with formation of mercury sulphide.

GOLD-BRONZE. Tungsto-potassic Tungstate. See TUNGSTATES.

GOMBO. The gombo (*Hibiscus syriacus*), a malvaceous plant cultivated in Syria and Egypt for the sake of its fruit, is also used for the manufacture of paper. The fibre is prepared for the purpose by mechanical treatment in running water, without the aid of any chemical process; and the paper produced from it is said to be equal in beauty and tenacity to the best rag paper (E. Landrin, *Compt. rend.* lxxix. 1132).

GRAHAMITE. This carboniferous mineral, originally found in Ritchie County, Virginia (1st *Suppl.* 653), occurs also in Mexico. In the Cristo mine in the north-western part of the State of Vera Cruz, it forms a vein between shales and a

roof connected with the vein and separating the shale from the overlying conglomerate; it is semigranular, cleavable, and separated in columns. An analysis by W. Wallace gave 62.14 per cent. of volatile matter, viz. 61.32 per cent. illuminating gas, 0.46 sulphur, and 0.36 water, and 37.36 per cent. coke, containing 31.36 carbon, 0.37 sulphur, and 5.86 ash. Both grahamite and albertite (a black shining mineral resembling cannel coal, from Albert County, New Brunswick), (*Chem. News*, vi. 182), appear to have been formed from petroleum by loss of hydrogen and assumption of oxygen (J. P. Kimball, *Sill. Am. J.* [3], xii. 277).

GRAMMATITE. See HORNBLÉNDE.

GRANITE. The following nomenclature for the several varieties of granite rocks is proposed by H. Rosenbusch (*Zeitschr. geol. Ges.* xxviii. 369; *Jahrb. f. Min.* 1877, 544); *Muscovite granite*, composed of quartz, orthoclase, plagioclase, potash-mica; *Granitite*: quartz, orthoclase, plagioclase, magnesia-mica; *Amphibole or Hornblende granite*: quartz, orthoclase, plagioclase, hornblende; *Granite*: quartz, orthoclase, plagioclase, potash-mica and magnesia-mica; *Hornblendiferous granite* or *Amphibole granite containing magnesia-mica*: quartz, orthoclase, plagioclase, magnesia-mica or hornblende. *Porphyritic granites* not unfrequently contain pyroxene.

Rosenbusch also describes the transitions of structure from granite, especially hornblende-granite, to quartz-porphry, and gives the composition of two extreme varieties, from the Vosges, analysed by Unger:

(1). Typical variety of granite from the Andlauthal below Hohwald. (2). Porphyritic variety from the Kirneckthal near Fontaine Laquiente:

SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	K ² O	Ni ² O	H ² O
(1). 71.785	17.518	2.279	1.026	1.892	0.778	2.890	2.045	0.818 = 101.031
(2). 68.629	17.184	3.586	0.204	2.414	1.111	3.667	2.110	1.066 = 99.971

On the relation between Granitic and Porphyritic structure, and on the genesis of Granite, see also K. A. Losson (*Jahrb. f. Min.* 1875, 542).

Action of Carbonic Acid Water on Granite.—Pavesi a. Rotondi (*Deut. Chem. Ges. Ber.* vii. 818) have examined the action of water containing carbonic acid on granite, by means of comparative analyses of the nucleus and decomposed crust of old moraine-blocks from the neighbourhood of Como. The specimens were taken from a depth of 8 meters. (1). Unaltered nucleus. (2). Decomposed crust:

Soluble in HCl	CO ²	Fe ² O ³	Al ² O ³	CaO
(1). 25.60	2.43	1.99	66.91	3.21 = 100.14
(2). 96.54	—	3.45	—	= 99.99

GRAPES. From experiments on the ripening of grapes by C. St. Pierre and L. Magnier (*Compt. rend.* lxxxvi. 401), it appears that, as the grapes approach maturity, they evolve carbon dioxide both in the dark and in daylight, this evolution taking place indifferently in air or in any inert gas. When the observation is carried on for a sufficient length of time, the quantity of carbon dioxide evolved is always found to be greater than that of the oxygen consumed. Grapes absorb or give off moisture accordingly as they are kept in damp or in dry places. As maturity approaches, the acids diminish and the quantity of sugar increases. The mechanism of ripening appears to be the following: The acids and glucose are formed in the plant and carried by the sap to the grape, where the acids are destroyed while the sugar becomes concentrated. When the grapes become over-ripe, the sugar is also consumed.

Ripening of Grapes removed from the Vine.—Experiments have been made by Pollacci (*Gazz. chim. ital.* 1877, 517) to determine whether the process of ripening in sour grapes continues after they are separated from the vine. The mode of experimenting consisted in taking bunches of sour grapes, dividing them as equally as possible both as to state of maturity, size, &c. of the grapes, and the weight; then estimating the glucose and the acid in one portion of the grapes just after gathering, and the same in another portion after the lapse of ten or twelve days, the grapes having been kept in the shade. In every instance the amount of glucose had increased while that of the acid had diminished; this effect was still more marked when the grapes were exposed to sunshine. These results show that grapes gathered whilst unripe continue

to ripen; the action, however, ceases after a certain time, so that the grapes never become fully ripe.

GRAPHITE. According to G. vom Rath (*Jahrb. f. Min.* 1874, 521), graphite occurs, partly massive, partly as a coating from 0.2 to 0.5 mm. thick, on calc spar, in fissures of a Middle Devonian limestone in the district of Wildewiese, Upper Röhrlthal, Westphalia. A graphite containing 64.02 per cent. carbon, 21.13 ash, and 4.8 water occurs, together with iron pyrites and brown hematite, near Dobschau in Hungary. It is easily incinerated in contact with the air, in which respect it resembles anthracite; it might therefore be called *graphite-anthracite* (K. John, *Verh. geol. Reichsanstalt.* 1874, 245).

Several specimens of graphite from Rottenmann in Styria have been examined by C. v. Hauer and C. John (*ibid.* 1875, 159). They yielded 86.0, 27.4, and 26.5 per cent. ash relatively to 14.0, 72.6, and 73.5 per cent. carbon. In other samples (*ibid.* 161), the proximate constituents of the ash and the sulphur were determined, with the following results:

	Total ash	SiO ²	Fe ² O ³	Al ² O ³	CaO	S
1.	32.5	21.50	1.75	7.50	1.25	0.31
2.	60.9	27.50	5.00	25.50	2.50	0.24
3.	73.8	39.50	4.00	6.75	2.25	0.38
4.	53.2	33.50	11.50	5.75	2.50	trace
5.	24.9	17.00	3.50	3.25	trace	0.22
6.	60.0	39.50	7.24	11.75	1.50	0.38
7.	31.0	21.50	3.50	4.25	1.25	trace

Two specimens of graphite from the Stephanovsky Mine in Siberia have been analysed by S. Kern (*Chem. News*, xxxii. 229):

C	SiO ²	Fe ² O ³	Al ² O ³	CaO MgO	Volatile matters	S
36.06	37.72	4.02	17.80	1.20	3.20	trace = 100
33.20	43.20	3.05	15.42	1.06	4.03	0.04 = 100

At Mugrau in Bohemia, graphite occurs in long layers enclosed in gneiss, and in immediate contact with limestone. The formation is included in the district bounded on the east by Flaben and Krumau, and on the west by Winterberg, with a N.W.N. 'strike,' and an inclination of from 30°–80°. Most of the graphite from this locality is of good quality. The gneiss appears to be considerably decomposed in the immediate neighbourhood of the graphite vein, being in some cases richer in iron, and occasionally passing into graphite-gneiss, the rock being thoroughly impregnated with graphite, and of a black colour. At the contact-zone of the graphite and limestone, the graphite is accompanied by calcite, chloropal (i. 921), and a new mineral called *ihleite* (q.v.)

Magnetic properties of Graphite.—The particles of iron carbide which are left behind when iron is dissolved in acids are magnetisable and become permanently magnetic. Of four pieces of native graphite examined, the most ferruginous, probably from Baireuth, exhibited diamagnetism between the poles of a powerful electromagnet; the other three were magnetic (A. L. Holz, *Pogg. Ann.* cli. 69).

On the Specific Heat of Graphite, see HEAT.

On the behaviour of Graphite at high temperatures, see CARBON (p. 404).

G. Rose found that laminar graphite is more difficult to burn than diamond—a statement confirmed by R. Blindow (*Deut. Chem. Ges. Ber.* ix. 19)—but that compact graphite burns more readily than diamond. When these several forms of carbon were heated in the muffle of an assay furnace, it was found that in the course of thirteen minutes there were burned: of laminar graphite, 27.45 per cent.; of diamond, 97.76; of compact graphite, 100 (*Berl. Acad. Ber.* 1872, 516).

Analysis.—For the valuation of graphite, Wittstein (*Dingl. pol. J.* ccxvi. 45) recommends the process used by Berthier for determining the value of a substance as fuel. 1 gram of the finely pulverised graphite is mixed with 25 grams of pulverised litharge; the mixture is introduced into an unglazed porcelain crucible, and covered with 25 grams of litharge; and the whole is slowly heated between the coals. 34 parts of reduced lead are equivalent to 1 part of carbon.

To determine the other constituents, 1 gram of the finely pulverised graphite is heated to low redness, and the loss of weight estimated as water, then fused with a mixture of sodium and potassium carbonate and a small quantity of solid potassium hydroxide, whereby a complete disintegration of the insoluble constituents, such as clay and quartz, is obtained. The loss of carbon consequent on the partial destruction of the graphite in this treatment has no essential influence on the result of the analysis,

inasmuch as the other constituents, as silica, alumina, ferric oxide, &c., can be estimated by weighing, and the final loss reckoned as carbon and added to the carbon directly obtained.

On the estimation of Graphite in Cast Iron, see IRON.

GRAPHITIC ACID. See CARBON (p. 403).

GREENSTONE. Analyses by G. Dietrich of two greenstones from the Adalbert Mine in Przibram, at the depth of 1000 meters, have been published by K. Vrbá (*Jahrb. f. Min.* 1876, 437): (1). Fine-grained mixture of predominant plagioclase with augite, chlorite, quartz, and fragments of ore. Grains of calcite are regarded by Vrbá as original constituents of the rock. Sp. gr. = 2.793. (2). Compact; poor in augite, which is almost wholly converted into chlorite. Sp. gr. = 2.867:

	SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	K ² O	Na ² O	CO ²
1.	58.82	10.17	5.05	7.12	10.27	4.00	0.68	2.55	1.47 = 100.13
2.	51.50	14.14	3.65	6.96	8.08	7.64	1.19	1.97	4.96 = 100.09

The greenstone of the Terrace Mine near St. Stephen's, Cornwall, contains scorodite, pharmacosiderite and olivenite in its hollows and clefts. The scorodite is mostly found in stellate groups of very small crystals, less frequently in rhombic pyramids of a bluish-green colour; the pharmacosiderite in small cubes and octohedrons of a deep green colour, and the olivenite in tabular crystals associated with scorodite (J. H. Collins, *Jahrb. f. Min.* 1876, 868).

On Greenstone Trachyte, see TRACHYTE.

GROUND PEA. *Arachis hypogæa*. The ash of this plant, cultivated in Virginia, has been analysed by W. S. Brown (*Chem. News*, xxiv, 147). In 100 parts of the pure ash—excluding ferric oxide, regarded as an accidental impurity—there were found:

	Root	Stem	Leaves	Husk	Seed
K ² O	23.043	25.902	15.880	37.395	37.134
Na ² O	18.816	3.063	2.897	3.763	3.342
CaO	28.130	43.440	53.712	20.145	3.749
MgO	8.706	13.296	4.844	13.506	14.262
P ² O ⁵	3.684	1.590	4.679	5.062	29.102
SO ³	13.015	10.613	15.235	17.719	11.742
Cl	1.162	1.501	2.533	0.486	0.346
SiO ²	3.705	0.933	0.791	2.003	0.401
	100.261	100.338	100.571	100.109	100.078
Deduct O equivalent to Cl	0.261	0.378	0.571	0.109	0.078
	100.000	100.000	100.000	100.000	100.000

The total amounts of ash in the several parts of the dried plants were as follows:

Root	Stem	Leaves	Husk	Seed
11.830	13.288	7.747	2.586	1.818

Oil = 47.34 per cent. Nitrogen = 3.415 per cent.

GUAIAECOL, C⁷H⁸O². This compound is formed by the distillation of calcium vanillate (p. 291) with slaked lime:

GUAIAECUM. The *Resina Guajacai peruviana aromatica*, used in perfumery, has been examined by A. Kopp (*Arch. Pharm.* [3], ix, 192). By distillation with water, it yielded 4 per cent. of a yellow volatile oil, having an odour recalling those of peppermint and lemons, and yielding by repeated fractionation a portion which boiled between 167° and 168°, and had the composition C¹⁰H¹⁶. By fusion with potassium hydroxide, the resin yielded protocatechuic acid, together with other products; and by treatment with strong nitric acid, a nitro-compound, C²³H³¹N²O¹⁰. The resin, previously freed from the volatile oil, yielded, by dry distillation, a brown oil, from which, by fractionation, a deep blue oil was obtained, boiling at 285°–290°, and having the composition C²⁰H³⁰O. By distillation over sodium, this blue oil yielded a colourless oil having the composition C²⁰H³⁰.

The statement of Hadelich (ii. 947) that the blue coloration of guaiacum, under the influence of oxidising agents, is due to the guaiaconic acid contained in it, has been confirmed by E. Schär (*Vierteljahrsschrift pr. Pharm.* xxii, 68).

GUANAJUATITE. A selenide of bismuth, from Guanajuato in Mexico, first noticed by Castello in 1873 (*Jahrb. f. Min.* 1874, 225), who regarded it as a sulpho-selenide of bismuth. It was afterwards analysed by Fernandez (*Sill. Am. J.* [3], xiii. 319), who regarded it as essentially a selenide of bismuth, and by Rammelsberg, who found it to contain 16·7 per cent. selenium and 65·4 bismuth, and suggested the presence of zinc (*Dana's Mineralogy*, 3rd Appendix, p. 22). This mineral was more fully examined by Frenzel (*Jahrb. f. Min.* 1874, 679), who assigned to it the composition 24·13 per cent. selenium, 6·60 sulphur, and 67·38 bismuth, leading to the formula $2\text{Bi}^2\text{Se}^3.\text{Bi}^2\text{S}^3$. Finally it has been analysed by J. W. Mallet (*Sill. Am. J.* [3], xv. 294), who found, in a specimen not quite free from argillaceous gangue:

Se	S	Bi	Al^2O^3	Fe^2O^3	SiO^2	H^2O
31·64	0·61	59·92	2·53	trace	3·47	1·46 = 99·63.

The gangue is said to consist of galapectite (halloysite); and if the amount of this mineral present be calculated from that of the alumina, the composition of the specimen analysed will be:

Guanajuatite	Halloysite	Quartz	Moisture
92·17	6·72	0·56	0·18 = 99·63

and the guanajuatite in the pure state will be found to consist of:

Se	S	Bi
34·33	0·66	65·01 = 100

leading to the formula of a *sesquiselenide of bismuth*, Bi^2Se^3 , in which a small portion of the selenium is replaced by sulphur.

The physical characters of the mineral, as described by Frenzel, are as follows: Lustre metallic. Colour lead-grey. Streak highly lustrous. Mild. Hardness = $2\frac{1}{2}$ –3. Sp. gr. = 6·25 at 21°. Occurs in compact masses having a fine-grained, laminar to fibrous structure; also in prismatic crystals, probably orthorhombic, exhibiting the brachypinacoid $\infty \text{P} \infty$, but no end-faces; they are for the most part indistinctly developed, in consequence of deep vertical striation. Cleavage distinct parallel to $\infty \text{P} \infty$.

Before the blow-pipe the mineral fuses, gives off a strong odour of selenium, and colours the flame blue. Fused with potassium iodide, it yields a fine red deposit of bismuth sulphide.

GUANAMIDE, $\text{C}^4\text{N}^3\text{H}^3\text{O}^2 = \text{H}^3\text{C}-\text{C} \begin{smallmatrix} \text{N}-\text{CO} \\ \text{NH}-\text{CO} \end{smallmatrix} \text{NH}$ (Nencki, *Deut. Chem. Ges. Ber.* ix. 232). A compound formed by heating 1 part of methyl-guanamine to 150° with 2 parts of strong sulphuric acid:

On mixing the cooled liquid with absolute alcohol, a bulky precipitate is thrown down; and on dissolving this precipitate in water, separating the sulphuric acid from the solution, evaporating the liquid to dryness, and treating the residue with concentrated hydrochloric acid, guanamide hydrochloride, $\text{C}^4\text{N}^3\text{H}^3\text{O}^2.\text{HCl}$, is obtained in needles.

Guanamide separated from this salt is very soluble in water, acids, and alkalis, slightly soluble in alcohol, and crystallises from a hot alcoholic solution in small rhombic needles. By mixing the concentrated aqueous solution of the hydrochloride with an alcoholic solution of platonic chloride, and leaving the liquid to evaporate over sulphuric acid, the *platinochloride*, $(\text{C}^4\text{N}^3\text{H}^3\text{O}^2.\text{HCl})^2\text{PtCl}_4$, is obtained in yellow druses of concentric needles.

Guanamide treated with 5 or 6 parts of nitric acid, sp. gr. 1·3, is oxidised, with violent reaction, to cyanuric acid:

Dichloroguanamidine, $\text{C}^4\text{N}^3\text{H}^3\text{Cl}^2\text{O}^3$, is formed by the action of chlorine on a concentrated aqueous solution of guanamide:

and separates in dazzling white anhydrous crystals. It is insoluble in cold, slightly soluble in hot water, soluble also in soda-ley, and is precipitated therefrom in great part by hydrochloric acid. By prolonged boiling with water, and more quickly by heating with alkalis, or by the action of sodium-amalgam in aqueous solution, it is resolved into cyanuric acid and a body smelling like chloroform, probably methylene chloride. Dichloroguanamidine is completely decomposed at 140°.

Tribromoguanamidine, $\text{C}^4\text{N}^3\text{H}^3\text{Br}^3\text{O}^3$, is produced by the action of bromine on a warm aqueous solution of guanamide. It forms microscopic crystals, insoluble

in water, alcohol, and ether. By boiling with water it is quickly resolved into cyanuric acid and bromoform :

GUANAMINES, $\text{C}^{n+2}\text{H}^{2n+3}\text{N}^3$ [$n = 1, 2, 3$, &c.] (M. Nencki, *Deut. Chem. Ges. Ber.* vii. 775, 1584; ix. 228, 232, 244). A series of bases produced by the action of heat on the guanidine-salts of the fatty acids. Their formation is represented by the general equation,

and their constitution may be represented by the formula

The following have been obtained :

Guanamine, $\text{C}^3\text{H}^5\text{N}^5 = \text{H}.\text{C}^3\text{H}^4\text{N}^5$.

Methyl-guanamine, $\text{C}^4\text{H}^7\text{N}^5 = \text{CH}^3.\text{C}^3\text{H}^4\text{N}^5$.

Propyl- and isopropyl-guanamine, $\text{C}^6\text{H}^{11}\text{N}^5 = \text{C}^3\text{H}^7.\text{C}^3\text{H}^4\text{N}^5$.

Butyl-guanamine, $\text{C}^7\text{H}^{13}\text{N}^5 = \text{C}^4\text{H}^8.\text{C}^3\text{H}^4\text{N}^5$.

Pentyl-guanamine, $\text{C}^8\text{H}^{15}\text{N}^5 = \text{C}^5\text{H}^{11}.\text{C}^3\text{H}^4\text{N}^5$.

Nencki originally represented the guanamines by the general formula—

$n = 0$ giving $\text{C}^3\text{H}^5\text{N}^5$

$n = 1$ „ $\text{C}^4\text{H}^7\text{N}^5 = \text{CH}^3.\text{C}^3\text{H}^4\text{N}^5$ (methylene-guanamine).

$n = 3$ „ $\text{C}^6\text{H}^{11}\text{N}^5 = \text{C}^3\text{H}^7.\text{C}^3\text{H}^4\text{N}^5$ (propylene-guanamine).
&c. &c.

The second term, $\text{C}^4\text{H}^7\text{N}^5$, which was the earliest obtained, was at first called *guanamine*; afterwards, when its lower homologue, $\text{C}^3\text{H}^5\text{N}^5$, was discovered, this latter was named *formoguanamine*, and the second term *acetoguanamine*, to indicate their production from formate and acetate of guanidine respectively. Subsequently the names *methylene-guanamine*, *propylene-guanamine*, &c., were adopted to indicate the formation of the several terms of the series from the first, $\text{C}^3\text{H}^5\text{N}^5$, by addition of CH^2 , C^2H^6 , C^3H^8 , &c.

The representation of the guanamines by the general formula $\text{C}^n\text{H}^{2n+1}.\text{C}^3\text{H}^4\text{N}^5$ ($n = 0, 1, 2, 3$, &c.), or $\text{C}^{n-1}\text{H}^{2n-1}.\text{C}^3\text{H}^4\text{N}^5$ ($n = 1, 2, 3$, &c.) above given, was proposed by Weith (*Ber.* ix. 458) and afterwards adopted by Nencki (*ibid.* 1013); and in accordance with this mode of representation, it is better to designate the first term of the series $\text{C}^3\text{H}^5\text{N}^5$ as *guanamine*, and the higher terms, as *methyl*-, *propyl*-, *guanamine*, &c., accordingly as they are derived from the first by substitution of CH^3 , C^3H^7 , C^4H^8 , &c., for an atom of hydrogen.

Guanamine, $\text{C}^3\text{H}^5\text{N}^5 = \text{H}.\text{C}^3\text{H}^4\text{N}^5 = \text{HC} \begin{array}{c} \text{N} - \text{C}(\text{NH}) \\ \text{NH} - \text{C}(\text{NH}) \end{array} \text{NH}$. *Formoguanamine*.

This base is produced by the action of heat on guanidine formate :

The carbon monoxide and water result from the decomposition of formic acid produced in the first instance (see the general equation above given). The heat must be raised to 200° , and kept at that point as long as crystals continue to separate; the liquid is then left to cool, and mixed with an equal volume of cold water; the undissolved base taken up by hot water, and converted by addition of a concentrated solution of oxalic acid into the oxalate; and this salt is decomposed by potash, which throws down the base in white rhombic needles,

Guanamine is a weak base, easily soluble in hot water, slightly soluble in alcohol, separating from water in anhydrous crystals, and melting at 350° . Its salts crystallise readily.

Methyl-guanamine, $\text{C}^4\text{H}^7\text{N}^5 = \text{CH}^3 - \text{C}^3\text{H}^4\text{N}^5$. *Acetoguanamine*, *Methylene-guanamine* (originally called *guanamine* by Nencki). To prepare this base, dry guanidine acetate is submitted to fractional distillation on a sand-bath, whereupon it melts to a pale yellow liquid. As the temperature rises, a little water and acetic acid distil over, ammonia in abundance is evolved, and the boiling liquid ultimately attains a temperature of $228^\circ - 230^\circ$, at which it remains constant. After being kept at this temperature for a quarter of an hour, it is allowed to cool, and the melted mass is exhausted with a little hot water. A small amorphous residue is then left, while the greater part of the mass dissolves in the water, forming a solution which on cooling

solidifies to a jelly consisting of methyl-guanamine acetate; and this, when freed from adhering liquid by filtration and pressure, and decomposed by dilute potash or soda, yields the free base. The reaction is represented by the equation—

The water, which is likewise given off, results from conversion of the ammonium acetate into acetamide.

Methyl-guanamine dissolves easily in alcohol, sparingly in cold, freely in hot water, and crystallises therefrom, when quickly cooled, in small nacreous laminae; but by slower cooling it may be obtained in large laminated crystals often several centimeters long, or in needles belonging to the orthorhombic system. The crystals contain water, which they give off when dried in the air. Methyl-guanamine is destitute of taste and smell; it is not poisonous, and passes through the animal organism almost without alteration. It melts at 265° , and sublimes partly without decomposition.

Methyl-guanamine is a weak base, forming crystallisable compounds with acids and with salts. The *hydrochloride*, $\text{C}^4\text{H}^7\text{N}^3.\text{HCl} + 2\text{H}^2\text{O}$, crystallises in monoclinic prisms and plates easily soluble in hot water. The *platinochloride*, $(\text{C}^4\text{H}^7\text{N}^3)^2.2\text{HCl.PtCl}^4$, is a yellow crystalline precipitate, easily soluble in water, sparingly in alcohol. The *nitrate*, $\text{C}^4\text{H}^7\text{N}^3.\text{NO}^3\text{H}$, crystallises in thick, anhydrous, monoclinic prisms, easily soluble in water. The dry salt decomposes when heated, with a slight explosion. The *argentonitrate*, $(\text{C}^4\text{H}^7\text{N}^3)^2.\text{NO}^3\text{Ag}$, is formed by mixing a warm aqueous solution of the base with silver nitrate, and separates as an amorphous precipitate, the greater part of which redissolves when heated, and separates on cooling in rhombic plates. The *sulphate*, $(\text{C}^4\text{H}^7\text{N}^3)^2.\text{SO}^4\text{H}^2 + 2\text{H}^2\text{O}$, crystallises from a warm acid solution in rhombic laminae, very soluble in water. The *acetate*, $\text{C}^4\text{H}^7\text{N}^3.\text{C}^2\text{H}^3\text{O}^2$, prepared by heating acetate of guanidine and recrystallising, gives off acetic acid when dried at 100° .

Methyl-guanamine is readily oxidised by dilute *nitric acid*. With strong nitric acid it forms a yellow product, which is precipitated from a dilute solution by ammonia in amorphous flocks. By boiling with strong aqueous *potash*, methyl-guanamine is decomposed, with evolution of ammonia and formation of guanide, $\text{C}^4\text{H}^6\text{N}^4\text{O} = \text{C}^4\text{H}^7\text{N}^3 + \text{H}^2\text{O} - \text{NH}^3$. Heated with strong sulphuric acid, it is converted into guanamide, $\text{C}^4\text{H}^5\text{N}^3\text{O} = \text{C}^4\text{H}^7\text{N}^3 + 2\text{H}^2\text{O} - 2\text{NH}^3$ (p. 900).

Propyl-guanamine, $\text{C}^6\text{H}^{11}\text{N}^3 = \text{CH}^3.\text{CH}^2.\text{CH}^2.\text{C}^3\text{H}^4\text{N}^3$ (Nencki, *Deut. Chem. Ges. Ber.* ix. 228). This compound is obtained, like the preceding, by heating guanidine butyrate to 230° for about an hour, exhausting the slightly yellow fused mass with hot water, and treating the filtrate with strong soda-ley, which throws down the base as a white crystalline precipitate. For purification it is converted into the hydrochloride (whereupon a highly nitrogenised body separates in white flocks); this salt, after recrystallisation from alcohol, is decomposed by soda-ley, and the precipitated base is several times crystallised from hot water.

Propyl-guanamine crystallises by slow cooling or evaporation in four-sided rectangular plates, but when thrown down quickly from a hot solution, it separates in spherical crystalline groups or in hemihedral forms (sphenoids) with curved faces. It dissolves in 53.7 parts of water at 14.5° , and in 7 parts at 100° . It is precipitated from its aqueous solution by strong caustic soda, not by ammonia either from acid or from neutral solutions. It is easily soluble in alcohol. Heated in capillary tubes, it begins to sublime at 210° , and at 230° volatilises for the most part without melting, and leaves a slight yellow residue. It dissolves in acids, forming well-crystallised salts, easily soluble in water and alcohol. The *hydrochloride*, $\text{C}^6\text{H}^{11}\text{N}^3.\text{HCl}$, forms brilliant rhombic prisms and laminae, and contains $1\frac{1}{2}$ molecules of water of crystallisation which it loses in air. An *argentonitrate*, $\text{C}^6\text{H}^{11}\text{N}^3.\text{NO}^3\text{Ag}$, which forms fine crystals, may be obtained by heating a concentrated aqueous solution with silver nitrate.

Isopropyl-guanamine, $\text{C}^6\text{H}^{11}\text{N}^3 = \text{CH}(\text{CH}^3)^2.\text{C}^3\text{H}^4\text{N}^3$, prepared, like the preceding, from isobutyrate of guanidine, crystallises from aqueous solution in pointed rhombohedrons resembling calcite, or in prisms with the two rhombohedrons aggregated in rows, as in quartz. It dissolves in 48.6 parts of boiling water, and in 176.7 parts of water at 18° ; in alcohol somewhat less easily than normal propyl-guanamine. It is distinguished from the normal base by being thrown down by ammonia from its solutions in strong mineral acids. *Nitrate of isopropyl-guanamine*, $\text{C}^6\text{H}^{11}\text{N}^3.\text{NO}^3\text{H}$, crystallises in small tufts of concentric needles. The *argentonitrate*, $\text{C}^6\text{H}^{11}\text{N}^3.\text{NO}^3\text{Ag}$, is more soluble in water than that of the normal base, and separates, on evaporation over sulphuric acid, in prismatic crystals.

Butyl-guanamine, $\text{C}^8\text{H}^{13}\text{N}^3 = \text{C}^4\text{H}^9.\text{C}^3\text{H}^4\text{N}^3$ (Bandrowski, *Deut. Chem. Ges. Ber.* ix. 240). Prepared by heating valerate (isopropylacetate) of guanidine.* Crystal-

* At the same time an amorphous body is formed, quite insoluble in water, soluble in soda-ley and in the stronger mineral acids, and precipitated by organic acids.

lises in shining white rhombic needles, which sublime at 100° , melt at 172° – 173° , and resolidify at 127° . It dissolves somewhat sparingly in cold water, more easily in hot water, very easily in alcohol and ether. The crystals are anhydrous.

Butyl-guanamine is a very weak base. The *acetate*, which crystallises in tufts of slender needles, decomposes even on exposure to the air. The *hydrochloride*, $C^4H^{13}N^3.HCl$, separates from highly concentrated solutions in well-defined shining needles, very soluble in water. The *sulphate*, $C^4H^{13}N^3.SO^2H^2$, crystallises in small shining laminae. The *argentonitrate*, $C^4H^{13}N^3.NO^3Ag$, obtained by warming and filtering an aqueous solution of its components, crystallises in delicate, glistening, sparingly soluble needles, which turn brown when exposed to light.

The base treated with strong sulphuric acid was converted into a butyl-guanamide, $C^4H^{11}N^3O^2 = C^4H^9C \begin{smallmatrix} N-CO \\ NH-CO \end{smallmatrix} NH$, oxidisable by nitric acid to cyanuric acid (probably together with *butyl-isonitril*).

Pentyl-guanamine, $C^5H^{15}N^3 = C^5H^{11}.C^4H^4N^3$ (*Amylene-guanamine*), is prepared from the guanidine salt of normal caproic acid, and may be obtained pure by precipitation from the hydrochloride. It forms shining, microscopic, quadratic pyramids, melts at 177° – 178° , and resolidifies at about 144° . The crystals are anhydrous, very slightly soluble in water, easily in alcohol. The hydrochloride crystallises in flat well-defined needles.

GUANIDE (bi-), $C^2H^7N^5$. See THIODICTYANDIAMINES.

GUANIDINE, $CH^3N^3 = HN=C \begin{smallmatrix} NH^2 \\ NH^2 \end{smallmatrix}$. *Formation and Preparation*.—1. By the action of heat on ammonium thiocyanate. When this salt is heated in an oil-bath to about 220° , ammonia and carbon disulphide are given off, and crystals of ammonium trithiocarbonate (Zeise's salt) sublime in consequence of a secondary decomposition.

The main reaction consists, first in the conversion of the ammonium thiocyanate into the isomeric compound, thiocarbamide (sulphurea), and secondly in the resolution of this compound into guanidine, ammonia, and carbon disulphide, according to the following equation :

The residue in the flask consists chiefly of guanidine thiocyanate, contaminated only with small quantities of ammonium thiocyanate and thiocarbamide; and from this salt the other salts of guanidine may be obtained by double decomposition (Delitsch, *J. pr. Chem.* [2], viii. 240; ix. 1).

According to Volhard (*J. pr. Chem.* [2], ix. 10), the conversion of ammonium thiocyanate into guanidine does not require a temperature higher than 170° , and at this comparatively low temperature the reaction appears to take place without formation of secondary products; it is necessary, however, to continue the heat for 100–120 hours; at about 180° – 190° , the same result is obtained in 20 hours. The residue in both cases consists mainly of guanidine thiocyanate, the yield being very satisfactory, and no gaseous product (such as CS^2 , &c.) being given off. Volhard regards the reaction as consisting, first, in the transformation of the ammonium thiocyanate into thiocarbamide, and secondly in the conversion of this compound, by loss of H^2S , into cyanamide, which, at the moment of its formation, unites with ammonium thiocyanate to form thiocyanate of guanidine: $CN^2H^2 + CNS.NH^4 = CN^2H^2.HCNS$. The formation of Zeise's salt is due to the combination of H^2S separated from the thiocarbamide with another portion of the ammonium thiocyanate.

Guanidine Thiocyanate purified by crystallisation from water or alcohol forms large flexible laminae having a peculiar fatty lustre; easily soluble in water and in alcohol; melting at 118° ; decomposing above 150° with evolution of ammonia, and leaving a residue of melam (Delitsch).

Guanidine Carbonate is obtained by mixing a solution of the thiocyanate with potassium carbonate (58 parts K^2CO^3 to 100 parts of the thiocyanate), evaporating down, and dissolving out the potassium thiocyanate with alcohol. Guanidine carbonate then remains, and may be freed from adhering potassium salt by recrystallisation from water (Volhard). It crystallises in trapez-hemihedral forms of the tetragonal system, and possesses the power of circular polarisation. The *sulphate* crystallises in the regular, the *lactate* in the orthorhombic system (Bodewig).

Guanidine carbonate heated to 100° with *benzoic anhydride* yields dibenzoyl-carbamide or carbonyl-dibenzamide, $CON^2H^2(C^6H^5O)^2$, identical with that which E. Schmidt obtained from benzamide and liquid phosgene (*2nd Suppl.* 263). It crystallises from alcohol in splendid needles, melts at 210° , and is resolved by prolonged

boiling with hydrochloric acid into benzoic acid and ammonia (D. McCreath, *Deut. Chem. Ges. Ber.* vii. 1739).

Guanidine carbonate fused with *urea* is converted into dicyano-diamidine, $C^2H^2N^4O$ (p. 600).

When guanidine hydrochloride is heated with *sarcosine*, or when its alcoholic solution is boiled with sarcosine, the two bodies unite directly, forming a compound which dissolves easily in alcohol, and separates therefrom in fine tabular crystals. It is, however, somewhat unstable, being easily resolved into its components under the influence of platinic chloride, mercuric oxide, &c. (E. Baumann, *Deut. Chem. Ges. Ber.* vii. 1151).

A periodide of guanidine, $CH^2N^3.HI.I^2$, crystallising in prisms having the colour of iodine, is obtained by the action of iodine dissolved in hydriodic acid on guanidine carbonate. The corresponding bromine-compound, $CH^2N^3.HBr.Br^2$, appears to be produced by the action of bromine (3 mols.) on guanidine carbonate (1 mol.) It forms large red prisms which readily lose bromine (Kamenski, *ibid.* xi. 619).

SUBSTITUTED GUANIDINES.

Bromoguanidine, CH^4BrN^3 , is obtained by acting on guanidine carbonate (1 mol.) with bromine (1 mol.) and treating the product with water. It crystallises in small yellow needles, very slightly soluble in water and in ether, easily soluble in alcohol. Heated in a capillary tube it detonates at a few degrees above 100° (Kamenski, *loc. cit.*)

Chloroguanidine, CH^4ClN^3 , prepared in like manner, crystallises in the same form as the bromine-compound, but is lighter in colour and more stable than the latter, not detonating till it is heated to 147° .

Nitrosoguanidine, $CH^4(NO)N^3$, is obtained by dissolving nitrate of guanidine in excess of nitrous and fuming nitric acid. After the solution has stood for twenty-four hours, it is poured into an excess of cold water, whereupon the nitrosoguanidine is precipitated in colourless, flexible, needle-shaped crystals, soluble in hot water and in boiling alcohol, insoluble in ether and chloroform. Submitted to a gradually increasing temperature, nitrosoguanidine loses ammonia at 220° , the crystals becoming opaque without change of form. At higher temperatures cyanogen-compounds are given off, and a stable yellow substance remains, which is probably hydromellone (Jousselyn, *Compt. rend.* lxxxv. 548).

Methyl-guanidine, $CH^4(CH^3)N^3$, is formed by the action of cyanamide on methylamine hydrochloride, or of methyl-cyanamide on ammonium chloride (*2nd Suppl.* 582).

Ethyl-guanidine, $CH^4(C^2H^5)N^3$. The hydriodide of this base, obtained by the action of iodine on an alcoholic solution of thiocarbamide, crystallises from water in small needles which melt and decompose at 149° . The *sulphate* contains $1\frac{1}{2}$ mol. water, is easily soluble in water, sparingly in alcohol; melts and decomposes at 169° (A. Letnii, *Deut. Chem. Ges. Ber.* viii. 767).

Phenyl-, Toly-, and Xylyl-guanidines.

Diphenyl-guanidine, $C^{12}H^{13}N^3 = CH^3(C^6H^5)^2N^3$. *Melaniline*.

Formation.—1. By the action of cyanogen chloride or bromide on anhydrous aniline. This is the process by which melaniline was first prepared by Hofmann (iv. 461). According to Weith a. Ebert (*Deut. Chem. Ges. Ber.* viii. 912), diphenyl-guanidine (m. p. 147°) is produced by passing gaseous cyanogen chloride through cooled aniline; but if the aniline be heated to its boiling point, the product consists of tetraphenylmelamine, $C^8H^8(C^6H^5)^4N^6$ (m. p. 217°).

2. By the action of lead oxide on a solution of diphenyl-thiocarbamide in alcoholic ammonia (Hofmann, *Ber.* ii. 452):

3. By boiling an alcoholic solution of phenyl-thiocarbamide with mercuri-phenyl-ammonium chloride (precipitated on mixing the boiling solutions of aniline and mercuric chloride) as long as mercuric sulphide continues to be formed, and evaporating the alcoholic filtrate (C. Forster, *Ber.* vii. 294):

4. Together with phenyl-carbamide, by the action of aniline on mercuric fulminate,

Dry mercuric fulminate is violently attacked by aniline, the mass being thrown out of the vessel and sometimes taking fire; but the action may be moderated by working with 100 grams of the fulminate, not dried but freed from the greater part of its moisture by pressure, and 100 grams of aniline (1 mol. fulminate to 3 mols. aniline) diluted with an equal volume of alcohol. The mixture becomes hot in about half-an-hour, and must then be cooled by placing the vessel in cold water, and frequently stirred. The product, consisting of mercury and a mass very much like amorphous phosphorus, is repeatedly exhausted with warm water containing hydrochloric acid; and the filtered solution, which contains phenyl-carbamide and a mercury-compound of diphenyl-guanidine, is treated with ammonia to decompose the latter and precipitate the mercury; then acidulated with hydrochloric acid, and evaporated to the crystallising point. Phenyl-carbamide then separates in needles (m. p. 149°), and the mother-liquors contain diphenyl-guanidine (m. p. 146°) (A. Steiner, *Ber.* vii. 1244; viii. 518).

5. By combination of ammonia with carbodiphenylimide (Weith, *Ber.* vii. 10):

Constitution and Reactions.—Diphenyl-guanidine is susceptible of three modifications, represented by the following formulæ:

Only one of these is however actually known. The diphenyl-guanidine (melaniline) which Hofmann obtained by the action of cyanogen chloride on aniline was found by him to melt at about 130° , whereas that which he afterwards obtained by the action of lead oxide on a solution of diphenyl-thiocarbamide in alcoholic ammonia melted at 147° . These two bases were, therefore, regarded by Hofmann as isomeric, the latter being designated as α -, the former as β -diphenyl-guanidine.

It has, however, been shown by Weith & Schroeder (*Ber.* vii. 937), that the diphenyl-guanidines obtained by the two processes above mentioned are identical in every respect, both melting at 147° , and exhibiting equal degrees of solubility in water and in alcohol; moreover they both react in the same manner with carbon disulphide, yielding thiocyanic acid and diphenyl-thiocarbamide (thiocarbamilide):

Two bye-products are also formed in this reaction, viz. a small quantity of phenyl-thiocarbimide, $CS=N-C^6H_5$, and a sulphuretted compound, not further examined, which crystallises in colourless needles melting at 152° – 153° .

These results are corroborated by Hofmann in a more recent communication (*Ber.* vii. 947), in which he states that the so-called β -diphenyl-guanidine, or melaniline, obtained by the action of cyanogen chloride on aniline, has the same melting point as that prepared from diphenyl-thiocarbamide, viz. 147° . He still, however, thinks it not impossible that, under certain conditions, an isomeric diphenyl-guanidine may be produced from cyanogen chloride and aniline: since a small quantity of melaniline prepared in that way some years ago was found to retain the lower melting point (131°) which it originally exhibited, even after recrystallisation from alcohol, and after conversion into platinum salt and reconversion into the base.

Of the three possible formulæ for diphenyl-guanidine above given, the third is the least probable as a representative of the base actually known, since none of the decomposition-products of this body containing more than one atom of nitrogen appear to contain two phenyl-groups attached to the same nitrogen-atom. Further evidence against this formula is afforded by the fact that no diphenylamine is produced by heating diphenyl-guanidine prepared in either way, with hydrochloric acid. The reaction of diphenyl-guanidine with carbon disulphide affords an argument in favour of the first, or symmetrical formula of the base, as it takes place in the manner represented by the equation:

If diphenyl-guanidine had the constitution represented by the second formula, the reaction with carbon disulphide should yield phenyl-thiocarbimide and monophenyl-thiocarbamide: thus

As, however, a small quantity of phenyl-thiocarbimide was actually found among the

products, it is possible that the symmetrical diphenyl-guanidine may have been accompanied by a small amount of the second modification.

Diphenyl-guanidine heated for several hours to 170°-180° gives off ammonia and aniline, and leaves a resinous cake consisting of tetraphenyl-melamine (Hofmann, *Ber.* vii. 1736):

Diphenyl-guanidine heated with *acetic anhydride* to 100° yields monophenyl-acetyl-carbamide, $\text{CH}^3(\text{C}^6\text{H}^5)(\text{C}^2\text{H}^3\text{O})\text{N}^2\text{O}$, in needles melting at 73°. If the heat be raised to 150°, carbon dioxide is evolved and acetyl-diphenyl-carbamide, $\text{CH}(\text{C}^6\text{H}^5)_2(\text{C}^2\text{H}^3\text{O})\text{N}^2\text{O}$, is obtained, crystallising in needles which melt at 115° (D. McCreath, *Ber.* viii. 1181).

Dinitro-diphenyl-guanidine, $\text{C}^{13}\text{H}^{11}(\text{NO}^2)_2\text{N}^3$, is produced by desulphuration of dinitro-thiocarbamilide with lead oxide in presence of ammonia; it may be extracted from the resinous product by hydrochloric acid. It is nearly insoluble in water, but dissolves in alcohol and in ether, and crystallises from alcohol in small yellow shining laminæ melting at 190° (Brückner, *Ber.* vii. 1234).

Ethyl-diphenyl-guanidine, $\text{C}^6\text{H}^5\text{N}=\text{C} \begin{smallmatrix} \text{NH.C}^2\text{H}^5 \\ \text{NH.C}^6\text{H}^5 \end{smallmatrix}$, is formed (often together with α -triphenyl-guanidine), by addition of aniline to carbethyl-phenylimide, $\text{C} \begin{smallmatrix} \text{N.C}^2\text{H}^5 \\ \text{N.C}^6\text{H}^5 \end{smallmatrix}$ (obtained by desulphurising a solution of ethyl-phenyl-thiocarbamide in boiling benzene with pulverised lead oxide). It forms a hydrochloride crystallising in needles, and a yellow platinochloride. It is decomposed by potassium hydroxide into carbon dioxide, aniline, and ethylamine (Weith, *Ber.* viii. 1530).

Dibenzoyl-diphenyl-guanidine, $\text{CH}(\text{C}^6\text{H}^5)_2(\text{C}^2\text{H}^3\text{O})_2\text{N}^3$, obtained by heating benzoic anhydride (1 mol.) and diphenyl-guanidine (1 mol.) to 100°, forms monoclinic crystals melting at 102° (McCreath, *ibid.* 383).

Triphenyl-guanidine, $\text{C}^{13}\text{H}^{17}\text{N}^3 = \text{CH}^3(\text{C}^6\text{H}^5)_3\text{N}^3$. This compound admits of the three following modifications:

but only the first two are at present known.

The α -modification is produced by the following reactions:

1. By the action of mercuri-phenyl-ammonium chloride on diphenyl-thiocarbamide (C. Forster, *Ber.* vii. 294):

2. From phenyl-isocyanochloride and aniline (Sell a. Zierold, *Ber.* vii. 1228):

3. From aniline and carbodiphenylimide, by direct combination:

The hydrochloride of carbodiphenylimide may be used in the reaction; also the polymeric modification (m. p. 168°-170°), (Weith, *Ber.* vii. 10).

4. By the action of aniline on carbethyl-phenylimide:

The chief product of this reaction, however, is ethyl-diphenyl-guanidine, as already explained (*supra*).

5. Together with phenyl-thiocarbimide, by heating carbodiphenylimide with diphenyl-thiocarbamide:

The action takes place at 100°, but becomes more energetic at 150°, and is still more quickly completed when a solution of carbodiphenylimide (1 mol.) in benzene is mixed with diphenyl-thiocarbamide (1 mol.) and hydrochloric acid (1 mol.) or hydriodic acid dissolved in alcohol, and the mixture is heated for a few minutes on the water-bath (p. 402), (Weith, *Ber.* ix. 810).

6. Small quantities of α -triphenyl-guanidine and benzonitril are produced, together

with phenyl isocyanate, by heating diphenyl-carbamide for four or five hours with phosphorus trichloride. The action appears to consist in the abstraction of water from the diphenyl-carbamide, and production of carbodiphenylimide, which latter acts upon another portion of the diphenyl-carbamide, producing phenyl isocyanate and α -triphenyl-guanidine (Weith, *loc. cit.*):

α -Triphenyl-guanidine crystallises from hot water, on cooling, in white needles melting at 143° (1st *Suppl.* 656). It begins to boil below 200° , and is decomposed by distillation, aniline passing over at first, mixed afterwards with α -triphenyl-guanidine, whilst the last portions of the distillate consist of almost pure carbodiphenylimide (m. p. 330° – 331° corr.) The decomposition of α -triphenyl-guanidine is therefore represented by the equation

The carbodiphenylimide and aniline, however, recombine as the temperature of the distillate becomes lower, reproducing the triphenyl-guanidine, so that the process is one of dissociation, like that which takes place in sal-ammoniac when heated (Weith, *Ber.* vii. 1303).

The *hydrochloride* of α -triphenyl-guanidine melts at 241° – 242° , and sublimes at a lower temperature in white slender needles (Weith, *Ber.* vii. 810). The hydrochloride of the triphenyl-guanidine which Sell a. Zierold obtained (p. 906) by the action of phenyl-isocyanochloride on aniline, is described as crystallising from aqueous alcohol in small white laminae melting at 207° . This would seem to show that the base of this salt is another modification of triphenyl-guanidine, and so in fact it is regarded by Sell a. Zierold; but its constitution, as indicated by its mode of formation, is clearly that of α -triphenyl-guanidine: hence there must either be an error in the determination of the melting point of the hydrochloride, or else the base, at the moment of its formation, must have undergone an atomic transposition.

β -Triphenyl-guanidine, $\text{NH}=\text{C}\begin{smallmatrix} \text{N}(\text{C}^6\text{H}_5)^2 \\ \text{NH}(\text{C}^6\text{H}_5) \end{smallmatrix}$, is formed by heating cyanilide (iv. 441) with diphenylamine hydrochloride, the heat being gradually raised during two hours to 125° :

It crystallises in large, colourless, strongly refracting, isometric tablets, nearly insoluble in water, easily soluble in alcohol and ether, less easily in benzene and ligroin; melting at 131° . The *hydrochloride* crystallises with 1 mol. water in colourless thick tables or prisms; 100 parts of water at 23° dissolve 28.4 parts of this salt. The *platinochloride* is at first a light yellow flocculent precipitate, which afterwards becomes darker and crystalline.

The colourless solution of the base in strong sulphuric acid acquires a splendid violet colour when heated. In a solution containing $\frac{1}{500}$ per cent. of the base, *chlorine-water* produces a distinct deposition of white flocks. The base heated to 260° with concentrated *hydrochloric acid* or *potassium hydroxide*, is resolved, after assumption of the elements of water, into carbon dioxide, ammonia, aniline, and diphenylamine:

When the base is heated to 150° – 160° for several hours with *carbon disulphide*, hydrogen sulphide is given off, and β -triphenyl-guanidine thiocyanate is produced, together with phenyl-thiocarbimide and diphenylamine:

(Weith a. Schröder, *Ber.* viii. 912).

Trichlorophenyl-guanidine, $\text{CH}^2(\text{C}^6\text{H}^4\text{Cl})^3\text{N}^3$, is produced, together with chlorophenyl-thiocarbimide, $(\text{C}^6\text{H}^4\text{Cl})\text{NCS}$, chloraniline, chlorophenyl-carbamide, and a sulphur-compound crystallising in needles melting at 102° – 103° , by the action of iodine on an alcoholic solution of chlorophenyl-thiocarbamide, $\text{CS}(\text{NH}.\text{C}^6\text{H}^4\text{Cl})^2$. It crystallises from solution in carbon disulphide, in large crystals easily soluble in alcohol and ether, melting at 115° – 120° (Beilstein a. Kurbatow, *Ber.* vii. 730).

Diacetyl-triphenyl-guanidine, $\text{C}(\text{C}^2\text{H}_3\text{O})^2(\text{C}^6\text{H}_5)^3\text{N}^3$, is prepared by heating triphenyl-guanidine [α] and acetic anhydride in molecular proportions to 100° for several hours; and *dibenzoyl-triphenyl-guanidine*, $\text{C}(\text{C}^7\text{H}_5\text{O})^2(\text{C}^6\text{H}_5)^3\text{N}^3$, in like manner

with benzoic anhydride. Both crystallise in laminae; the acetyl-derivative melting at 131°, the benzoyl-derivative at 185° (McCreath, *Ber.* viii. 383).

Tetraphenyl-guanidine, $\text{CH}(\text{C}^6\text{H}_5)_4\text{N}^3$ (Weith, *Ber.* vii. 843). Of this compound there are two possible modifications, viz.:

but only the first is actually known.

Tetraphenyl-guanidine is produced, together with a polymeric diphenyl-cyanamide, $n[\text{CN.N}(\text{C}^6\text{H}_5)_2]$, by the action of gaseous cyanogen chloride on fused diphenylamine. If a very strong heat be applied, the product consists mainly of the polymeric diphenyl-cyanamide. To prepare tetraphenyl-guanidine, diphenylamine is heated in an oil-bath to 150°–170°, and a stream of pure cyanogen chloride is passed into it for a few hours. The product is dissolved in alcohol, and the solution, acidulated with hydrochloric acid, is poured into a large quantity of water, whereby unaltered diphenylamine is removed and the hydrochloride of tetraphenyl-guanidine produced; the filtrate is evaporated to a small bulk, and the oily layer of hydrochloride which separates and crystallises on cooling is decomposed by soda and recrystallised from ligroin.

Tetraphenyl-guanidine is insoluble in water, easily soluble in alcohol, ether, and benzene, and forms pyramidal crystals, sometimes modified, according to Kenngott, by longitudinal and transverse faces. It melts at 130°–131°.

The salts of tetraphenyl-guanidine are for the most part sparingly soluble in water, and all crystallise well. The *hydrochloride* is easily soluble and crystallises in tablets (probably rhombic) containing $5\text{H}_2\text{O}$, and efflorescing on exposure to the air. Its solution is neutral, and gives with ferric chloride a rusty-brown precipitate which, after some time, changes into large yellow hexagonal plates of an *iron double salt*. The *platinochloride* is obtained as a light yellow precipitate which dissolves in boiling alcohol, and crystallises therefrom in shining laminae. The *nitrate* crystallises from boiling water in tufts of long needles having a satiny lustre. The *sulphate* forms slender needles very slightly soluble in water. The *hydriodide* crystallises from hot water in long colourless needles. The *chlorate* is a precipitate composed of slender needles, and so sparingly soluble that it is thrown down by potassium chlorate from 1 per cent. solutions of guanidine salts. Strong sulphuric acid, even in the cold, colours it a fine brick-red, changing first to violet and then to blue.

Potassium chromate produces in solutions of tetraphenyl-guanidine salts, a light yellow amorphous precipitate. *Chlorine-water* and *chloride of lime* produce in the solution of the hydrochloride, thick white precipitates. Strong *sulphuric acid* dissolves the pure base without colour at ordinary temperatures, but the solution, when heated, becomes violet red. *Carbon disulphide* does not act upon the base even at 180°.

Action of Potash.—When the hydrochloride of tetraphenyl-guanidine is heated to 200° with solid potash, it is decomposed, giving off ammonia and diphenylamine; and when the salt is heated with hydrochloric acid in sealed tubes to 330°–340°, the same products are obtained, together with carbon dioxide, which in the former case unites with the potash. The reaction in both cases may be represented by the equation:

No aniline is produced in either case: hence the tetraphenyl-guanidine must have the constitution represented by the symmetrical formula above given; unsymmetrical tetraphenyl-guanidine would yield mono- as well as di-phenylamine.

The formation of tetraphenyl-guanidine by the action of cyanogen chloride on diphenylamine may be represented by the following equations:

The polymeric diphenyl-cyanamide, $n\text{C}^{13}\text{H}^{10}\text{N}^2 = n[\text{CN.N}(\text{C}^6\text{H}_5)_2]$, formed in large quantity, together with only a small quantity of tetraphenyl-guanidine, by the action of cyanogen chloride on diphenylamine at a very high temperature (250°), may easily be obtained pure and colourless by crystallisation from alcohol. It differs essentially in its properties and reactions from the metameric compound, carbodiphenylimide, $(\text{C}^6\text{H}_5)_2\text{N}=\text{C}=\text{N}(\text{C}^6\text{H}_5)$ (p. 401). It crystallises in shining acute rhombohedrons, melts at 292°, is insoluble in water, and is dissolved only in traces by alcohol, ether, benzene, &c. It is somewhat soluble in hot oil of turpentine, and crystallises therefrom in colourless laminae. At a very high temperature it partly distils unaltered, and is partly resolved into benzonitril, carbon, &c. Heated with strong sulphuric acid, it dissolves with splendid violet colour (the reaction exhibited

by the sulpho-acids of diphenylamine). Heated to 250° in sealed tubes with hydrochloric acid, it is resolved into carbon dioxide, ammonia, and diphenylamine; and the same result is obtained by heating it very strongly with potassium hydroxide. Hence it follows that in each of the groups forming the polymeric diphenyl-cyanamide, the two phenyl-groups must be attached to the same atom of nitrogen, the reactions above-mentioned taking place as shown by the equation:

Carbodiphenylimide, on the other hand, which has only one phenyl-group attached to each nitrogen atom, yields by similar treatment nothing but carbon dioxide and aniline.

That the diphenyl-cyanamide obtained by the action of cyanogen chloride on diphenylamine, is really a polymeride, and, according to all analogy, $(\text{C}^{13}\text{H}^{10}\text{N}^2)_n$, that is to say, perphenyl-melamine, is shown by its behaviour with aniline and diphenylamine, on which it does not exert the slightest action, whereas the simple diphenyl-cyanamide, $\text{C}^{13}\text{H}^{10}\text{N}^2$, would form tri- and tetraphenyl-guanidine respectively. The polymeric diphenyl-cyanamide is not converted into the simple cyanamide by distillation. Dehydrated tetraphenyl-guanidine hydrochloride, heated to 280°–300° in sealed tubes for four or five hours, is resolved into diphenylamine hydrochloride and the polymeric diphenyl-cyanamide: hence the occurrence of the latter in the preparation of tetraphenyl-guanidine.

Phenyl-tolyl-guanidine, $\text{CH}^3(\text{C}^6\text{H}_5)(\text{C}^6\text{H}_4.\text{CH}^3)\text{N}^3$. The hydrochloride of this base is formed, together with small quantities of phenyl-thiocarbamide and paratolyl-thiocarbamide, when a mixture of diparatolyl-thiocarbamide, hydrochloric acid, and carbodiphenylimide is heated with alcohol to the boiling point for about an hour (Weith, *Ber.* ix. 810).

Metoluidine.—This base, homologous with diphenyl-guanidine or melanine, was first obtained by W. Wilson (*Chem. Soc. Jour.* 1850, 154), who prepared it by passing cyanogen chloride over toluidine spread in a thin layer over the surface of a bent glass tube. The product thus obtained is a resinous mass consisting almost entirely of the hydrochloride of ditolyl-guanidine, from which the base may be obtained by dissolving the mass in very dilute hydrochloric acid, and precipitating the filtrate with potash. For purification, the precipitate is boiled for some time to expel unaltered toluidine, then washed, and crystallised from aqueous alcohol. It is also produced, similarly to diphenyl-guanidine (p. 904), by desulphuration of ditolyl-thiocarbamide in presence of ammonia (Hofmann, *Ber.* vii. 1736). It is sparingly soluble in cold, more easily in hot water, and crystallises in laminæ (Wilson); in slender needles melting at 168° (Hofmann). When heated, it behaves like diphenyl-guanidine, giving off ammonia, and leaving tetratolyl-melamine, in the form of a resinous mass which slowly acquires a crystalline structure and forms a hydrochloride crystallising in concentric groups of slender needles.

Tritolyl-guanidine, $\text{C}^{22}\text{H}^{23}\text{N}^3 = \text{CH}^2(\text{C}^7\text{H}^7)_3\text{N}^3$, is formed by heating monoparatolyl-carbamide with paratoluidine and phosphorus trichloride (Weith, *Ber.* ix. 820).

Dixyl-guanidine, $\text{C}^{17}\text{H}^{21}\text{N}^3 = \text{CH}^3(\text{C}^8\text{H}^9)_2\text{N}^3$, is readily formed by desulphurising dixyl-thiocarbamide with lead oxide in presence of alcoholic ammonia. It crystallises in white slender needles, quite insoluble in water, and melting at 156°–158°. Its salts crystallise remarkably well (Hofmann, *Ber.* ix. 1292).

A *trixyl-guanidine*, $\text{CH}^2(\text{C}^8\text{H}^9)_3\text{N}^3$, is formed by desulphurising an alcoholic solution of xyl-thiocarbamide with lead oxide in presence of xylydine (Hofmann).

Cyanoguanidines and Ovalylguanidines
(Landgrebe, *Ber.* x. 1587).

Dicyanodiphenyl-guanidine, $\text{C}^{18}\text{H}^{18}\text{N}^5$, is identical with dicyanmelanine, the compound which Hofmann obtained by passing cyanogen gas into a saturated solution of melanine (diphenyl-guanidine) in cold alcohol (iv. 465).

Dicyanoditolyl-guanidine, $\text{C}^{17}\text{H}^{17}\text{N}^5$, is formed in like manner by passing cyanogen into an ethereal solution of ditolyl-guanidine, the liquid solidifying to a pulp of long needles. It is sparingly soluble in water, more easily in ether and in alcohol; the alcoholic solution turns brown and decomposes at about 50°. From ether the base separates in well-defined limpid prisms, which begin to decompose at 70°–80°, and are converted into a brown resin at 150°. The alcoholic solution forms white precipitates with *silver nitrate* and *mercuric chloride*. With *acids*, dicyanoditolyl-guanidine reacts exactly like the corresponding phenyl-compound.

o**Ditolyloxalyl-guanidine** or **Cyanditolyloxamide**, $C^{17}H^{15}N^3O^2$, homologous with melanoximide or cyanodiphenyl-oxamide (iv. 286), is formed, like the latter, by the action of dilute acids on dicyanoditoly-guanidine:

It is insoluble in water, slightly soluble in cold alcohol and ether; crystallises from hot alcohol in colourless needles often grouped in rosettes; melts at 188.5° . By *acids* and *alkalis* it is resolved into oxalic acid and ditoly-guanidine. Heated with *aniline*, it forms, with evolution of ammonia, a base, $C^{20}H^{19}N^3O^2$, the hydrochloride of which crystallises from alcohol in small needles.

Ditolyloxalyl-guanidine and dicyanoditoly-guanidine, treated in boiling alcoholic solution with a dilute acid, are converted into ditoly-parabanic acid, $C^{17}H^{14}N^2O^3$, homologous with diphenyl-parabanic acid (iv. 340):

Ditoly-parabanic acid is most easily produced from the oxalyl-compound, but resinous products are always formed at the same time. It crystallises in nacreous laminae melting at 144° , easily soluble in benzene and in alcohol, sparingly in ether, carbon disulphide, and glacial acetic acid. With acids and alkalis it reacts like diphenyl-parabanic acid (iv. 340).

The compounds just described may be represented by the following formulæ, in which R stands for C^6H^5 , C^6H^7 , &c.

β -Dicyanotriphenyl-guanidine,

The hydrochloride of this base, $C^{21}H^{17}N^5.HCl + 3H^2O$, is obtained by heating the mixed solutions of dicyanodiphenyl-guanidine and aniline hydrochloride, then adding water, and crystallising the resulting precipitate several times from hot alcohol. It forms yellow-brown needles, which give off their water and turn red at 140° , and decompose at 250° . The *free base*, $C^{21}H^{17}N.1\frac{1}{2}H^2O$, may be prepared by dissolving the hydrochloride in hot alcohol containing ammonia, heating the liquid for some time, and adding water; it then separates as an amorphous precipitate which soon becomes crystalline. By repeated crystallisation from alcohol it is obtained in dark brown needles with violet iridescence, which give off their water of crystallisation at 120° , and melt at 172.5° . It is insoluble in water, but dissolves in alcohol, ether, and carbon disulphide. Its salts crystallise well, the *platinocloride* in yellow needles, easily soluble in alcohol.

The base appears to be identical with that which Hofmann obtained, together with cyananiline, by the action of cyanogen on aniline, and isomeric with that which he prepared by the action of cyanogen on α -triphenyl-guanidine (*2nd Suppl.*, 583).

GUANIDOCARBONIC ETHERS (Nencki, *Ber.* vii. 1588; *J. pr. Chem.* [2], xvii. 237). *Diethylic Guanidocarbonate*, $C^4H^{12}N^3O^4$, or $\text{HN}=\text{C}(\text{NH.COOC}^2\text{H}^5)^2$, is prepared by gradually adding ethylic chlorocarbonate to a concentrated alcoholic solution of guanidine contained in a small flask which is kept cool. The ether then separates in needle-shaped crystals, and the alcoholic mother-liquor contains guanidine hydrochloride:

Diethylic guanidodicarbonate is insoluble in water, but dissolves easily in absolute alcohol and ether, with moderate facility also in dilute alcohol, and is best crystallised therefrom. It melts at 162° . Dilute sulphuric and hydrochloric acid decompose it readily. Heated to 100° in a sealed tube with alcoholic ammonia, it is converted into urethane and ethylic guanidomonocarbonate, $C^4N^3H^8O^3$, which, being a basic compound, is also called *guanoline*:

Two molecules of guanoline contain the elements of 1 mol. guanidine and 1 mol. diethyllic guanidodicarbonate :

The formation of guanline was once observed on adding an aqueous solution of guanidine (containing a little ammonia) to ethylic chlorocarbonate.

Guanoline crystallises from aqueous or alcoholic solution in rhombic laminae containing $\text{C}^4\text{H}^2\text{N}^3\text{O}^2 \cdot \text{H}^2\text{O}$. The hydrated base melts at 100° ; the anhydrous base at 114° – 115° . The *nitrate*, $\text{C}^4\text{H}^2\text{N}^3\text{O}^2 \cdot \text{NO}^3\text{H}$, crystallises in fine rhombic prisms; the *neutral sulphate* has the composition $(\text{C}^4\text{H}^2\text{N}^3\text{O}^2)^2\text{SO}^4\text{H}^2$; the *platinochloride* is $(\text{C}^4\text{H}^2\text{N}^3\text{O}^2)^2 \cdot 2\text{HCl} \cdot \text{PtCl}_4$.

β . *Guanidopropionic acid*, $\text{C}^4\text{H}^2\text{N}^3\text{O}^2 = \text{HN}=\text{C} \begin{smallmatrix} \text{NH}^2 \\ \text{NH} \cdot \text{CH}^2 \cdot \text{CH}^2 \cdot \text{CO} \cdot \text{OH} \end{smallmatrix}$ metamerie with guanoline and with creatine, is formed on adding ammonia to a solution of β -amidopropionic acid (2 pts.) and cyanamide (0.7 pt.):

It is a very stable compound, not decomposing till heated to 205° – 210° (E. Mulder, *Ber.* viii. 1261; ix. 1902).

GUANINE, $\text{C}^5\text{H}^2\text{N}^3\text{O}$. This base has the composition of amidosarcine, $\text{C}^5\text{H}^2(\text{NH}^2)\text{N}^4\text{O}$, and may be represented by the constitutional formula :

(Grimaux, *Ann. Ch. Phys.* [5], xi. 356); see URIC ACID.

Guanine has been found: (1). Together with other bases in the extract obtained by boiling yeast with water (p. 783). (2). To the amount of 5 to 8 per cent. together with sarcine, in the sperm of the salmon (Piccard, *Ber.* vii. 1714). (3). In small quantity in the urine of a pig, which was fed exclusively on bran, and appeared to be suffering from gout (Pecile, *Liebig's Annalen*, cxxxiii. 141).

GUANO. The following analyses of Peruvian guanos, from as yet unworked deposits, taken during the survey of H.M.S. *Petrel*, have been made by Voelcker (*Journ. Roy. Agr. Soc.* 1874, 541).

The total amount of these deposits is about 7,301,000 tons, to which the deposits at Papillon de Pica contribute 5,000,000. With one exception, the guanos are not equal to the old Chinchá guano, which contained 14 per cent. of nitrogen, but they are mostly in excellent condition, dry, and free from lumps. Guano does not seem to alter steadily in composition with the depth from surface, its composition apparently depending less on its age than on other circumstances. The nitric acid of the Peruvian nitre beds may possibly be derived from ancient guano.

Phosphatic guanos (Voelcker, *Journ. Roy. Ag. Soc.* [2], xii. 440-459). Argentine guano, from the Bolivian coast, affords the best example of the rapidly dried recent excrement of sea-birds; this guano is acid to litmus, and contains 19-21 per cent. of nitrogen. Bird-dung, exposed to the weather in various climates, undergoes change, and guanos of various qualities are produced. The ultimate effect of rain is to destroy the organic matter; the guano then remaining is said to be 'phosphatic,' and contains very little nitrogen. These phosphatic guanos are of great value as materials for high-class superphosphate. The annexed table gives more or less complete analyses of a number of phosphatic guanos. In many instances, the bases present are insufficient to form tribasic salts with the phosphoric acid; this is especially the case in the stony masses, known as 'crust' guanos, frequently found in deposits much altered by weather. Mejillones guano is a deposit near the coast of Bolivia, estimated at several million tons; the phosphoric acid, on an average of 12 analyses, is equal to 72.1 per cent. tricalcic phosphate. Some of the guanos from islands in the Gulf of California contain over 80 per cent. of tricalcic phosphate. Curaçoa Island is on the coast of Venezuela; a rock-phosphate from Great Curaçoa yielded 81.9 per cent. tricalcic phosphate. The five guanos next mentioned in the table are of little importance. Baker, Howland, and Jarvis Islands lie near the equator, in the Pacific Ocean; their guano is now nearly exhausted; the analysis of Jarvis Island guano represents the present inferior importations; calcium sulphate is often present. Shaw's, Malden, Enderbury, and Starbuck Islands are coral islands in the South Pacific Ocean; the guano is of high quality, but apt to be contaminated with fragments of the coral rock. The South American guanos are seen, from the analyses, to contain a large quantity of water and sand, and to be richer in nitrogen than the others mentioned; they vary much in composition. Patos Island is on the coast of Lower California. Bird's Island belongs to the Pacific group.

Bats' Guano. By A. Voeleker (*Jour. Roy. Agri. Soc.* 1878, 60-72). This material is found in the caves inhabited by bats; large quantities have been discovered in Arkansas and Texas, and on the Bahama Islands; the deposits from the latter are known as Guanahani guano. Both texture and composition are very variable. Some specimens are light-coloured, dry, and powdery, and full of the undigested wings of insects. Other specimens are dark, damp, and lumpy, and of an earthy texture. The guano has very little odour. The following table shows the principal ingredients of a new and old deposit from caves in Arkansas, and the mean composition of eight cargoes imported from the Bahamas, with the highest and lowest percentages:—

	Arkansas Guano		Bahama Guano		
	Old deposit	New deposit	Highest per-centages	Lowest per-centages	Mean
Water	6.74	33.53	31.40	9.45	21.02
Organic matter	21.32	44.63	27.97	10.74	14.96
Ash	71.94	21.84	79.14	50.76	61.02
Nitrogen as organic matter and ammonia	2.48	6.62	1.93	0.53	0.89
Nitrogen as nitric acid	0.46	2.18	1.06	0.23	0.47
Total nitrogen	2.94	8.80	2.99	0.80	1.36
Phosphoric acid	6.64	3.76	21.09	4.59	13.49

As with most other guanos, the recent deposits are rich in nitrogen and poor in phosphates, while in the older and more decomposed deposits the proportion is reversed. Nitrates are present in all specimens. A small part of the phosphoric acid exists in the soluble form. The chief constituents of the ash, besides phosphates, are siliceous matter, and carbonate and sulphate of calcium, but the proportions are very variable. The composition of bats' guano from Spain, Jamaica, and Penang (the latter is known as 'Typelawer') was found to range nearly within the limits above given (see also p. 765).

FISH GUANO. A sample of Norwegian fish guano steamed and deprived of fat, supplied by the firm of Otto Radde in Hamburg, has been analysed by H. Vohl (*Dingl. pol. J.* ccxv. 461) with the following results:

P ₂ O ₅	CaO	MgO	NaCl	KCl	Fe ₂ O ₃	S and CO ₂	SiO ₂	H ₂ O	N	Organic substance
13.894	16.431	0.468	1.392	trace	0.023	1.534	3.069	0.886	6.393	8.673
										47.167
37.697 ash										62.303 volatile and organic matter

This guano contains about 12 per cent. nitrogen, and gives up to cold water 33-34 per cent. of its weight, the solution containing, besides easily soluble phosphates, 15 per cent. nitrogen in the residue dried at 100°. It passes into putrefactive decom-

position at 11°, whereas fish guanos still containing fat are very slow in putrefying. Disintegration with sulphuric acid is not advantageous, as the sulphuric acid is chiefly taken up by the organic matter; even when it was added to the amount of 30 per cent. the product contained only 3·58 to 3·60 per cent. soluble phosphoric acid. Better results were obtained by treating the guano first with an alkali and then with sulphuric acid, but this mode of decomposition is for the most part too costly.

The decomposition of the insoluble nitrogen-compounds in fish-guano is sometimes effected by moistening with water or urine, and leaving the mass in ferment. For 50 kilos. of manure 30 litres of urine or water are necessary; 5 kilos. of gypsum are added, and the heaps are covered with gypsum or earth to prevent loss of nitrogen. The temperature rises to above 40°, and when it begins to fall, the fermentation is over (A. Paget, *Chem. Centr.* 1877, 206). It has, however, been found by several experimenters that the best method of bringing the nitrogenous matter, and likewise the phosphoric acid, into the soluble state, is to feed cattle with the guano and use their excrements as manure. In the following experiments, fish-guano, mixed with groats, was given to two sheep, which ate it readily. The guano contained 56·04 per cent. albuminoids (9·44 nitrogen), 2·11 fat, and 41·85 mineral matter.

The following analyses show the composition of the dried excrements of the animals; A when each sheep was fed on 656·85 grams of dry hay and 400 grams of groats per day, and B when 150 grams of fish meal were added to the above rations:

	A		B	
	No. I.	No. II.	No. I.	No. II.
Albuminoids	10·12	9·75	10·94	10·81
Fibre	41·33	42·23	34·16	34·07
Fat	3·50	3·22	3·19	3·26
Non-nitrogenous extractive matter	34·10	33·96	31·19	31·64
Ash	10·95	10·84	20·52	20·22
Total weight of dry excrement per day	427·04	420·51	442·90	445·68

Water containing carbonic acid in solution, dissolved 18·35 per cent. of the phosphoric acid contained in the fish-guano, and 67·5 per cent. of the phosphoric acid in the fresh sheep dung. After the dung had been kept for two months, and decomposition had set in, the solubility of the phosphoric acid rose to 73·24 per cent. These results show that the value of the fish-guano as a manure is increased by passing through the alimentary canal of the animals (O. Kellner, *Landw. Versuchs-Stationen*, xx. 423).

The proportions of phosphoric acid, nitrogen, and ash in various guanos and other manures have been determined by P. Wagner (*Ber. d. Landw. Versuchs-St. Darmstadt*, 1874):

	Phosphoric acid	Nitrogen	Ash
Fish guano	11·6	8·1	41·2
Whale guano	11·4	6·5	44·1
Frey Bentos guano	15·70	6·21	41·02
Peru guano	10·7—15·9	3·3—14·3	—
„ (disintegrated)	8·7— 8·10	8·1—10·3	—
Bone-meal	18—19	3·4	—
Steamed bone-meal	20·26	3·25	—

On the Composition of Guano, see also Chevreul (*Compt. rend.* lxxvi. 1376, 1500; lxxvii. 155, 453, 569, 901; *Chem. Soc. Jour.* 1873, 1052; 1874, 90).

The name 'European guano' is applied to various mixtures of horn, blood, urine, dung, calcium phosphate, wool, vegetable albumin, &c., containing, on the average, 5·2 per cent. nitrogen, 6·2 soluble phosphoric acid, and 0·8 potash.

GUANOLINE, $C^4H^9N^3O^2$. See GUANIDO-CARBONIC ETHERS (p. 910).

GUANOVULITE (F. Wibel, *Ber.* vii. 322). A mineral, found by C. Gottsche, forming the interior of a crushed bird's egg from crude Peruvian guano, the shell of which consisted of calcium phosphate and carbonate, coloured brown by organic matter. It is yellowish-white, with a silky to satiny lustre and laminar structure. Hardness = 2. Sp. gr. = 2·33–2·65 at 15°. When heated it remains unaltered at 100°, but at 141° it gives off 10·91 per cent. consisting of water and ammonia with a little sal-ammoniac, and at 190° it blackens; the entire loss amounts to 36·10 per cent. Analysis showed that the mineral has the composition $(NH^4)^2SO^4 \cdot 2K^2SO^4 \cdot 3KHSO^4 \cdot 4H^2O$, with traces of ammonium chloride, lime, soda, phosphoric acid, organic matter, &c.

That it cannot be wholly derived from the constituents of the egg itself, is evident from the fact that some of the eggs are almost filled with it; the quantities of potash and sulphuric acid are much larger than would be contained in the fresh egg, and must, therefore, have been introduced by diffusion, whilst the soda, phosphoric acid, &c., were removed by the same process. The most remarkable feature is, however, the presence of the acid potassium sulphate, which has hitherto been known only in the rare volcanic mineral, misenite. On evaporating a solution of guanovulite at ordinary temperatures, it separates out unchanged, in crystals belonging to the rhombic system, but the solution, when heated, becomes strongly acid, and deposits the three constituents separately.

GUARANA. For the preparation of caffeine from this substance, the following method is recommended by F. V. Greene (*Pharm. J. Trans.* [3], viii. 87) in preference to that given by Stenhouse (i. 708). Powdered guarana is mixed with three times its weight of finely divided litharge, and boiled in distilled water until, on leaving it to cool, the insoluble portion rapidly subsides. The cool, clear liquid is then filtered, and the residue washed with boiling water, till the washings produce no precipitate with phosphomolybdic acid or platinum chloride. The small amount of lead in the filtrate is then precipitated by sulphuretted hydrogen, and the solution on evaporation yields colourless crystals of caffeine, which may be recrystallised from alcohol.

The tannin of guarana is found by Green (*ibid.* 328) to differ in several of its reactions from ordinary tannin, for which reason he regards it as a distinct compound, and proposes to call it *Paullitanic acid*.

GUAYACANITE. The variety of enargite from the Cordilleras of Chile, so named by Field (ii. 488), is regarded by Frenzel as identical with luzonite (see ENARGITE, p. 733).

GUM. It is commonly supposed that the formation of gum in plants is due to a transformation of the cell-wall, but from microscopic observations by E. Prillieux (*Compt. rend.* lxxviii. 155) it appears that gum is produced in the interior of the vessels in the form of small drops which gradually unite. According to Mercadante, on the other hand (*Berl. Ber.* ix. 581), gum and starch are formed simultaneously in the plant-cell, the gum on the walls, the starch in the interior. At a later stage, the gum increases in quantity while the starch diminishes; but this result is not due to a conversion of the starch into gum, the starch being, in fact, converted into the soluble modification, which serves for the nutrition of the plant.

According to Schützenberger, ordinary gum (arabin) is contained in considerable quantity in the extract obtained by boiling yeast with water (p. 783).

On the Gum of Sugar-beet and the so-called 'fermentation-gum,' obtained from Beet-juice which has passed into the state of mucous fermentation, see ARABIN (p. 118).

On Kauri or Cowdie gum, the produce of *Dammara australis*, see DAMMARA RESIN (p. 625).

Quebracho Gum.—The *Quebracho colorado* (*Loxopterygium Lorentii*, Grisebach) is a tree belonging to the Anacardiaceous order, indigenous in, and peculiar to, the northern part of the Argentine Republic. The so-called gum, or rather thickened juice, collects in the cracks and hollows of the wood, in ruby-red concretions somewhat resembling colophony, but more brittle; it is easily pulverised, and yields a brick-red powder. It is scentless, but has a slightly astringent taste. Sp. gr. 1.3756 at 15°. It is easily soluble in alcohol, acetone, and acetic ether; dissolves also in amyl alcohol and acetic acid, but is insoluble in benzene, carbon bisulphide, chloroform, and turpentine oil; nearly insoluble in cold water and in ether; nevertheless an ethereal solution, having an emerald-green colour, may be obtained by agitating the gum with ether and water. Boiling water dissolves it completely, and deposits part of it on cooling. It dissolves also in strong sulphuric acid, and is precipitated therefrom by water. Heated in a platinum capsule it swells up and burns, leaving a shining porous cinder, which burns away slowly on continuing the heat. If the combustion be completed in a stream of oxygen, the unburnt residue is scarcely appreciable.

A 1 per cent. solution of the gum in absolute alcohol, in a layer 7 mm. thick, exhibits an absorption-spectrum having a dark band commencing between the solar lines A and B, and terminating at C; another extending for a short distance on each side of D; and a third beginning half-way between D and E and extending to all the more refrangible part of the spectrum. The same solution in a layer 25 mm. thick absorbs the whole of the spectrum, excepting a narrow space from C half-way to D. A solution of dragon's blood, which in some respects resembles quebracho gum, exhibits a very different spectrum, containing a dark band extending for a short distance on each side of C, and a second beginning just beyond D and occupying all the rest of the spectrum,

Reactions.—Quebracho gum, subjected to dry distillation, yields between 100° and 120° a distillate which remains liquid on cooling, and between 240° and 245° a distillate which solidifies to colourless prisms of pyrocatechin (m. p. 105° nearly, b. p. 240° – 245°). The gum is strongly attacked by concentrated *nitric acid*, and when heated with the same acid somewhat diluted with water, it is oxidised to oxalic acid and trinitrophenol or picric acid. Fused with *potash* it yields proto-catechuic acid, $C^7H^5O^4$, or $C^7H^3(OH)^2.COOH$, and phloroglucin, $C^6H^4O^2$.

The formation of these products renders it probable that quebracho gum contains one of the bodies called catechins (see p. 415): but, in consequence of the great tendency of these bodies to alteration, their actual presence in the gum has not been satisfactorily demonstrated. The existence of catechin in an anacardiaceous plant would be a novelty, this body having hitherto been found only in the leguminous, rubiaceous, and cedruaceous orders (Pedro N. Arata, *Anales de la Sociedad Científica Argentina*, July 1878).

Sonora gum is a name given in Mexico to crude shellac (*q.v.*)

GUM-RESINS. See RESINS.

GUN-COTTON. From analyses made by reduction with ferrous salts, Champion a. Pellet (*Compt. rend. lxxxiii. 707; lxxxiv. 609*) conclude that Abel's compressed gun-cotton consists not of trinitrocellulose, as stated by Abel (*1st Suppl. 659*), but of pentanitrocellulose. Abel, on the other hand (*Compt. rend. lxxxiii. 1011*), shows that the analyses on which this conclusion is founded are defective, inasmuch as no care was taken to free the gun-cotton from admixed nitro-derivatives of fatty and resinous substances, by washing with alcohol and ether. Gun-cotton, prepared with the utmost care in his own laboratory, exhibited the composition of trinitrocellulose, as determined several years ago by Walter Crum and by Pelouze, whereas commercial gun-cotton was found to be a mixture of about 85 per cent. trinitrocellulose with about 4 or 5 per cent. of unattacked cellulose and 10 per cent. dinitrocellulose.

Böttger (*Dingl. pol. J. cxix. 315*) finds that gun-cotton is dissolved by a boiling solution of *sodium stannite*, and that the regenerated cellulose is precipitated on adding to the liquid an excess of hydrochloric acid. As cellulose itself is not dissolved by sodium stannite, this reaction affords an easy method of determining the amount of unaltered cotton in a sample of gun-cotton.

On the Heat of Combustion of Gun-cotton, see EXPLOSION (p. 767).

On the Heat disengaged in its Formation, see HEAT.

On the Spectrum of Exploding Gun-cotton, see Lohse (*Pogg. Ann. cl. 641; Jahresb. f. Chem. 1873, 151*).

GUNPOWDER. *Decomposition.*—The following equations, representing different stages of the decomposition of gunpowder, are given by Debus (*Brit. Assoc. Reports, 1875 [2], 40*):

From the thermic effects produced by the explosion of gunpowder, Berthelot infers (*Compt. rend. lxxxii. 475*) that the explosion gives rise to the formation of all the compounds that are permanent under the circumstances of the experiment, chiefly sulphur, potassium carbonate, and potassium sulphate, together with carbon monoxide and dioxide, nitrogen, and vapour of water. The proportions of these several products vary with the local circumstances of the mixing and of the ignition. If the products remained in contact for a considerable time, their reciprocal actions would bring them into the condition which is consistent with the greatest possible evolution of heat,—that is to say, it would lead to their ultimate conversion into K^2SO^4 and CO^2 ; but the sudden cooling prevents the completion of this reaction. Nevertheless each of the products is formed in a regular manner, and the chemical transformation of powder may in all cases be represented by a system of very simple equations.

On the Heat of Combustion of Powder, see p. 767; also De Tromenec (*Compt. rend. lxxvi. 384; Jahresb. f. Chem. [1873], 1026*).

On a method of testing the Fineness of Gunpowder, depending on the intensity of its combustion, see Chabrier (*Compt. rend. lxxviii. 1138; Jahresb. f. Chem. 1874, 1122; Chem. Soc. J. [1874], 1023*).

An apparatus for measuring the pressure produced by the gases of burning powder in the chamber of the gun, and the pressure which the shot produces in driving the air before it, has been devised by Deprez a. Sebert (*Compt. rend. lxxviii. 1835; Jahresb. f. Chem. 1874, 1120*).

On the Composition and Analysis of Wood-Gunpowders, see F. W. Toms (*The Field*, 1878, No. 1336, p. 143; *Chem. Soc. J.* xxiv. [1878], p. 923).

GURJUN BALSAM. From the residue left in the preparation of a large quantity of this balsam, Flückiger obtained a neutral crystalline substance, $C^{28}H^{16}O^2$, which dissolved in petroleum-spirit, and separated therefrom in prismatic crystals belonging to the triclinic system, and melting at 126° – 130° . This substance does not unite either with bases or with acids, but dissolves with reddish colour in sulphuric acid and is reprecipitated by water. It is not altered by fusion with potassium hydroxide. By dry distillation it yields an oil which is not affected by ferric chloride (*Arch. Pharm.* [3], xii. 58).

GYPSUM. *Occurrence and Formation.*—On the formation of Gypsum by the action of sulphur on calcium carbonate in presence of water, see CARBONATES (p. 411).

The gypsum and anhydrite of Airolo and Val Canaria have been described by K. von Fritsch (*Jahrb. f. Min.* vii. 299). These formations exhibit the tremendous force exerted by the expansion consequent on the conversion of anhydrite into gypsum, a force by which the crystals enclosed in the surrounding rock have been rent asunder. These crystals, which in the anhydrite are developed with perfect regularity, &c. found in the gypsum only as disintegrated fragments. Amongst these enclosed crystals are: bitter spar ($4R.0R$ in the anhydrite, cleavage-rhombohedrons in the gypsum); quartz; iron pyrites converted into brown iron ore; disthene (often superficially metamorphosed into transparent mica or talc); laminae of mica and talc (probably for the most part formed from disthene, as this mineral occurs frequently in the anhydrite, rarely in the gypsum, whereas for mica and talc the reverse holds good); very rarely tourmaline.

On the Crystalline Forms of Gypsum from Eichstadt near Merseburg, from the Pappelsberg in the Siebengebirge, and of gypsum twins from Eisleben, see Laspeyres (*Jahrb. f. Min.* 1876, 200; *Chem. Soc. J.* 1876, ii. 53); also Reusch (*Min. Mittheil.* 1876, 67).

Gypsum crystals from the miocene clay of Sütel in East Holstein, where they occur abundantly, are described by P. Klien (*Jahrb. f. Min.* 1876, 556). The usual forms of gypsum occur in this locality, but occasionally curious groups are found which bear a resemblance to twins, but are not so in reality. One crystal in these groups is larger in size than any of the rest, and at the same time serves as a support for the other crystals, which seem to radiate outwards from its centre. These crystals mostly enclose ferric oxide, which is distributed parallel to the various crystal faces, often assuming the appearance of a kernel in the crystal, enveloped by ferric oxide. Sometimes this deposition is repeated, giving rise to the formation of parallel zones.

On the 'Crystal-tectonic' of gypsum, see Klien (*ibid.* 563; *Chem. Soc. J.* 1877, i. 582).

Elasticity.—The coefficients of elasticity in gypsum are proportional to the cubes of the lengths of the axes of the coloured rings producible by pressure, and therefore also (see HBAR) to the cubes of the axes of the ellipses representing the distances to which a uniform temperature is extended in different directions by a given source of heat (Jannettaz, *Compt. rend.* lxxxii. 839).

Reaction with Sulphur.—In the extraction of sulphur from the ore by distillation, the sulphur is said by the workmen to be partly destroyed by the gypsum. This effect may be explained by the reaction represented in the equation $CaSO_4 + 2S = 2SO_2 + CaS$ (A. Cossa, *Gazz. Chim. ital.* 1874, 241).

Hardening of Burnt Gypsum.—Experiments by E. Landrin (*Ann. Chim. Phys.* [5], iii. 433) have shown that the rapidity with which burnt gypsum takes up water depends upon the temperature at which it has been burnt, and the time during which it has been exposed to that temperature. The best result is obtained by exposing the gypsum to a temperature of 100° – 300° , for 12 to 20 hours. Gypsum which has been heated to 400° likewise absorbs water quickly when stirred up with it; but hardens less, in proportion as it has been exposed to that temperature for a longer time. It is only at a cherry-red heat that gypsum loses the power of taking up water, but even at this temperature it does not give off sulphuric acid or experience any other chemical change.

The action of water on gypsum may be supposed to take place as follows. On coming in contact with water, part of the gypsum immediately becomes crystalline, while another part dissolves, and the liquid thus formed solidifies like a supersaturated solution, as soon as a crystal is formed by the evaporation of the water. The hardest product has the composition $CaSO_4 \cdot 2H_2O$, and contains 20 per cent. water. Ordinary burnt gypsum still retains 8 per cent. water, so that by stirring up the gypsum with

only 12 per cent. water, a paste should be formed which would solidify to a compact mass more quickly than any other. In practice, indeed, a paste thus composed is found to solidify too quickly, and for this reason it is customary to use at least 33 pts. water to 100 gypsum, and often a great deal more. The greater the quantity of water used, the looser is the solidified mass. To obtain a paste which solidifies slowly and ultimately becomes very hard, solutions of glue, dextrin, glycerin, &c., are used instead of water. Another method often adopted is to add a large quantity of water, and strew common salt on the surface of the solidifying mass; the salt takes water from the paste, which then solidifies quickly. The desired properties of slow solidification and great ultimate hardness are found united in the so-called *alumed gypsums* or *English cements*, which are made by steeping burnt gypsum for a few minutes in a 12–20 per cent. solution of alum, and then heating it to dull redness. It is commonly supposed that this process leads to the formation of double sulphates of calcium and alkali-metal. This view, however, is not confirmed by Landrin's analyses of a number of these gypsums, the results of which are shown in the following table:—

	French Cement	English Cement		Stucco
		1	2	
Calcium Sulphate	96·75	98·19	98·02	98·55
Calcium Carbonate	1·05	0·41	0·37	0·36
Silica	0·72	—	0·42	0·51
Water	1·48	1·45	1·19	1·08

These numbers show that the constituents of the alum do not enter into the gypsum, as supposed by Gmelin and by Schott (*2nd Suppl.* 590). As massive native gypsum is for the most part rich in calcium carbonate (a sample from Paris was found to contain more than 4 per cent.); the treatment with alum serves merely to convert this calcium carbonate into sulphate. The alum for this purpose cannot be replaced by the simple sulphates of aluminium, potassium, sodium, ammonium, &c.; but the same effect may be produced by sulphuric acid. Crude gypsum, left in contact for some time with sulphuric acid of 8 to 10 per cent., and then burnt, yielded a preparation which exactly resembled alumed gypsum, and had the further advantage of a fine white colour, due to the destructive action of the sulphuric acid on admixed organic substances. The sulphuric acid cannot be replaced by hydrochloric acid, as the hygroscopic calcium chloride produced by the latter could not be completely removed. Gypsum which has been treated with sulphuric acid and afterwards burnt at a high temperature, behaves like strongly heated pure calcium sulphate; it dissolves in water more slowly than ordinary gypsum, does not become heated in combining with water, and solidifies less quickly than ordinary gypsum. The setting may be accelerated by heating the paste, or by using warm water for the mixing. If the gypsum be mixed with quick lime, the latter slakes during the mixing with water, thereby raising the temperature, and accelerating the evaporation, and consequently the setting of the gypsum. The resulting calcium hydroxide becomes saturated with carbonic acid, and thereby increases the solidity of the gypsum. The best proportion of lime to be added to the gypsum is 10 per cent.

H

HÆMATEIN. See HÆMATOXYLIN.

HÆMATIN. See HÆMOGLOBIN.

HÆMATINONE. For the preparation of this red glass (iii. 3), the following process is recommended by Kayser (*Institut.* 1876, 279). Sixty parts of pure sand, 10 cupric oxide, 3 ferrosoferric oxide, 10 calcined borax, and 10 calcined soda, are fused together at a high temperature, whereby the cupric oxide is reduced, after which the heat is lowered to dull redness, and kept at that point for some time. The product is a deep red glass flux covered over with a thin layer of cupric oxide glass. In Pettenkofer's process (iii. 3), which consists in adding cupric oxide mixed with ferrosoferric oxide as a reducing agent to a lead glass, a partial reduction of the lead oxide takes place at the same time, whereby the glass acquires a brownish or even blackish colour.

HÆMATOÏDIN. See HÆMOGLOBIN.

HÆMATOXYLIN, $C^{16}H^{14}O^6$. This compound is related to brazilin and resorcin in the manner shown by the equation :

(Liebermann a. Burg, *Deut. Chem. Ges. Ber.* x. 1883).

A solution of hæmatoxylin boiled in a platinum dish in an atmosphere free from ammonia acquires merely a brownish or brownish yellow colour; but, if boiled in a test-tube, it assumes in a few minutes a purple colour, showing that the glass has been decomposed, and has given up alkali to the water; for it is only in presence of oxygen and alkali that hæmatoxylin acquires the purple-red colour of hæmatein. On account of its sensitiveness to alkalis, hæmatoxylin may be very advantageously used as an indicator in acidimetry, especially for the estimation of non-volatile acids, which, by its aid, may be directly titrated with alkaline bicarbonates (O. Maschke, *Ber.* vii. 1535; *Arch. Pharm.* [3], vi. 34): see also H. W. Mitchell (*Amer. Chemist*, vi. 91).

According to Frébault (*J. Pharm. Chem.* [4], xxiii. 338), the red colour of hæmatein is destroyed by iodine or potassium iodide in presence of an alkali; and the reaction may be employed, best in very dilute solutions, for determining the amount of hæmatoxylin in logwood, and for the estimation of iodine.

HÆMIN. See the next article.

HÆMOGLOBIN AND ITS DERIVATIVES. *Reactions.*—Hæmoglobin is resolved by the action of iodine into hæmatin and globulin, as may be proved, both by comparing the absorption-spectrum after the addition of the iodine with that of pure hæmatin, and by observing the reaction itself under the microscope. In the latter case, not only is the actual precipitation of the hæmatin visible, but crystals of the iodide may be obtained by gently warming the substance on the microscope slip, with a drop of glacial acetic acid. These crystals belong to the rhombohedral system, and exhibit a stellate arrangement, often resembling the form of a Maltese cross (Husson, *J. Pharm. Chim.* [4], xxii. 326).

According to Rossbach (*N. Rep. Pharm.* xxii. 512), alkaloids increase the affinity of hæmoglobin for ozone, and retard the transference of the latter from hæmoglobin to other bodies. According to E. Schaer, on the other hand (*Deut. Chem. Ges. Ber.* vii. 1345), the separation of ozone from hæmoglobin is not retarded under normal circumstances by hydrochloride of quinine or by acetate of strychnine.

Estimation of Hæmoglobin.—Schutzenberger a. Risler's method of estimating oxygen in blood by means of a standard solution of sodium hyposulphite, Na^2SO^2 , has been applied by Quinquaud (*Compt. rend.* lxxvi. 1489), to the determination of the amount of hæmoglobin contained in blood. The larger the quantity of hæmoglobin present, the greater is the amount of oxygen taken up by the blood when shaken up with air. 1,000 grams of human blood, containing 125 grams of hæmoglobin, absorb 200 c.c. oxygen. The blood of poultry takes up per litre 170 c.c. oxygen; it must, therefore, contain 82 grams of hæmoglobin per litre, a quantity agreeing exactly which Hoppe-Seyler calculated from the amount of iron in poultry blood.

On the Spectroscopic Estimation of Hæmoglobin in Human Blood, see Wiskemann (*Zeitschr. f. Biologie*, xii. 434; *Chem. Soc. J.* 1877, ii. 808).

Peroxyhæmoglobin.—By the action of acids on blood, a peroxidised product has been obtained, from which the oxygen can be again extracted by strong reducing agents, with formation of oxyhæmoglobin, and subsequently of reduced hæmoglobin. This substance, called *peroxyhæmoglobin* by Sorby, *methæmoglobin* by Hoppe-Seyler, *nitrihæmoglobin* by Gamgee, may be prepared by acting upon blood with oxidising agents, such as potassium permanganate.

Peroxyhæmoglobin, in alkaline solution, has a three-banded spectrum. In acid solutions the spectrum has four absorption-bands similar to those of acid hæmatin. The most characteristic band has a wave-length of about 633, but by addition of acid to the blood, the position of the band changes with the intensity of the acidity, being moved towards the red end of the spectrum (Jaderholm, *Zeitschr. f. Biologie*, xiii. 255).

Hæmatin. Cazeneuve prepares pure hæmatin by dissolving 1 litre of defibrinated blood with 2 litres of a mixture of 3 parts ether and 2 parts alcohol of 85°. After twenty-four hours, the liquids having been stirred from time to time, the ethereal solution is decanted off and replaced by a fresh quantity of liquid containing 2 per cent. of oxalic acid. This dissolves out the colouring matters, and on the addition of ether holding ammonia gas in solution, to exact saturation of the oxalic

acid, hæmatin is precipitated. The precipitate is washed successively with ether, alcohol, and water, and the residue finally treated with ether saturated with hydrochloric, hydrobromic, or hydriodic acid, yields characteristic crystalline compounds (*J. Pharm. Chim.* [4], xxiv. 116).

Cazeneuve assigns to hæmatin the formula, $C^{88}H^{72}N^8Fe^2O^{10}$, agreeing with the latest determination by Hoppe-Seyler (*2nd Suppl.* 201). Its barium salt has the composition $C^{88}H^{68}BaN^6Fe^2O^{10}$ (*Bull. Soc. Chim.* [2], xxvii. 485).

When blood is treated with concentrated soda-solution, there is obtained after some time a bright red solution of reduced hæmatin, which subsequently coagulates. By dissolving this in water and treating it with dilute acetic acid, the colouring-matter is precipitated as oxyhæmatin. It may be somewhat purified by dissolving in ammonia-water, and reprecipitating with acetic acid; but it still contains albumin and a chlorinated compound insoluble in water.

Hæmatin, though usually insoluble in dilute as well as in concentrated acids, even hydrochloric acid, dissolves in concentrated acetic acid, and shows the same four-banded absorption-spectrum that it gives in acid, alcoholic, or ethereal solutions (*1st Suppl.* 355). A constant difference exists between the spectra of these solutions. In the alcoholic solution the absorption-band in the red is farther from Fraunhofer's line D than it is in the ethereal solution. In the former the centre of the band has a wave-length of about 627; in the latter, of about 638. This four-banded spectrum belongs, therefore, to hæmatin, and not, as stated by Preyer, to a colouring matter free from iron, the so-called hæmatoïn.

By evaporating the acid ethereal solution, yellowish-brown rhombic crystals and spindle-shaped thin tables are obtained. In a similar manner, by using sulphuric, hydrochloric, or other acid, crystals may be procured whose solubility in acids and alkalis corresponds with that of hæmatin crystals, as also do the absorption-spectra which are given by their solutions. Although these crystals contain iron, they are in all probability identical with Preyer's hæmatoïn-crystals and with Lehmann's hæmatin-crystals; whilst they are closely related to hæmin-crystals (Jäderholm, *Zeitschr. f. Biologie*, xii. 193).

Hoppe-Seyler (*Deut. Chem. Ges. Ber.* vii. 1065) finds that the colouring matter which he obtained by the action of reducing agents on hæmatin (*2nd Suppl.* 202), is identical with the compound called urobilin by Jaffé and hydrobilirubin by Maly (*ibid.* 190).

On crystalline compounds of Hæmatin with Acids, see Husson (*Compt. rend.* lxxxi. 477).

Hæmatoïdin (iii. 3). This substance is produced by treating blood with sodium borate and glacial acetic acid. Its crystals, apparently triclinic, exhibit under the microscope such varied and multiple forms of arrangement, that it is difficult to fix on any one of them as characteristic of the substance; it may be observed, however, that immediately surrounding the crystals, granulations of a reddish colour always occur, apparently resulting from the precipitation of the iron of the hæmatin at the moment of its conversion into hæmatoïdin (Husson, *J. Pharm. Chim.* [4], xxii. 326).

Hæmin. Thudichum a. Kingzett (*Chem. Soc. J.* [1876], ii. 255) prepare this substance by a modification of Wittich's process, which consists in treating blood with seven times its bulk of a cold solution of potassium carbonate containing 1 part of the salt in 2 parts of water. The thick mixture is filtered on calico, then pressed in cloths, and afterwards treated with alcohol; the resulting solution, containing potassium carbonate is poured off, after standing for some time; and the residue, after being freed from liquor by pressing, is dried at the ordinary temperature. The product is then exhausted with warm absolute alcohol at a temperature not exceeding 40°, and the extracts so obtained are treated with an absolute alcoholic solution of tartaric acid. In this way the potash is precipitated and the hæmin remains dissolved, and on evaporation of the solution, is precipitated on cooling in very minute bluish-black crystals consisting of rhombic plates.

The analyses of this product yielded, as a mean result, 7.651 per cent. iron, 3.022 chlorine, and 0.608 phosphorus, whence it is inferred, that hæmin consists, not simply of hæmatin hydrochloride, as hitherto supposed, but of a mixture of that compound with hæmatin and a crystallisable phosphorised substance.

Hæmin heated in hydrochloric acid gas takes up 3.3 per cent. of its weight of that gas. It dissolves in a large quantity of nitric acid, without evolution of gas, forming a red-brown solution from which water throws down red flocks, leaving a nearly colourless liquid containing only a small quantity of iron, the greater portion of that metal being contained in the precipitate. The iron cannot be removed from hæmin by treatment with glacial acetic acid and citric acid, or with glacial acetic acid and benzene, the hæmin in fact not being altered by this treatment. The statement of

Paquelin a. Joly (*Compt. rend.* lxxviii. 1579), that the colouring matter of blood—which they call *hæmatosin*—does not contain iron, is therefore erroneous.

The liquid obtained by treating hæmin with acetic acid and benzene yielded a phosphorised substance, forming with cadmium chloride a compound whose analysis showed that this phosphorised body is identical with the substance called *myelin* (q.v.) obtained from brain.

HAIR. The black pigment obtained by Hodgkinson a. Sorby from black and dark-brown feathers, is likewise found in hair of similar colour (p. 769).

HAÏ-THAO. This substance, also called *gelose*, is used for finishing cotton goods. It is obtained from an alga, occurring abundantly in Cochin China and in the Mauritius, in the form of coarse, flat fibres, which are about 30 c'n. long. It is without smell or taste, and consists of a transparent colourless mass, covered with a net of non-transparent veins. It is insoluble in cold water, and dissolves completely in hot water only after boiling for ten minutes, forming a transparent, thin, dirty-white solution, which on cooling deposits a yellowish-grey jelly, soluble on boiling. The jelly is neither acid nor alkaline, and does not show any signs of fermentation or putrefaction even when kept for about eight days. Thao dissolves in cold strong sulphuric, hydrochloric, or nitric acid, and is reprecipitated on adding water. To alkalis it behaves in the same way as to water, and is insoluble in alcohol both cold and hot.

With regard to its use for finishing cotton materials, experiments seem to show that it can be used only in hot solutions. With a dilution of 1 part of thao to 300 parts of water, the solution first begins to fix itself on the textures. With 1 part to 100 parts of water, the materials are rendered soft to the touch, and the texture gains in substance but not in stiffness. Thao fills the thread more completely than dextrin or starch, and produces a moister and finer texture. By adding glycerin to the thao-solution, a still softer and at the same time stronger material is obtained; the addition of talc, pipeclay, &c., yields a material of a fatty touch, and much finer and more delicate than that obtained from a dextrin or starch solution. Cotton finished with thao is not acted upon by cold water, as is the case with dextrin and starch; thao cannot, however, be used without ultramarine, as it gives to cotton a yellow tinge. With twilled materials thao draws the substance together, and thus prevents them from coming out well. It is only indeed for fine textures, which are to be rendered soft and firm to the touch, that the use of thao can be recommended. Where a heavy, stiff, and cheap finishing material is required, it cannot compete with dextrin or starch (Heilmann, *Dingl. Pol. J.* cxxiii. 522).

HALLOYSITE. A mineral resembling halloysite has been found by J. Rumpf (*Min. Mitth.* 1874, 282) on the Michaelerberg, near Tüffer in Styria, on the confines of the Leitha limestone and trachyte. It occurs in amorphous lumps of yellow, red, and brown colour. Analyses by R. Haller of an orange-red variety (a) and a liver-brown variety (b) gave the following results:

	SiO ²	Al ² O ³	CaO	MgO	Fe ² O ³	H ² O	Sp. gr.
a.	31.01	40.47	2.26	1.64	trace	24.27 = 99.65	2.06
b.	25.66	30.82	1.37	—	14.34	27.68 = 99.87	

HALOGENS. On the Mutual Displacement of Halogen Elements, see **CHEMICAL ACTION** (p. 429). On the thermic phenomena accompanying these reactions, and the Oxidation of Haloid Salts, see **HEAT**.

Estimation of Halogen elements by means of Ammonium Thiocyanate (Volhard, *Liebigs Annalen*, etc. 1-61). The chlorine, bromine, or iodine is completely precipitated by adding an excess of a standard solution of silver nitrate, and the excess of silver is determined by adding a solution of a ferric salt and then a standard solution of ammonium thiocyanate, till the red colour of ferric thiocyanate shows itself, indicating the complete precipitation of the silver. A deci-normal solution of silver nitrate is used, and the thiocyanate solution is made to correspond with it by titration against it in presence of a ferric salt.

In applying this process to the estimation of chlorine, certain precautions are necessary, on account of the decomposing action exerted by silver chloride on the soluble thiocyanate. If the thiocyanate solution is added in excess to an ammoniacal solution of silver chloride, and the mixture is afterwards acidulated with nitric acid, the whole of the chlorine of the silver chloride passes into solution; but if the thiocyanate solution is dropped into a nitric acid solution containing silver nitrate and suspended silver chloride, together with the ferric salt as indicator, and the liquid is not shaken more than is necessary to secure complete mixture, the action on the silver chloride proceeds so slowly that the correctness of the result is not impaired. If, however, the agitation is violent and prolonged, the silver chloride, by decom-

posing a portion of the thiocyanate, will give results too low. It must further be remembered that after the pale-brown colour has once appeared, it is scarcely increased in intensity by further addition of the thiocyanate: hence it is necessary to acquire by practice the power of at once recognising the first appearance of the tint. The weighed metallic chloride is dissolved in 300 or 400 c.c. of water, mixed with 5 c.c. of cold iron-alum solution, and with sufficient nitric acid to remove the colour imparted by the ferric salt; deci-normal solution of silver nitrate is then added in slight excess, and the addition of the thiocyanate solution is at once proceeded with, the liquid being constantly shaken and stirred round to secure rapid mixture. The titration is finished when the liquid retains its pale-brown colour after standing still for ten minutes. The number of c.c. of silver nitrate solution used, diminished by the number of c.c. of thiocyanate solution, and multiplied by 0.00355, gives the weight of chlorine present in grams. If the weight of chlorine in solution is not known even approximately, a few drops of the standard thiocyanate solution may be added occasionally during the running in of the silver nitrate solution. As long as the silver solution is not in excess, the colour produced by the thiocyanate disappears slowly; but as soon as excess has been added, the colour caused by adding a drop of thiocyanate immediately vanishes, leaving the liquid milk-white. In calculating the result, the quantity of the standard thiocyanate thus used must be added to the quantity required for titrating the excess of silver, and the whole subtracted from the quantity of silver nitrate solution employed. Filtration from the silver chloride is not to be recommended, as it occasions waste of time; neither is the employment of an aliquot part of the clear liquid after subsidence advisable, since the accuracy of the result is thereby diminished. After a little practice results may be obtained of sufficient precision to be valuable for atomic weight determinations.

Bromine.—The action of silver bromide upon thiocyanate solution does not go nearly as far as that of silver chloride; in fact, experiment shows that the process applied to the estimation of bromine gives the final reaction at once and without difficulty, the results being very accurate. The point when excess of silver solution has been added can be judged with sufficient accuracy by the clarification of the liquid after brisk agitation.

Iodine.—Silver iodide does not exert any decomposing action on the thiocyanate; nevertheless the process is liable to be rendered inaccurate by silver iodide carrying down with it potassium iodide or silver nitrate, or both, and thus more or less withdrawing them from the reaction. To avoid this source of error, the following method of proceeding is necessary:—The iodide is dissolved in 300 or 400 times its weight of water in a stoppered bottle, and the silver solution is added to it until the precipitate coagulates on shaking; this shows that an excess of silver nitrate is present; 0.1 or 0.2 c.c. more of silver solution should then be added, and the liquid well shaken: by this means any unaltered alkaline iodide is converted into silver iodide. Either of two methods may then be used for completing the estimation: after addition of the ferric solution and nitric acid, thiocyanate solution is added until a decided coloration is obtained, and the liquid shaken until the colour disappears, the process being repeated until a faint colour remains after shaking; or excess of thiocyanate is at once added, the liquid well shaken, and the thiocyanate in excess titrated by silver solution, which should be added either until a faint brown colour remains, or else in slight excess, the excess being then titrated back by thiocyanate. The latter method is the more rapid, but the two give almost identical results.

Detection and Estimation of the Halogens when Thiocyanates are present.—To detect and separate the halogens, the thiocyanates must first be destroyed. To effect this, when a chloride is present, the precipitate obtained by excess of silver nitrate in the solution acidulated with nitric acid is filtered off, well-drained, and heated, together with the filter, with sulphuric acid diluted with half its volume of water, until the precipitate unites into black masses; a few drops of nitric acid are then added, and the heating continued. On diluting with water, all the chlorine remains as undissolved silver chloride, whilst the silver thiocyanate has been completely decomposed. Another plan is to dissolve 2 or 3 grams of the thiocyanate in 400 or 500 c.c. of water and heat on the water-bath, with occasional addition of nitric acid in small quantity as long as it produces any further reaction: the mixture is then further heated, the water lost by evaporation being replaced, until a drop no longer gives the thiocyanate reaction with a ferric solution decolorised by nitric acid. The liquid made alkaline with ammonia is evaporated to two-thirds of its bulk on the water-bath, and is then ready for precipitation by silver solution. By proceeding in this manner the thiocyanate is entirely destroyed, without loss of chlorine. If only a trace of chloride has to be detected, it is better to warm with nitric acid in a less dilute condition until evolution of gas ceases, add excess of sodium carbonate, evaporate to

dryness, ignite the residue, take up with warm water, and test with silver nitrate, after adding excess of nitric acid. The methods above described are inapplicable when bromine or iodine is present, as they would cause loss of these halogens. The silver precipitate may then be digested in a sealed tube with nitric acid for three or four hours at 160°, and the liquid diluted with water; or, the substance may be fused with potassium nitrate and sodium carbonate, a large excess of the latter being used to avoid explosion. The latter method is better modified by mixing the substance with sodium carbonate, both being perfectly dry, and gradually dropping the mixture into fused potassium nitrate.

Separation of Chloride and Iodide.—If a mixture of silver chloride and silver iodide is mixed with ammonia in excess and sufficient ammonium thiocyanate, and digested at ordinary temperatures for an hour, the chloride is completely decomposed, the iodide remaining quite unaltered. On acidifying with nitric acid and washing the precipitate, the chloride will be contained entirely in the filtrate together with thiocyanate; the iodide will remain as insoluble silver iodide mixed with silver thiocyanate. After destroying the thiocyanate in the filtrate and precipitate respectively by the methods above given, the chloride may be titrated by the thiocyanate process, and the iodide weighed.

Estimation of the Halogens in Organic Compounds.—The thiocyanate method is remarkably well suited to the estimation of halogens in organic substances, the organic matter being previously destroyed and the halogen brought into the form of an inorganic compound by either of the ordinary methods,* provided no loss of the halogen is incurred. Combustion with lime free from halogens is quite trustworthy; but Volhard prefers mixing the substance with forty times its weight of a mixture of sodium carbonate with twice its weight of potassium nitrate, and burning in a covered crucible, or in an inclined combustion tube, according to the nature of the substance. These salts are chosen as being easily obtained free from halogens. In the case of very volatile substances, a layer of potassium nitrate is placed above the mixture containing the substance, and is fused before heating the mixture.

Another method of estimating the halogen elements in organic compounds is given by E. Kopp (*Deut. Chem. Ges. Ber.* viii. 769). The substance mixed with pure ferric oxide is introduced into a combustion-tube about 60 cm. long and 5 to 6 mm. in diameter, so as to form a loose layer from 12 to 13 cm. long; above this are placed several coils of fine pianoforte wire, and the rest of the tube is filled with dehydrated sodium carbonate. The part of the tube containing the iron wire is then heated to redness, and the heating is gradually extended to the closed end of the tube. By this treatment, the organic substance mixed with the ferric oxide is completely decomposed, and the halogens are retained in the form of iron-compounds having but little volatility. The tube is then left to cool, cleaned on the outside, and cut into fragments on a sheet of paper; the fragments are boiled with distilled water; the filtered liquid is acidulated with nitric acid; and the halogen-element contained in it is precipitated with silver nitrate in the usual way. This mode of treating the contents of the tube is apt however to be attended with loss, partly from the flying off of small glass splinters, and partly from the deliquescence of some of the halogen salts, in consequence of which they are absorbed by the paper. To obviate these sources of error, Klobukowski (*Ber.* x. 290) modifies the latter part of the manipulation by removing the tube from the furnace while it is still hot (but no longer red-hot), wiping it rapidly with a dry cloth, closing it with the finger, and plunging it into a tall beaker one-fifth full of distilled water, whereby the hot part of the tube is broken into small fragments. The cold part containing sodium carbonate is then washed out with distilled water; the contents of the beaker, together with the washings, are heated in the water-bath for 30 or 40 minutes; the liquid is filtered; the residue washed with hot water; and the solution of sodium chloride, bromide, or iodide thus obtained is precipitated with silver nitrate.

HASCHISCH. This substance, obtained from Indian hemp (*Cannabis indica*), has been examined by Preobraschensky (*Russ. Zeitschr. Pharm.* 1876, 705), who has obtained from it, together with resinous substances, a volatile base which in external appearance and the properties of its salts bears a strong resemblance to nicotine. The same base is obtained by distilling the herb with water.

HATCHETTOLITE. See NIOBATES.

* Carius's method of heating the organic substance with nitric acid in a sealed tube, modified by addition of a known quantity of silver nitrate, does not give good results, as the violent escape of gas which takes place on opening the tube is apt to occasion loss of liquid; and moreover the silver precipitate, at the high temperature of the reaction, is brought into a very dense state, which renders the washing out of the excess of silver nitrate a matter of great difficulty. A further objection to the process is that it affords no means of ascertaining when the decomposition is complete.

HAUYN. A microchemical reaction of minerals belonging to the hauyn family has been observed by A. Knop (*Jahrb. f. Min.* 1875, 74). When a thin section of a rock in which these minerals are present is heated for a few minutes in a platinum crucible with flowers of sulphur, the cross sections of hauyn and nosean exhibit a fine sky-blue colour. Whether this reaction is likewise exhibited by sodalite has not yet been ascertained, but it does not occur with the feldspars, or with nephelin, leucite, apatite, or natrolite.

HEAT. THERMOMETRY and CALORIMETRY. *Zero-point of Thermometers.*—For the determination of this point of the scale, C. Tellier (*Compt. rend.* lxxv. 572) recommends the immersion of the thermometer in water which has been cooled down, without solidifying, to a few degrees below 0° , and then made to freeze by agitation, or by the introduction of a fragment of ice, as the water is thereby brought back exactly to 0° , whereas water obtained by the melting of ice may have a temperature somewhat higher than the ice itself. B. F. Craig, on the other hand (*American Chemist*, 1875, iii. 325), objects to this method on the ground that the true zero-point is not the freezing point of water, but the melting point of ice; and this may be determined by plunging the instrument into melting snow, taking care that no water collects round the bulb. The excess of temperature sometimes indicated by thermometers is, for the most part, due, not to an originally incorrect determination of the zero-point, but to a contraction of the bulb which takes place in course of time.

T. M. Morgan (*Chem. News*, xxix. 111) observed that a thermometer which had been used for several days in distillations, and completely immersed in the vapour, showed temperatures 3° too low, in consequence of evaporation and precipitation of a portion of the mercury on the upper part of the tube; but by allowing the mercury to run down to the end of the tube, the condensed portion was re-collected, and the instrument then gave correct indications. In Geissler's thermometers a small quantity of hydrogen is enclosed, in order to prevent the volatilisation of the mercury.

On the determination of the Freezing and Boiling Points, see also Wiebe, as reported by Lowenherz (*Ber.* 1877, 469–474, 647; *Jahresb. f. Chem.* 1877, 91).

Differential Thermometers.—L. Pfaundler (*Wien. Acad. Ber.* [2te Abth.], lxxii., Dec. Heft.) explains the theory of the modified forms of Berthelot's differential air-thermometer (1st Suppl. 663), which he introduced some years ago, in order to eliminate the influence of barometric changes on the indications of the instrument. The parts common to the several forms are as follows: In the space whose temperature is to be determined, is a glass vessel V, communicating by means of a vertical capillary pressure-gauge with a second vessel V', whose temperature is known and is kept constant. At 0° , the vessels V and V' contain portions of air having a definite ratio of pressure. As long as this state of things is maintained, and the temperature in V' remains constant, the temperature to be measured is determined solely by the difference of height h of the two columns of mercury. This being known, it is easy to deduce a general formula applicable to all thermometers of this kind, the individual forms of which are included in it as special cases.

Let t be the unknown ordinary temperature of the vessel V.

T " " absolute " " " V.

t' the known ordinary temperature of the vessel V'.

T' " " absolute " " " V'.

P the gas-pressure at 0° in the vessel V (in millimeters).

P' " " " " " V'.

h the observed " difference " height, at t° , of the " two mercury columns.

The sign of h is to be considered positive when the pressure of the mercury-column is directed on the air in V.

We have then $P(1 + \alpha t) = P'(1 + \alpha t') + h$: whence, in centigrade temperatures,

$$t = \frac{P'}{P} t' + \frac{1}{\alpha P} + \frac{1}{\alpha} \left(\frac{P'}{P} - 1 \right)$$

or, more simply, in absolute temperatures,

$$T = \frac{P'}{P} T' + \frac{1}{\alpha P} h.$$

Since $\frac{P'}{P}$, $\frac{1}{\alpha P}$, and $\frac{1}{\alpha} \left(\frac{P'}{P} - 1 \right)$ are magnitudes which remain constant so long as the filling of the instrument does not vary, it is clear that the absolute temperature to be measured is the sum of two quantities, one of which is proportional to the

absolute temperature of the space V' , the other to the difference of height h . The preceding formula shows that in all cases the delicacy of the instrument, *i.e.* the increase of h for a rise of temperature of 1° , depends alone on P , and therefore on a quantity quite within the control of the instrument-maker. Pfundler's paper contains a full description of the several constructions, and gives the proportions of filling for $P = P'$, $P < P'$, $P > P'$, and $P = 0$.

PYROMETERS. *Siemens's Electrical Pyrometer* depends for its action on the regular increase of electric resistance in a metallic conductor, produced by rise of temperature. It consists essentially of a platinum spiral, duly protected, and so arranged that its resistance to an electric current can be measured while it is exposed to the temperature to be estimated (*Dingl. pol. J.* ccix. 419).

From experiments conducted by a Committee of the British Association, and reported by G. C. Foster, these pyrometers, after once or twice heating, exhibit an increase of resistance, but afterwards do not appear to undergo further alteration (*Chem. News*, xxviii. 173). From further experiments conducted by Foster, however, it appears that when the platinum spiral is protected by an iron tube, the instrument does not give constant results, on account of the great increase of resistance produced by heating. If, on the other hand, the use of iron be avoided, the indications of the instrument are sufficiently exact for most industrial applications. A full description, with drawings, of the electric pyrometer is given by Siemens (*Dingl. pol. J.* ccxvii. 291-297).

An *air-pyrometer*, provided with a condensed air pressure-gauge, is described by G. Codazza (*Dingl. pol. J.* ccx. 255).

A *calorimetric pyrometer*, for the measurement of high temperatures, is described by J. Salleron (*Mém. Scient.* [3], iii. 841; *Chem. News*, xxviii. 77). A cylinder of copper or platinum, surrounded by an envelope of the same metal to diminish the loss of heat by conduction or radiation, is raised to the temperature to be determined, and then quickly plunged into the water of a calorimeter. The temperature of the water is then noted, and the temperature to be determined is calculated from it by known methods.

An *acoustic pyrometer*, for measuring changes of temperature by the alterations thence resulting in the number of wave-lengths of the air in tubes, is described by A. M. Meyer (*Pogg. Ann.* cxlviii. 287; *Phil. Mag.* [4], xlv. 18).

A modification of Bunsen's ice-calorimeter (*2nd Suppl.* 595), in which common ice can be used instead of pure snow, and the observations are made with greater facility, is described by Schüller a. Wartha (*Ber.* viii. 1011).

Berthelot (*Ann. Chim. Phys.* [5], x. 168, 391, 447-458) describes a number of calorimetric instruments for measuring the quantities of heat given out in the absorption of gases by liquids; also an apparatus for determining the specific heat of liquids (*ibid.* xii. 559).

SPECIFIC HEAT.

a. Of Solids.—(1). Carbon, Boron, and Silicon.—H. F. Weber has continued his researches on the specific heat of carbon at different temperatures (*2nd Suppl.* 596), and has made similar observations on the specific heats of boron and silicon (*Jahresb. f. Chem.* 1874, 64).

The following table exhibits the true specific heats γ_t of these elements, deduced from the mean results of the several groups of experiments, together with a comparison of the mean heat-capacities C_{0-t} of laminar graphite and amorphous charcoal:

Diamond	Graphite	Crystallised Boron	Crystallised Silicon
$\gamma_{-50.5} = 0.0635$	$\gamma_{-50.3} = 0.1138$	$\gamma_{-39.6} = 0.1915$	$\gamma_{-39.8} = 0.1360$
$\gamma_{-10.6} = 0.0955$	$\gamma_{-10.7} = 0.1437$	$\gamma_{26.6} = 0.2382$	$\gamma_{21.6} = 0.1697$
$\gamma_{10.7} = 0.1128$	$\gamma_{10.8} = 0.1604$	$\gamma_{76.7} = 0.2737$	$\gamma_{57.1} = 0.1833$
$\gamma_{33.4} = 0.1318$	$\gamma_{61.3} = 0.1990$	$\gamma_{125.8} = 0.3069$	$\gamma_{86.0} = 0.1901$
$\gamma_{58.3} = 0.1532$	$\gamma_{138.5} = 0.2542$	$\gamma_{177.2} = 0.3378$	$\gamma_{128.7} = 0.1964$
$\gamma_{85.5} = 0.1765$	$\gamma_{201.6} = 0.2966$	$\gamma_{233.2} = 0.3663$	$\gamma_{184.3} = 0.2011$
$\gamma_{140.0} = 0.2218$	$\gamma_{249.3} = 0.3250$		$\gamma_{232.4} = 0.2029$
$\gamma_{206.1} = 0.2733$			
$\gamma_{247.6} = 0.3026$			
$\gamma_{306.7} = 0.4408$			
$\gamma_{306.5} = 0.4489$			
$\gamma_{985.0} = 0.4589$			
Laminar Graphite	Dense amorphous charcoal	Porous Wood-charcoal	
$C_{0-21.6} = 0.1605$		$C_{0-23.5} = 0.1653$	
$C_{0-99.7} = 0.1904$	$C_{0-90.9} = 0.1906$	$C_{0-99.2} = 0.1935$	
$C_{0-225.3} = 0.2350$	$C_{0-225.8} = 0.2340$	$C_{0-223.6} = 0.2385$	

The facts and general points of view established by the experimental results above recorded, may be arranged in the following groups :

(1). The specific heats of the isolated elements, carbon, boron, and silicon, vary to an extraordinary amount with change of temperature. From the lowest attainable temperatures, the specific heats of these elements increase regularly as the temperature rises, till, from a certain* temperature upwards, they remain nearly constant. For carbon, this temperature is near 600° , for silicon about 200° . For a rise of temperature from -50° to 600° , the specific heat of carbon increases to seven times, and that of boron to 2.5 times its value at the lower temperature. The specific heats of the elementary bodies are indeed, for the most part, not constant quantities, but are influenced by the physical state of the elements as much as by their chemical nature. The assumption hitherto made by physicists that the influence of temperature on the specific heat of the elements is quite insignificant, and easily explicable by the alterations of molecular structure produced by heat, and that, in regard to the fundamental law relating to the specific heats of the elements, it may be completely neglected, must, for the future, be regarded as untenable.

(2). The final and nearly constant values which the specific heats of carbon, boron, and silicon attain with increasing temperature are, in round numbers, 0.46 for C, 0.50 for B, and 0.205 for Si. The products of these numbers into the atomic weights of the three elements deduced from vapour-density determinations, are 5.5 , 5.5 , and 5.8 , numbers which approach nearly to the atomic heats of the metals and of the other solid non-metallic bodies (aluminium 5.7 , sulphur 5.5). Carbon, boron, and silicon enter therefore at certain temperatures into the range of the Dulong-Petit law, and conform to it at all higher temperatures. This law of the specific heats of the solid elements may now therefore be regarded as universal. The usual mode of stating it requires, however, to be somewhat altered, perhaps as follows :

The specific heats of the solid elements vary with the temperature; and for each element there is in the scale of temperature a certain point t° , above which the variation of the specific heat with increasing temperature becomes quite insignificant.—The product of the atomic weight into that value of the specific heat which holds good for temperatures above t° , yields, for all the solid elements, a nearly constant value comprised between the limits 5.5 and 6.5 . The smallest quantities of the elements carbon, boron, and silicon, hitherto found to enter into the molecules of their gaseous compounds, viz. 12, 11, and 28, are not multiples of the atomic weights of these elements, but the true atomic weights themselves.

(3). All the opaque modifications of carbon (the graphitic, dense and porous forms) exhibit the same specific heat; the opposite assumption hitherto admitted rests on defective investigations. Below red heat there exist in a thermic point of view, only two allotropic modifications of carbon, the transparent and the opaque. The specific heats of these two modifications differ the more widely as the temperature is lower, and as the temperature rises they steadily approach one another, till at 600° and above they become equal. From red heat upwards, there are, so far as specific heat is concerned, no allotropic modifications of carbon; from the point of the temperature-scale at which the optical difference between the two modifications of carbon vanishes, the thermic difference likewise disappears.

Mixter a. E. S. Dana (*Liebig's Annalen*, clxix. 388), by means of Bunsen's ice-calorimeter, find, for the specific heat of boron, the number 0.2518 ; of silicon 0.1710 ; of zirconium 0.6660 [at what temperatures?]

Schüller a. Wartha, by means of their ice-calorimeter (p. 925), have found the specific heat of distilled zinc $= 0.09393$; that of artificial titanite anhydride $= 0.1785$ and 0.1779 , and that of native rutile $= 0.1737$.

On the specific heats of *Cerium*, *Lanthanum*, and *Didymium*, see p. 418; of *Glucium*, p. 868.

2. Of Alloys.—The specific heats and expansions of several fusible alloys have been determined by W. Spring (*Ann. Chim. Phys.* [5], vii. 178–228), with the following results. The specific gravities are reduced to the vacuum and to 4° ; the volumes to 0° .

Rose's Alloy.

Bi = 48.9; Sn = 23.6; Pb = 27.6 per cent.—Sp. gr. = 9.5125.

Temperature	Volume	Specific Heat
29.0°	1.00682	0.0474
38.5°	1.01295	0.0562
68.2°	1.00700	0.0545
100.0°	1.04500	0.0881

D'Arcet's Alloy.

Bi = 49.2; Sn = 21.2; Pb = 27.6 per cent.—Sp. gr. = 9.6401.

Temperature	Volume	Specific Heat
29.0°	1.01485	0.0621
35.0°	1.01825	—
41.5°	1.01600	0.0528
56.5°	1.02493	0.0650
101.3°	1.09980	0.0907

Lipowitz' Alloy.

Bi = 50.0; Sn = 12.8; Pb = 26.9; Cd = 10.4 per cent.—Sp. gr. = 9.7244.

Temperature	Volume	Specific Heat
28.0°	1.03210	0.0634
50.0°	1.00115	0.0544
90.5°	1.05042	0.0625

Wood's Alloy.

Bi = 55.7; Sn = 13.7; Pb = 13.7; Cd = 16.8 per cent.—Sp. gr. = 9.1106.

Temperature	Volume	Specific Heat
53.25°	1.00265	0.0575
93.0°	1.03735	0.0918

These numbers show that the alterations of specific heat in the alloys mentioned follow the alterations of volume produced by heat, independently of the temperature.

β. Specific Heat of Liquids. 1. Of Mercury. According to A. Winkelmann, *Pogg. Ann.* (clix. 152–165), the specific heat of mercury diminishes with rise of temperature. Between 49.6° and 19.7° it is 0.03312, and between 142.2° and 25.5° it is 0.03278. Calculating from these numbers the values of the constants in the formula, $C = C + at$, we find $C = 0.03336$; $a = -0.000069$.

2. Of Water. J. Bosscha (*Pogg. Ann.* 1874; *Tubelbd.* 549–557) has endeavoured, by means of his own observations on the expansion of mercury (*Pogg. Ann. Ergänzbd.* v. 276; *Jahresb. f. Chem.* 1869, 82, 83) and the detailed account of Regnault's observations, to eliminate from the experiments of the latter on the specific heat of water (iii. 34), the errors which he supposes to have arisen from uncertainties in the temperature-determinations on which the results were founded. The following table exhibits a comparison of Regnault's values with Bosscha's corrected values, and likewise those calculated from the formula:

$$C = 1 + \delta \left(\frac{T + t}{2} - 18 \right)$$

in which, as a mean calculated from forty of Regnault's observations, $\delta = 0.0022$.

Limits of Temperature	Mean Sp. Heat according to Regnault	Corrected Sp. Heat	Calculated from the formula	Difference
110°–20°	1.0054	1.0112	1.0103	+ 0.0009
119°–23°	1.0063	1.0123	1.0117	+ 0.0005
134°–25°	1.0068	1.0126	1.0137	– 0.0011
157°–26°	1.0085	1.0148	1.0163	– 0.0015
173°–24°	1.0114	1.0176	1.0179	– 0.0002
188°–29°	1.0157	1.0215	1.0200	– 0.0015

These numbers show that the formula, $c = 1 + 0.0022(t - 18^\circ)$, represents the observations as nearly as can be expected from these experiments. If it be assumed

that the specific heat of water in the neighbourhood of the freezing point varies according to the same law as at other temperatures, the preceding formula may be replaced, with sufficient exactness, by $c = 0.00022t$, in which the specific heat of water at 0° is taken as unity.

3. Of Saline Solutions. Elaborate experiments on the specific heat of saline solutions have been made by C. Marignac (*Ann. Chim. Phys.* [5], viii. 410), in continuation of those already reported (*2nd Suppl.* 601). The results are given in the following table:

Chlorides, Bromides, Iodides

So far as these numbers are within the limits of experimental error, it may be inferred from them that the specific heat of a saline solution increases for the most part with its temperature; and the mean values show that this increase is greater as the solution is more concentrated. It must be observed, however, that these numbers show, not the absolute increase of the specific heat, but only the amount by which this increase exceeds that of the specific heat of the water, inasmuch as Marignac's experiments give, in all cases, the specific heat of the solutions as compared with that of water between the same limits of temperature.

The observations above recorded show unmistakably a certain degree of parallelism between the several series of salts. The bases for the most part range themselves in the same series, although to this rule there are numerous exceptions. For the greater number of salts, the experiments show that the specific heat of a saline solution is much less than the sum of the specific heats of its constituents, that is to say the salt and the water. This, however, is by no means a universal rule, for most of the acetates exhibit the contrary relation, especially those of zinc, lead and nickel; solutions of acetic acid exhibit a similar departure from the rule.

Specific Heat of Mixed Saline Solutions.—The following experiments by Marignac show that the differences between the molecular heats of solutions of mixed salts, and those of their constituents, are very small, and do not exceed the limits of experimental error:

	Single Solutions		Sum	Mixed Solutions		
	Molecular Heat			Sp. Heat	Mol. Heat	Temp.
Na ² Cl ² . . .	+ 50 Aq	893 }	1808	0.8810	1814	20°–50°

On the relations between the Specific Heat of Solutions and Liquid Mixtures and the quantities of heat evolved or absorbed in the act of dissolution or of mixture, see HEAT OF CHEMICAL COMBINATION (pp. 975-977, 980 and 993).

γ. Specific Heat of Gases. The determination of the ratio, $\frac{c_p}{c_v} = k$, of the specific heat of gases at constant pressure to the specific heat at constant volume (iii. 40), has lately been made the subject of numerous investigations. The following results have been obtained by Röntgen (*Pogg. Ann.* cxlviii. 580):

For air, $k=1.4053$ Mean of 10 experiments in which the greatest deviations from the mean were +0.0020 and -0.0021.
 „ CO₂, $k=1.3052$ Mean of 10 exp. Greatest deviations +0.0020 and -0.0028.
 „ hydrogen, $k=1.3852$ Mean of 8 exp. Greatest deviations +0.0045 and -0.0032.

E. Wiedemann (*Ann. Phys. Chem.* [2], ii. 195-217) has investigated the specific heats of vapours and their alterations according to the temperature. In the following table c_0 denotes the specific heat at 0° under constant pressure, referred to the unit of weight; 2α the alteration produced by one degree of temperature. For comparison, the same magnitudes are given for the vapour of carbon disulphide, as determined by Regnault; also the specific heats of the corresponding liquids according to Regnault, and that of benzene according to Schüller (*Pogg. Ann.* Ergbd. v. 251):

	Vapour		Liquid	
	c_0	α	c_0	α
Chloroform	0.1341	0.0000677	0.23235	0.000050716
Carbon Disulphide	0.1315	0.0000963	0.23523	0.000081515
Ethyl Bromide	0.1354	0.0001780		
Ether	0.3725	0.0004268	0.52901	0.0002958
Acetone	0.2984	0.0003869	0.5064	0.0003965
Acetic Ether	0.2738	0.0004350	0.52741	0.0005232
Benzene	0.2237	0.0005114	0.37980	0.0007200

These numbers show that the greater the specific heat of any liquid at a given temperature, the greater also is that of its vapour. The variations in the specific heats of liquids and of the corresponding vapours, are of the same order of magnitude, and, in a series of instances, nearly equal to one another.

In the next table, n denotes the number of atoms contained in a molecule of the liquids named in the first column; d the density of the several vapours; c_0 the specific heat under constant pressure referred to the unit of weight; c_p and c_v the specific heats at constant pressure and constant volume referred to equal volumes (spec. heat of air = 1); $\frac{c_p}{c_v}$ the ratio of the two; $\frac{L}{H}$ the ratio of the energy, L , of the progressive motions to the total energy, H , contained in the gas; α' the magnitude α (preceding table) referred to the volume, its double value representing the alteration of the specific heat referred also to the volume:

	n	d	c_0	c_p	c_v	$\frac{c_p}{c_v}$	$\frac{L}{H}$	α'
Air	2	1	0.2389	1	0.7119	1.405	0.607	0.000
Hydrogen	2	0.0692	3.410	0.9877	0.6996	1.411	0.617	0.000
Carbon Monoxide	2	0.9674	0.2426	0.9822	0.6941	1.415	0.622	0.000
Carbon Dioxide	3	1.5290	0.1952	1.248	0.959	1.300	0.450	0.001389
Carbon Disulphide	3	2.6325	0.1315	1.448	1.160	1.248	0.372	0.001061
Nitrogen Monoxide	3	1.5250	0.1983	1.266	0.977	1.294	0.441	0.001461
Ammonia	4	0.5894	0.5009	1.236	0.947	1.303	0.454	0.007593
Chloroform	5	4.192	0.1342	2.358	2.070	1.139	0.208	0.001176
Ethylene	6	0.9674	0.3364	1.361	1.072	1.270	0.403	0.00334
Ethyl Bromide	8	3.7316	0.1354	2.106	1.818	1.159	0.237	0.002768
Acetone	10	2.0220	0.2984	2.468	2.180	1.132	0.198	0.003274
Benzene	12	2.6043	0.2237	2.523	2.235	1.129	0.184	0.004581
Ethyl Acetate	14	3.0400	0.2619	3.333	3.045	1.094	0.141	0.005537
Ethyl Oxide	15	2.5563	0.3725	3.984	3.696	1.078	0.116	0.004564

It is remarkable that the variation of the specific heat α' referred to the volume increases, for the most part, with the number of atoms in the molecule.

The difference between the specific heat of the same gas at constant pressure and at constant volume is due to the fact that when the gas is heated under constant pressure, and therefore allowed to expand, there is a certain amount of work employed in separating the particles of the gas, and a certain quantity of heat must be expended in performing this work, just as if the gas were confined in a cylinder with a movable piston which had to be raised; whereas, when the gas is heated under constant volume and therefore not allowed to expand, there is no such work to be done, and therefore all the heat applied is expended in raising the temperature of the gas, that is to say, in increasing the *vis viva* of its molecules. Now Clausius has calculated, on the principles of the mechanical theory of heat, that in a perfect gas the ratio of $c_p : c_v$ should have the value 1.67. But the numbers in the preceding table show that for all the ordinary gases and for many vapours, the ratio, as determined by experiment, is considerably less than this, varying from 1.405 for air to 1.078 for ether-vapour. Hence it may be inferred that when these gases, all of which are diatomic, are heated under constant volume, part of the heat is expended in performing, not external work, but a certain amount of work within the two-atom molecule. That this is the correct view is shown by the case of mercury-vapour, which is a monatomic gas, and in which, as appears from the recent experiments of Kundt a. Warburg on the ratio between the lengths of the same wave of sound in air and in mercury-vapour (*Deut. Chem. Ges. Ber.* viii. 945), this interior work is not produced, and consequently the ratio $c_p : c_v$ is exactly that which is indicated by theory, viz. 1.67.

If similar experiments were made on the vapour of sulphur, which at temperatures not far removed from its boiling point, is hexatomic, and on those of phosphorus and arsenic, which are tetratomic, it is probable that the ratio of the two specific heats would be found to be less than in the ordinary diatomic gases.

EXPANSION BY HEAT.

1. **Of Gases.** Andrews (*Proc. Roy. Soc.* xxiii. 514; xxiv. 455) infers from further experiments on the change of volume of carbon dioxide at different pressures and temperatures that, for the ordinary gaseous state, Gay-Lussac's law does not hold good either at constant pressure or at constant volume; but that the expansion by heat of a body in the ordinary gaseous state, whether it be measured by the increase of volume under constant pressure, or by the increase of elastic force under constant volume, is not a simple function of the initial volume or of the initial elastic force, but a complex function which changes with the temperature.

According to Mendelejeff a. Kajander (*Deut. Chem. Ges. Ber.* viii. 1681), the expansion-coefficient of atmospheric air under a pressure of 750–770 mm. is $\alpha = 0.0036893$; in a subsequent communication (*Compt. rend.* lxxxii. 450), the same authors give for the expansion-coefficient under ordinary atmosphere pressure, $\alpha = 0.0036843$.

Troost a. Hautefeuille (*Compt. rend.* lxxxiii. 333) have determined the compressibility and expansion-coefficients of certain vapours which can be mixed without entering into chemical combination. In the following table, the 'contraction' signifies the difference between the volume as found by observation, and that which it should be according to Boyle's law, when the pressure is increased from 0.5 to 1 atmosphere.

Vapour	B. P.	Contraction		Mean Expansion-coefficient	
		at 100°	at 180°	from 100° to 125°	from 125° to 180°
Silicon chloride . . .	59°	2.07 per cent.	0.455 per cent.	0.00449	0.00399
Carbon tetrachloride . .	78.1°	1.38 "	1.367 "	0.00470	0.00414
Phosphorus trichloride .	78°	" "	1.548 "	0.00489	0.00417

Hence it appears that, for each of these vapours, the result of a density-determination at a given temperature must vary with the pressure, and at a given pressure with the temperature; and in calculating the elastic force of a mixture of two vapours, of known weight, volume, and temperature, from the sum of the elastic forces of the separate vapours, making use of the theoretical data applicable to these vapours under low pressure and high temperature, numbers are obtained, the sum of which exceeds the total pressure found by observation. This is a circumstance which requires to be taken into account in the determination of the densities of vapours mixed with air or nitrogen gas, as in Playfair a. Wanklyn's experiments on the density of nitrogen tetroxide (iv. 76), and those of Wurtz on the vapour-density of phosphorus pentachloride (*Compt. rend.* lxxvi. 601).

Expansion of Mercury. A. Wüllner (*Pogg. Ann.* cliii. 440–447) has discussed the experiments of Regnault on the absolute expansion of mercury at different temperatures (iii. 56), and has calculated a new formula which represents the experimental results more exactly than that of Regnault, or than the formula deduced by Bosscha (*Pogg. Ann. Ergänzungsband*, v. 276). The mean coefficient of expansion of mercury for temperatures between 0° and 100°, calculated by Wüllner's formula, is somewhat greater than that given by Regnault's formula, and for lower temperatures (0°–30°) Wüllner's formula gives a value of the mean coefficient about 1 per cent. larger than that deduced from the formula of Regnault, thus:

	Wüllner	Regnault
0°–100°	0.00018253	0.00018153
0°–30°	0.00018153	0.00017976

A table of the results calculated according to the formulæ of Regnault, Bosscha, and Wüllner is given in the *Jahresb. f. Chem.* 1874, 70.

Expansion of Solids. Experiments on the expansion of metals and of woods have been made by P. Glatzel (*Ann. Chim. Phys.* clx. 497–514; *Chem. Soc. J.* 1877, ii. 20), with a new apparatus constructed by Fues of Berlin. The numbers in the following table give the increase of length, in millimeters, of bars 1 decm. long for a rise of 1°, so that if α denote the usual coefficient of expansion, i.e. in parts per million, these numbers must be denoted by 100 α . For comparison the numbers obtained by Fizeau by his optical method (1st *Suppl.* 675) are also given.

	Glatzel	Fizeau	
Steel	0.001256	0.001322	Different sorts.
		0.001101	
		0.001095	
Iron	0.001387	0.001210	"
		0.001188	
		0.001166	
Copper	0.001705	0.001696	
Tin	0.002212	0.002234	
Aluminium	0.002354	0.002318	
Lead	0.002936	0.002924	
Cadmium	0.003121	0.003069	

In the determination of all these values by Glatzel, both the lengthening of the bar by heating, and its subsequent shortening by cooling down to the temperature of the air, were taken into account; and in this it was noticed, as previously found by other observers, that the bars on cooling did not assume exactly their original length, but became shorter.

For woods, the following values of 100 α were obtained in the direction of the fibres.

Maple	0.000502	Beech	0.000716
Hornbeam	0.000604	Pear	0.000721
Rosewood	0.000608	Oak	0.000746
Spruce fir	0.000608	Poplar	0.000761
Box	0.000623	Mahogany	0.000784
Elm	0.000635	Ash	0.000951
Alder	0.000699	Ebony	0.000970

The peculiarities above noticed in heating and cooling in the case of the metals were likewise observed in the woods.

The expansion of phosphorus has been investigated by Pisati and de Franchis (*Gazz. chim. ital.* 1874, 457). The specific gravities of solid and melted phosphorus at various temperatures were found to be as follows:—

	Solid		Fused
at 0°	1.83676	at 40°	1.74924
„ 20°	1.82321	„ 100°	1.69490
„ 44°	1.80681	„ 280°	1.52867

The volume-ratio between solid and liquid phosphorus was found to be 1.03446 at 40° and 1.0504 at 44°. For the latter temperature H. Koppe had previously found the value 1.0343 (*Liebig's Annalen*, xciii. 129). The volume of solid phosphorus at t° , referred to that at 0°, is given by the equation:

$$V_t = V_0 + 0.000200t + 0.000000115t^2;$$

the volume of liquid phosphorus between 50° and 280°, referred to that at 50°, by

$$V_t = V_{50} + 0.0002969(t-50^\circ) + 0.0000002115(t-50^\circ)^2.$$

The mean expansion-coefficient for solid phosphorus is

$$K = 0.0003674 + 0.000000211t.$$

that of liquid phosphorus at 50°, and above, is

$$K = 0.0005167 + 0.000000370(t-50).$$

The statement of Schrötter (*Liebig's Annalen*, lxxiii. 247) that melted phosphorus at 44° has a higher specific gravity than solid phosphorus at 10°, may be explained by the contraction which attends the partial conversion of ordinary into red phosphorus. In the experiments of Pisati a. de Franchis, this change was as far as possible prevented.

Sulphur.—Despretz found in 1838 that the expansion-coefficient of melted sulphur increases with tolerable regularity as the temperature rises (from 110° to 250°), H. Kopp (*Liebig's Annalen*, xciii. 129) found the expansion between 126° and 152° to be uniform, but different in amount from that given by Despretz. A new determination has been made by G. Pisati (*Gazz. chim. ital.* 1874, 29) by two methods, with the dilatometer and the weight-thermometer, the result of which is to show that at 150° the expansion is not quite uniform, but exhibits only very slight variations, and that between 150° and 160° a sudden and very considerable diminution in the rate of expansion takes place, whilst between 160° and 300° it increases, but so slowly, that even at 300° the rate still falls short of the value which it had at 150°. The mean coefficients determined by Pisati are about $\frac{1}{5}$ smaller than those of Despretz, and (between 126° and 152°) about $\frac{1}{50}$ larger than those given by Kopp. The coefficient of expansion diminishes from the melting point to about 170°, where it attains a minimum, and then exhibits a normal increase. Moitessier (*Jahresb. f. Chem.* 1866, 27) attributes these variations to the formation, during the heating, of the insoluble modification of sulphur, which has a smaller coefficient of expansion than soluble sulphur. The quantities of insoluble sulphur (in percentages of the total amount) formed at different temperatures were found to be as follows:

143°	148.5°	159.9°	167.4°	179.4°	213.5°	249.9°	284.9°	440°
0	2.54	7.03	14.77	22.60	27.09	26.31	29.31	30.27

According to these numbers, the effect of the less expansible insoluble sulphur in diminishing the expansion coefficient of the whole increases from 143° to about 200°, and then becomes nearly constant.

Pisati, by heating melted sulphur to 300°, and then cooling it to 125°, obtained a curve of expansion agreeing very nearly with that laid down from Moitessier's determinations.

According to Scichilone (*Gazz.* 1877, 501), sulphur, precipitated from sodium persulphide and purified by repeated crystallisation from carbon sulphide, gives, when gradually heated up to 440°, values of the coefficient of expansion agreeing with those obtained by Moitessier.

Ebonite. F. Kohlrausch (*Pogg. Ann. Ergänzbd.* vi. 314) finds that the expansion-coefficient of ebonite for 1° is—

$$\begin{aligned} &0.0000770 \text{ between } 16.7^\circ \text{ and } 25.3^\circ \\ &0.0000842 \quad \quad \quad 25.3^\circ \quad \quad 35.4^\circ \\ &\text{therefore } \alpha_t = 0.000061 + 0.00000076t. \end{aligned}$$

These numbers show that both the expansion of ebonite, and the rate of its increase with rise of temperature, are very considerable. In this respect ebonite presents a marked contrast to soft caoutchouc, the difference being probably due to the sulphur in the ebonite. A rod of ebonite about 1 cm. thick was found, when heated, to take a considerable time to contract to a constant length—an effect which is attributed by Kohlrausch, not only to the bad conduction of the material, but to the fact that expansion by heat, like elastic alteration of form, does not take place instantaneously, but goes on with gradually diminishing rapidity after the alteration of temperature has taken place, as indeed is indicated by Matthiessen's experiments on glass rods (*Proc. Roy. Soc.* xiv. 551).

FUSION AND SOLIDIFICATION.

The softening and melting points of **metallic alloys** have been determined by R. Gnehm (*Monit. scient.* [3], iv. 424) by the following method:—Two rings of the alloy free from oxide were fitted one into the other, and suspended by a hooked iron wire in a heated bath of oil or paraffin; and the temperatures were noted at which the rings first became elongated into ellipses, then into a vertical strip, and finally melted. The following are the results:

Alloy		Softening point	Melting point
Tin	Lead		
2	5	185°	189°
2	6	189°	194° to 195°
2	7	192°	198°
2	8	202°	208° to 210°

Melting Points of Fat and Wax. C. H. Wolff (*Dingl. pol. J.* cccvii. 411) has determined the melting points of the following kinds of fat and wax, by a modification of the method described by Löwe (*Dingl. pol. J.* cci. 250; *Chem. Soc. J.* 1871, 973).

	m. p.		m. p.
Ceresin	71.35°	Paraffin	49.5°
Yellow wax. . . .	64.0°	Spermaceti	45.2°
White wax	62.8°	Mutton suet	45.6°
Yellow wax in cakes * . .	60.1°	Japan wax	41.3°
Stearin	51.45°	Cacao butter	31.8°

Melting Points of Homologous Compounds. The following regularities in the melting points of homologous compounds have been observed by A. Baeyer (*Deut. Chem. Ges. Ber.* 1877, 1286). Both in the oxalic series and in the series of normal fatty acids, a member having an uneven number of carbon-atoms has, without exception, a lower melting point than the acid which contains one more carbon-atom. In the oxalic series of acids, the melting point of the acids with uneven numbers of carbon-atoms rises with increasing quantity of carbon, whereas that of the acids with even numbers of carbon-atoms falls, so that the two series meet at a certain intermediate point. In the fatty acid series, the melting points rise both in the even and in the uneven series, with exception of the lowest members. This is seen from the following table, taken from Fittig's *Lehrbuch*:

Melting Points of the Acids of the Oxalic Series.

Normal Succinic, $C^4H^6O^4$	180°	Normal Pyrotartaric, $C^8H^8O^4$	97°
Adipic, $C^6H^{10}O^4$	148°	α -Pimelic, $C^7H^{12}O^4$	102°
Suberic, $C^8H^{14}O^4$	140°	Azelaic, $C^9H^{16}O^4$	106°
Sebacic, $C^{10}H^{18}O^4$	127°	Brassylic, $C^{11}H^{20}O^4$	108°

Melting Points of the Normal Fatty Acids.

Acetic, $C^2H^4O^2$	+ 17°	Propionic, $C^3H^6O^2$, remains fluid	
Butyric, $C^4H^8O^2$	0°	Valeric, $C^5H^{10}O^2$

Melting Points of Metallic Salts. T. Carnelley (*Chem. Soc. J.* 1876, i. 489–509; 1877, i. 365–388; 1878, *Transactions*, 273–281) has determined the melting points of a large number of metallic salts by the two following methods:

1. *The Specific Heat Method.*—The principle of this method is as follows: When a small quantity of the salt is placed in a weighed platinum crucible, and the latter is suspended in the flame of a Bunsen's burner or of a blowpipe, the temperature of the crucible after a time reaches that at which the salt fuses, if the latter is not beyond a certain limit; and now if the crucible, the instant the salt is seen to melt, be dropped

* Probably mixed with Japan wax.

into a known weight of water, of known temperature, and the rise in temperature noted, then, from the well-known equation for specific heats (iii. 27), we obtain the initial temperature of the crucible at the moment the salt melted, and therefore the temperature at which the fusion occurred, assuming that the mean temperature of the crucible is the same as that of the salt at the moment of melting. (For description and figures of apparatus, see the first paper above cited.)

Solidifying points may be determined in a similar manner, but with this difference, that when the salt has completely melted, the lamp is turned out, and the crucible while still suspended is carefully watched, and at the moment when the salt begins to solidify, dropt at once into the calorimeter, after which the process is the same as before. The point of solidification may usually be seen without difficulty, but sometimes the solidified salt forms a perfectly transparent glass, in which case it is very difficult, if not impossible, to tell when the salt becomes solid. In that case it is best to place a bright gas flame at the opposite side of the crucible, so that its image may be seen reflected from the surface of the melted salt, which image, the moment the salt solidifies, becomes blurred and indistinct, or disappears altogether.

The following table exhibits the melting and solidifying points of several salts determined by this method and the differences between them:

	M. p.	S. p.	Difference
KNO ₃	353°	332°	21°
KClO ₃	372°	351°	21°
KCl	434°	415°	19°
KI	639°	622°	17°
KBr	703°	685°	18°
K ₂ CO ₃	838°	832°	6°

2. *The Time-method.*—This method depends upon the following principle: If three metallic salts, A, B, and C, which fuse at different temperatures, such that A fuses before B, and B before C, be arranged on a cold block of smooth iron, and this be placed in a muffle kept at a constant high temperature, and if x be the number of seconds which elapse between the melting of A and B, and y the number of seconds between the melting of A and C, then the ratio $\frac{y}{x}$ is approximately constant for the

same three salts, whatever may be temperature of the muffle, provided only it is considerably higher than that at which C fuses. This principle affords the means of determining the melting point of a refractory metallic salt by comparison with salts whose melting points have been determined by other methods. The following table shows the mean results of comparative experiments made by this method and by the specific heat method.

Salt	HgCl ²	NaNO ³	AgBr	TlH	AgCl	AgI	NaI	CaBr ²	Li ² CO ³	KBr	NaBr	CaCl ²	NaCl
Time method	320	345	453	472	490	591	654	707	699	733	731	745	815
Specific heat method	315	345	453	466	477	554	661	710	729	733	742	753	811
Difference	+ 5	0	0	+ 6	+ 13	+ 37	- 7	- 3	- 30	0	- 11	- 8	+ 4

Of the two methods, Carnelley considers the one depending on specific heats to be the more accurate, since the results obtained by it for the same salt agree more nearly among themselves than do those arrived at by the time method, while the exact point at which the salt melts is more easily seen in the case of the former. It has, moreover, the advantage of being entirely *independent of any fixed melting points*; whereas, in the time method, the melting points of the standard salts, as found by the other method, have to be assumed, so that the results which it yields are not wholly independent.

The specific heat method is, however, liable to an error arising from the overheating of the wire which suspends the crucible, and tending to make the results too high. This error may be reduced to a minimum by using a very thin suspending wire. The following table gives the melting points of a considerable number of salts determined with attention to this precaution. The new determinations relating to the salts previously examined are all lower than those given in the two preceding tables, partly from the cause just mentioned, and partly in consequence of a more exact determina-

tion of the heat-value of the calorimeter used in the experiments. For comparison, the melting points of some of the salts, as determined in the ordinary way with the mercurial thermometer (corrected, when not otherwise stated), or by other methods, are given in foot-notes. The values determined by the specific heat method are the means of several observations:

The letter a before a number denotes that the salt referred to melts above that temperature.

(¹) 146 (Carnelley); determined by thermometer. (⁷) 184 (Carnelley).

(²) 219 (Carnelley); Dictionary, iv. 104; 198 (Pohl, *Jahresb.* 4, 59; not stated whether correct or not. Determined by covering the bulb of a thermometer with a layer of fused salt, and then placing in an empty tube and heating); 218°, resolidifies at 212° (Carnelley).

(³) 200 (Carnelley). Anhydrous oxalic acid.

(⁴) 223 (Oppenheim, *Clarke's Constants of Nature*, but reference there given incorrect); 244 (Williams); 244 (Carnelley).

(⁵) 264 (Carnelley).

(⁶) 287 (Williams); 288 (Carnelley).

(⁷) 314 (Braun, *Pogg. Ann.* 154, 190); 310 (Person, *Ann. Chim. Phys.* 1847, xxi. 329); resolidifies at 313 (Schaffgotsch, *Pogg. Ann.* cli. 293); 319 (Carnelley).

(⁸) 342 (Braun, *Pogg. Ann.* cli. 190; 339 (Person, *Ann. Chim. Phys.* xxi. 329); resolidifies at 338 (Schaffgotsch, *Pogg. Ann.* cli. 293).

(⁹) 384 (Pohl, *Jahresb.* iv. 59), vide under AgNO³. It cannot be correct, since KClO³ melts above KNO³. It is not stated whether 334° is the corrected temperature or not; if not the correction would make it several degrees higher.

(¹⁰) Did not melt but volatilised. The temperature given represents that at which all the salt had volatilised without melting. It therefore melts above 405.

(¹¹) Above 260 (Crookes, *Chem. Soc. J.* 1864, 139).

(¹²) Very difficult to see when it melted. Appeared to soften and melt gradually.

(¹³) Prepared by precipitating AgNO³ with an excess of NaPO³, the latter being obtained by fusing

In the case of some of the salts mentioned in the above table, it was impossible to determine the melting point in the ordinary way, as they decomposed into metallic oxide and free acid, owing to the presence of moisture in the air and from combustion of the lamp flame. The method adopted, therefore, was to heat the salt in question with two or three others of known melting point on a sheet of platinum, and observe between which two it melted. By this means the salt did not appear to decompose till after fusion, the melting point being reached much sooner than when the large platinum crucible was used.

VAPORISATION.

Boiling Points. A simple apparatus for the exact determination of boiling points is described by Berthelot (*Ann. Chim. Phys.* [5], xii. 562). It consists of a long-necked glass flask, having a capacity of 100–200 c.c. The neck is enclosed in a wide glass tube, closed with two perforated corks, and passes through the lower cork, and the tube of a thermometer passes through both, while its bulb is wholly immersed in the vapour. The lower cork is also traversed by a bent tube, which serves to carry off the vapour to a condenser, and thus prevent any excess of pressure in the apparatus.

FIG. 3.

Another apparatus for the determination of boiling points under the normal barometric pressure is described by H. Bunte (*Liebig's Annalen*, clxviii. 139); and an apparatus for determining boiling points at all pressures below that of the atmosphere is described by Lothar Meyer (*ibid.* clxv. 303). The air is pumped out of the distillatory apparatus by means of a Bunsen's pump, and this apparatus is connected with a second distillatory apparatus and pump, in such a manner that the action of the pump stops as soon as the desired pressure is attained, but begins again as soon as any alteration of pressure takes place.

Determination of Boiling Points with small quantities of Substance.—A method for this purpose is described by H. Chapman Jones (*Chem. Soc. Jour.* 1878, xxxiii. 175), founded on the principle—previously applied to the determination of boiling points by Regnault—that the boil-

ing point of a substance is the temperature at which the tension of its saturated vapour is equal to the standard atmospheric pressure. A piece of glass tube, 4 mm. internal diameter and 200 mm. long, is bent in the form of a U, so that one end, which is open, extends at least 15 mm. beyond the other, which is closed. The bend is made in the form of a circle about 20 mm. in diameter. The liquid, two or three drops of which suffice for the determination, is introduced—by a method described at length in the paper above cited—into the closed end of the U-tube; the open end is placed

microcosmic salt. Became black on heating; fused mass, after cooling in water, was yellow, probably from conversion into Ag^+PO^+ .

(¹⁴⁸) 580 (Braun, *Pogg. Ann.* cliv. 190).

(¹⁴⁹) 450 (Rodwell, *Chem. News*, xxxi. 4). This was simply deduced from the fact that it melted somewhat above the melting point of zinc, 412.

(¹⁵⁰) Difficult to see, as it appeared to soften and then melt.

(¹⁵¹) Became black on heating; fused mass, after cooling in water, was yellow, probably due to formation of Ag^+PO^+ .

(¹⁵²) 666 (Braun, *Pogg. Ann.* cliv. 190).

(¹⁵³) Very deliquescent. Melting point very difficult to see.

(¹⁵⁴) Wt. %: became very dark on heating (dark-green?), then whitish-yellow.

(¹⁵⁵) 960 (Braun, *Pogg. Ann.* cliv. 190).

(¹⁵⁶) Becomes dark grey on heating, and white again at a red heat.

(¹⁵⁷) Undergoes some change on heating, as $\text{Pb}(\text{PO}^+)^2$.

(¹⁵⁸) 910 (Braun, *Pogg. Ann.* cliv. 190).

(¹⁵⁹) 1280 (Braun, *Pogg. Ann.* cliv. 190).

(¹⁶⁰) Artificial vaundinite.

(¹⁶¹) 780 (Braun, *Pogg. Ann.* cliv. 190).

(¹⁶²) 920 (Braun, *Pogg. Ann.* cliv. 190).

(¹⁶³) 1150 (Braun, *Pogg. Ann.* cliv. 190).

underneath the surface of some mercury contained in a small porcelain crucible. The whole is then slung by means of copper wire into a water or paraffin bath, and the temperature of the bath is gradually raised. The liquid will of course boil and the vapour will drive the air before it. On cooling, the whole tube—called a *tension-tube*—is filled with mercury, a bubble of liquid occupying the top of the bend. The tube is then inverted and the liquid transferred to the closed end of the tube. Any water or paraffin is now removed from the tube, and some mercury emptied from the open limb. The method of determining the boiling point is as follows:—The tube is immersed in a paraffin bath, care being taken that the open end is freely exposed to the air. The temperature is then gradually raised, and as the temperature approaches the boiling point of the substance, the mercury falls in the closed limb, the tube being gently tapped. At the moment the mercury levels in the two limbs are equal, the temperature of the bath is taken by a delicate thermometer placed close to the liquid in the closed limb. The bath is allowed to cool, and the temperature at which the levels pass each other again noted; and in this manner six observations are made, the mean of which gives the uncorrected boiling point.

FIG. 4.

As an example of the determination by this method of the boiling point of a liquid under different pressures, the numbers obtained with carbon disulphide—usually said to boil at 46.6° under ordinary pressure, may be cited:

Pressure in mm. . . .	736.0	744.5	752.0	762.0
B. p. at these pressures . .	45.1°	45.5°	46.0°	46.3°
B. p. at 760 mm. . . .	46.0°	46.1°	46.3°	46.2°

By using a spermaceti bath, boiling points up to 300° may be determined.

Another apparatus for the same purpose is described by P. T. Main (*Chem. News*, xxxv. 59). It consists of two principal parts—a boiler-tube and a pressure-tube. The boiler-tube is a thin, narrow, glass tube, V-shaped, hermetically sealed at its short end, and open at the long end; the short end may be about 2 inches in length, the long end about 18 inches. The pressure-tube is a vertical glass tube, which can be connected with the open limb of the boiler-tube by a drying-tube, and dips into water contained in a wider glass tube: by raising or lowering this wider tube, the pressure within the open limb of the boiler-tube may be made greater or less than the atmospheric pressure. The boiler-tube is held so that the bend of it is its lowest point; in this position the liquid to be operated on is distilled or poured into it in such quantity that on inclining the tube, the air in the closed limb may be displaced by the liquid, which may be made to occupy the whole of this limb and a small portion of the open limb. By boiling this portion of liquid in the tube sufficiently, all dissolved air or gases may in general be expelled from the liquid, the space above which in the closed limb is then occupied by the vapour of the liquid only. The boiling point of the liquid must be known or determined first approximately, which is easily done by a preliminary experiment; and it may then be determined accurately (if less than that of water) by immersing the boiler-tube in water at a temperature a little higher than the boiling point of the liquid, connecting it with the pressure-tube, and increasing or diminishing the pressure by means of this so as to make it exactly equal to that of 760 mm. of mercury at 0° . By carefully lowering the temperature of the water till the liquid in the boiler-tube stands at exactly the same level in both limbs, and taking a few observations of the temperature while the liquid is steady in the boiler-tube, or oscillating slowly about this mean position, it is possible to determine the boiling point at 760 m.m., with considerable accuracy, with so little as 1 c.c. of liquid.

For liquids whose boiling points are higher than that of water the process would necessitate the use of dense aqueous solutions, or of some other liquid which can be heated to higher temperatures than water without boiling or decomposing.

High Boiling Points.—A method for the approximate estimation of the boiling points of substances which boil above the range of the mercurial thermometer is given by Carnelley and Carleton-Williams (*Chem. Soc. J.* [1878], xxxiii. 281). It consists in noticing whether certain salts melt on exposure to the vapour of the boiling substances, the melting points of the salts determined by Carnelley (pp. 936–938) being utilised for the purpose.

For temperatures below 500° the substance may be boiled in an ordinary distilla-

tion flask, provided with a perforated cork, through which pass several capillary tubes containing salts which melt at known temperatures. Substances which boil above 500° must be heated in a tube of hard glass by means of the blowpipe. The tube is held in a slanting position, and passes through a hole in the centre of a piece of sheet iron, in order to protect that portion which is above the boiling liquid from the action of the flame. The capillary tubes containing the salts must also be made of hard glass. When the vapour of the boiling substance attacks glass, it is often difficult to observe whether the salts have melted. In this case it is advisable to protect the tubes from corrosion by inclosing them in thin glass sheaths.

In the following table the boiling points determined by this method (Column III) are compared with the actual temperature (Column IV) measured by a mercurial thermometer, the stem of which was completely immersed in the vapour of the boiling liquid. Column I contains the formulæ of the substances, and II the salts used in determining the boiling point. The symbol + is used to indicate that the salt melts, and - to show that no change takes place.

I	II	III	IV	Remarks
HgCl ² . .	{ + NaClO ³ - NaNO ³	{ 302°-316°	303°	{ In this Dictionary (iii. 897) the b. p. given is 295°.
HgBr ² . .	{ + NaNO ³ - KNO ³	{ 316°-339°	319°	
SbCl ³ . .	{ + AgNO ³ - HgI ²	{ 218°-241°	221°	{ According to Kopp, 223°. Capitaine, 230°.
Diphenyl .	{ + HgBr ² - Ti ² CO ³	{ 244°-278°	257°	
Benzoic acid, m.p. 121°	{ + HgBr ² - Ti ² CO ³	{ 244°-278°	249°	{ Kopp (<i>Jahresb.</i> viii.), m. p. 121.4; b. p. 249.2.

Now on referring to the list of melting points previously mentioned, it will be seen that but few of the salts melt below 300° ; for these temperatures, therefore, the boiling point cannot be brought within such narrow limits as for higher temperatures. It must also be remembered that the method is meant to be used only for temperatures for which a mercurial thermometer cannot be employed, and in cases where merely an approximate knowledge of the temperature is required. The accuracy can obviously be increased by determining the melting points of a larger number of salts.

The following numbers show that good results are obtained at high temperatures:—

I	II	III	Remarks
Hg. . .	{ + NaNO ³ + KNO ³ - KClO ³	{ 339-359°	{ The boiling point of Hg has been carefully determined by Reg- nault (<i>Jahresb.</i> xvi. 70) and by Dulong and Petit. The former found it to be 357.25°, and the latter 360°. Regnault (<i>Relation des Expé- riences, &c.</i> , ii. 527) states the b. p. of sulphur to be 447°. Hit- torf gives the same number, but according to Dumas, sulphur boils at 440°. Most of the de- terminations of the boiling points of S and Hg appear to have been made by means of the iodine pyrometer.
Sulphur purified by recrystal- lisation from carbon disul- phide . .	{ + TiI + ZnI ² - AgCl	{ 446-451	

The method has been successfully applied in fractionating high-boiling hydrocarbons, and in determining the boiling points of the following substances:—

I	II	III	Remarks
Anthracene, the specimen melts at 212.5°	$\left. \begin{array}{l} + \text{KNO}^3 \\ - \text{KClO}^3 \end{array} \right\}$	$339-359^{\circ}$	Graebe and Liebermann (<i>Lieb. Ann.</i> , Supp. vii. 264) state that anthracene boils a little above 360° , but they do not describe how they measured the temperature.
HgI^2	$\left. \begin{array}{l} + \text{NaNO}^3 \\ + \text{KNO}^3 \\ - \text{KClO}^3 \end{array} \right\}$	$339-359$	Prepared by triturating iodine and mercury in presence of a small quantity of alcohol.
AsI^3	$\left. \begin{array}{l} + \text{ZnBr}^2 \\ - \text{Ba}(\text{ClO}^3)^2 \end{array} \right\}$	$394-414$	Prepared by subliming a mixture of As and iodine.
BiCl^3	$\left. \begin{array}{l} + \text{Ba}(\text{ClO}^3)^2 \\ + \text{TiCl} \\ - \text{TiI} \end{array} \right\}$	$427-439$	Two specimens, one prepared by dissolving bismuth in aqua regia, the other by burning the metal in chlorine, gave the same results. The chloride decomposes slowly on long continued boiling; chlorine is evolved, and golden needle-shaped crystals are deposited.
BiBr^3	$\left. \begin{array}{l} + \text{AgCl} \\ + \text{Ti}^4\text{V}^2\text{O}^7 \\ + \text{AgPO}^3 \\ - \text{PbCl}^2 \\ - \text{AgI} \end{array} \right\}$	$454-498$	Prepared by the action of bromine on the pure metal.
SbI^3	$\left. \begin{array}{l} + \text{PbI}^2 \\ + \text{Ba}(\text{ClO}^3)^2 \\ - \text{TiCl} \\ - \text{AgCl} \end{array} \right\}$	$417-427$	Prepared by heating a mixture of iodine and antimony. The crude product was purified by sublimation over metallic antimony. The iodide melts at 171° (corr.), and decomposes slightly when boiled. The vapour has an intense dark red colour.
ZnBr^2	$\left. \begin{array}{l} + \text{RbBr} \\ + \text{Li}^2\text{CO}^3 \\ - \text{KBr} \\ - \text{NaBr} \end{array} \right\}$	$695-699$	
PbCl^2	$+ \text{Na}^2\text{SO}^4$	Above 861	Prepared in the wet way; recrystallised from boiling water; attacks glass.
PbBr^2	—	—	Does not boil before the blowpipe. Attacks glass very rapidly.
CdCl^2	$+ \text{Na}^2\text{SO}^4$	Above 861	Two specimens gave the same results; a deposit separates out on boiling.

For the following substances a higher temperature is obtained by immersing the salts in the boiling liquid instead of in the vapour, whereas in the instances given above, the same result was obtained in both cases.

I	In vapour		In liquid		Remarks
	II	III	IV	V	
ZnCl ²	$\left\{ \begin{array}{l} + V^2O^5 \\ + CaBr^2 \\ - RbBr \\ - KBr \end{array} \right\}$	676-683°	$\left\{ \begin{array}{l} + KBr \\ + NaBr \\ - CaCl^2 \end{array} \right\}$	708-719°	Attacks glass, and becomes turbid on boiling.
TlCl	$\left\{ \begin{array}{l} + Li^2CO^3 \\ + NaBr \\ - CaCl^2 \\ - KCl \end{array} \right\}$	708-719	$\left\{ \begin{array}{l} + CaCl^2 \\ - 2(Pb^2V^2O^7)PbO \\ - KCl \end{array} \right\}$	719-731	Turns to a pale yellow liquid, which changes to a cherry red, and finally again turns yellow.
TlI	$\left\{ \begin{array}{l} + NaCl \\ + Pb(PO^3)^2 \\ - Pb^2P^2O^7 \\ - Na^2CO^3 \end{array} \right\}$	800-806	$\left\{ \begin{array}{l} + Pb^2P^2O^7 \\ - Na^2CO^3 \end{array} \right\}$	806-814	Decomposes slightly on boiling.
Cd	$\left\{ \begin{array}{l} + KCl \\ + MoO^3 \\ - NaCl \\ - Na^2CO^3 \end{array} \right\}$	763-772	$\left\{ \begin{array}{l} + MoO^3 \\ NaCl \text{ begins to melt.} \end{array} \right\}$	772	Deville and Troost (<i>Compt. rend.</i> xlix. 240) give 860° as the boiling point of Cd, but how this number was obtained is not clearly stated.

Relation of Boiling Point to Chemical Constitution.—The differences of boiling point in metameric bodies are explained by A. Naumann (*Deut. Chem. Ges. Ber.* vii. 173; *Jahresb.* 1874, 15) as follows: A comparison of the properties of bodies in their different states of aggregation leads to the supposition that a liquid molecule is made up of a considerable number of gas-molecules, and that in the passage from the liquid to the gaseous state, the complex liquid molecule is split up into the simple gas-molecules. According to the laws of universal attraction, the gas-molecules which make up the liquid molecule will, under otherwise similar circumstances, offer a greater resistance to any force tending to separate them, in proportion as they are more closely aggregated; and therefore the closer the aggregation, the higher will be the boiling point of the liquid. The most easily comparable relations are found in metameric bodies, in which the elementary atoms are the same in number and in kind, but differently arranged, especially in those which contain but a small number of different elements—the hydrocarbons for example—and in which therefore the disturbing influence of the different qualities of the atoms is reduced to a minimum; or in certain oxygenated compounds, which, by their similarity of chemical character, appear to have their oxygen-atoms similarly united to the other elements. The arrangement of the atoms of the individual molecules in single chains admits of a closer packing of these molecules than that which they can assume when, in consequence of the presence of lateral chains, the grouping of the atoms approximates to the spherical form. The more therefore the grouping of the atoms deviates from the rectilinear and approaches to the spherical form, the less closely will the gas-molecules be grouped in the liquid molecule, and the lower will be the boiling point.

Influence exerted on the Boiling point of Oxygenated Carbon-compounds by the position of the Oxygen-atom.—This influence, likewise investigated by Naumann (*Ber. vii. 206; Jahresh. 1874, 17*), may be expressed as follows: In metameric bodies of similar chemical character and otherwise corresponding structure, the more nearly the oxygen stands to the middle of the chain of atoms, the lower will be the boiling point. The following may be taken as examples:—

Normal Alcohols	{	$C^4H^{10}O$ { Primary Butyl Alcohol, $CH^3.CH^2.CH^2.CH^2OH$	116°
		Secondary „ „ $CH^3.CHOH.CH^2.CH^3$	99°
	{	$C^5H^{12}O$ { Primary Pentyl Alcohol, $CH^3.CH^2.CH^2.CH^2.CH^2OH$	137°
		Methyl-propyl Carbinol, $CH^3.CHOH.CH^2.CH^2.CH^3$	120°-123°
Iso-al- cohols	{	$C^6H^{14}O$ { Primary Hexyl Alcohol, $CH^3(CH^2)_4CH^2OH$	150°-156.6°
		Methyl-butyl Carbinol, $CH^3.CHOH(CH^2)_3CH^3$	140°-142°
	{	$C^5H^{12}O$ { Isopentyl Alcohol, $(CH^3)_2CH-CH^2-CH^2OH$	128°-132°
		Methyl-pseudopropyl Carbinol, $CH^3.CHOH.CH(CH^3)_2$	104°-108°
Mixed normal Ethers	{	$C^4H^{10}O$ { Methyl-propyl Oxide, $CH^3.O.CH^2.CH^2.CH^3$	49°-52°
		Diethyl Oxide, $CH^3.CH^2.O.CH^2.CH^3$	-35.5°
	{	$C^6H^{14}O$ { Ethyl-butyl Oxide, $CH^3.CH^2.O.CH^2.CH^2.CH^2.CH^3$	-91.7°
		Dipropyl Oxide, $CH^3.CH^2.CH^2.O.CH^2.CH^2.CH^3$	85°-86°
Mixed iso- ethers	{	$C^6H^{14}O$ { Methyl-isopentyl Oxide, $CH^3.O.CH^2.CH^2.CH(CH^3)_2$	92°
		Ethyl-isobutyl Oxide, $CH^3.CH^2.O.CH^2.CH(CH^3)_2$	78°-80°
Compound Ethers	{	$C^5H^{10}O_2$ { Propyl Acetate, $CH^3.CO.O.CH^2.CH^2.CH^3$	101.98°
		Ethyl Propionate, $CH^3.CH^2.CO.O.CH^2.CH^3$	98.80°
	{	$C^6H^{12}O_2$ { Butyl Acetate, $CH^3.CO.O.CH^2.CH^2.CH^2.CH^3$	124.30°
		Propyl Propionate, $CH^3.CH^2.CO.O.CH^2.CH^2.CH^3$	122.44°
		Ethyl Butyrate, $CH^3.CH^2.CH^2.CO.O.CH^2.CH^3$	121.07°
	{	$C^7H^{14}O_2$ { Butyl Propionate, $CH^3.CH^2.CO.O.CH^2.CH^2.CH^2.CH^3$	145.99°
		Propyl Butyrate, $CH^3.CH^2.CH^2.CO.O.CH^2.CH^2.CH^3$	143.42°

The cause of this regularity appears to be that the more nearly the oxygen is placed to the middle of the chain, the more closely do the similar atoms of the several molecules approach one another—that is to say, the oxygen-atoms of the one to the oxygen-atoms of the other, and the carbon-atoms of the one to the carbon-atoms of the other. On the other hand, the position of the oxygen near the end of the chain leads to a more frequent approximation of the dissimilar atoms of the individual molecules, viz., the carbon-atoms of the one to the oxygen-atoms of the other; and this leads to the inference that the approximation of gas-molecules by their similar atoms does not bind them together into a liquid molecule so firmly as approximation by their dissimilar atoms.

Influence of Chlorination on the Boiling Points of Organic Compounds (L. Henry, *Ber. vi. 734*). The usual effect of the substitution of chlorine for hydrogen is to raise the boiling point. This takes place regularly and constantly in those derivatives in which the group CH^3 is associated with another positive hydrocarbon-group like CH^3 itself or C^2H^5 , &c., as in the chloro-derivatives of ethane and of toluene:

	Mol. wt.	B. p.		Mol. wt.	B. p.
$\text{CH}^3.\text{CH}^3$	30	Gas	$\text{C}^6\text{H}^5.\text{CH}^3$	92	111°
$\text{CH}^3.\text{CH}^2\text{Cl}$	64.5	10°	$\text{C}^6\text{H}^5.\text{CH}^2\text{Cl}$	126.5	176°
$\text{CH}^3.\text{CHCl}^2$	99	60°	$\text{C}^6\text{H}^5.\text{CHCl}^2$	161	208°
$\text{CH}^3.\text{Cl}^3$	133.5	75°	$\text{C}^6\text{H}^5.\text{CCl}^3$	195.5	214°

The presence of a negative group or radicle, on the other hand, produces in all the chlorine-derivatives—after the first—a very considerable diminution in the rise of the boiling point, as may be strikingly seen in the several chlorinated acids, amides, chlorides, aldehydes, &c., of the acetic series.

	B. p.	M. p.		B. p.
$\text{HOCO}.\text{CH}^3$	118°	17°	$(\text{C}^2\text{H}^5\text{O})\text{CO}.\text{CH}^3$	74°

The boiling points of cyanogen-compounds are considerably lowered by the presence of a negative radicle, thus—

	B. p.
Hydrogen Cyanide, $\text{H}.\text{CN}$	26°
Cyanogen Chloride, $\text{Cl}.\text{CN}$	15°
Dicyanogen, $\text{CN}.\text{CN}$	21°
Propionitril, $\text{CH}^3.\text{CH}^2.\text{CN}$	96°
Acetyl Cyanide, $\text{CH}^3.\text{CO}.\text{CN}$	93°

On the contrary:

	B. p.
Propane, $\text{CH}^3.\text{CH}^2.\text{CH}^3$	Gas
Acetone, $\text{CH}^3.\text{CO}.\text{CH}^3$	55°

but again:

	B. p.
Ethylglycollic Nitril, $\text{C}^2\text{H}^5\text{O}.\text{CH}^2.\text{CN}$	154°–155°
Ethyleyanoformate, $\text{C}^2\text{H}^5\text{O}.\text{CO}.\text{CN}$	115°–116°

The monochloro-derivative of acetonitril boils at a much higher temperature than acetonitril itself, but the more highly chlorinated derivatives exhibit a considerable retrogradation in their boiling points, notwithstanding the gradual increase of their molecular weights:

	Mol. wt.	B. p.
$\text{CH}^3.\text{CN}$	41.0	81°–82°
$\text{CH}^2\text{Cl}.\text{CN}$	75.5	123°–124°
$\text{CHCl}^2.\text{CN}$	110.0	112°–113°
$\text{CCl}^3.\text{CN}$	144.5	83°–84°

In these compounds the methyl-group CH^3 , by conversion into CCl^3 , may be supposed to assume the functions of a negative radicle, and therefore to influence the boiling point in the manner above explained.

Relation between Boiling point and Vapour-density in Homologous Compounds.—According to F. Bunden (*Phil. Mag.* [4], xli. 528), the absolute boiling temperature of homologous hydrocarbons and ethers is proportional to the square-root of their vapour-density, as indicated by the formula:

$$T = 51.5\sqrt{d} \text{ or } t = 51.5\sqrt{d} - 273,$$

which was found to be true with regard to 71 bodies of the two classes just mentioned. For aldehydes, alcohols, and acids, on the other hand, the coefficient was not found to

be constant; and to isomeric bodies of equal molecular weight, but different boiling point, the law is clearly inapplicable.

Boiling of Saline Solutions.—C. G. Müller (*Deut. Chem. Ges. Ber.* ix. 1629) observes that saline solutions may be heated nearly to boiling by passing steam into them. Solutions of calcium chloride of various degrees of concentration, and boiling at 104°, 122·5°, 127°, and 150·5°, were brought, by the introduction of aqueous vapour at 100°, to the temperatures of 100°–103°, 121·5°, 127°, and 147·5° respectively. Concentrated solutions of $\text{SO}^{\circ}\text{Na}^{\circ}$, NaCl , and $\text{NO}^{\circ}\text{K}$, boiling, at 104·5°, 110°, and 114·5°, were raised by a current of steam to 104°, 109°, and 112·5°. An alcoholic solution of potassium acetate, boiling at 87°, was heated by alcohol vapour from 78·3° to 84°. When a thermometer, moistened with a solution of calcium chloride, is heated to 100° over a flame, and then brought into an atmosphere of aqueous vapour, it shows, not 100°, but the boiling temperature of the solution with which it is moistened, until all the salt is washed away. If a test-tube be filled to a third with water, moistened on the outside with solution of calcium chloride, heated to boiling over a flame, and then introduced into the vapour-space of a flask in which water is boiling, the water in the tube will be thrown into violent ebullition, lasting for about a minute, in consequence of the rise of temperature caused by the absorption of the steam by the calcium chloride. The temperature produced in a saline solution by the absorption of aqueous vapour is, however, always a little below the boiling point of the solution, in consequence of the cooling action of the vapour which is in excess: hence also a strong stream raises the temperature less than a weaker one.

The aqueous vapour given off from a boiling saline solution has, according to Müller, a temperature of only 100°, whereas, according to Magnus and Wüllner, its temperature is nearly the same as that of the solution itself. Müller considers that, if steam at 100° passed as above mentioned into a solution of calcium chloride, can raise its temperature to 147·5°, the vapour which forms within the boiling liquid may act in the same manner, and this view he regards as corroborated by the following facts: (1). The boiling of the liquid, that is to say, the tumefaction produced by the rising of vapour-bubbles to the surface and there bursting, begins below the maximum temperature, which is afterwards only gradually attained. A solution of calcium chloride, for example, having a maximum boiling point of 126°, begins to boil at 110°, and the temperature rises to 126° in about thirty seconds. (2). Saline solutions of high boiling point exhibit a higher temperature in gentle than in violent ebullition. The above-mentioned solution of calcium chloride showed a temperature of 126° when it boiled strongly, and of 127·5° when it boiled gently. If the flame be taken away from under the liquid while boiling violently, the thermometer is seen to rise 1 or 1·5 degrees. These effects may be explained by supposing that the vapour of water which rises through boiling saline solutions has a temperature of only 100°, and that the rise of temperature in the liquid is due to the absorption of a portion of it, while a rapid stream of vapour has a somewhat cooling effect. The bubbles of vapour which rise within the liquid act, in short, in the same manner as vapour introduced from without. Wüllner (*Ber.* x. 256) remarks that facts similar to those described by Müller as to the heating of saline solutions to their boiling points by the action of aqueous vapour at 100° were noticed more than fifty years ago by Faraday and by Gay-Lussac (*Ann. Chim. Phys.* 1822), and that the latter states, as the result of direct experiment, that the temperature of the vapour evolved from a liquid under any pressure whatever is always the same as that of the stratum of liquid in immediate contact with it. Pfaundler (*Ber.* x. 463) objects, on theoretical grounds, to the views put forward by Müller, who, on the other hand, still maintains, on the ground of the experiments above cited, and of others not yet published, that the bubbles of vapour which rise in saline solutions have, at the moment of their formation, a temperature of only 100°, and that the higher temperature which they may exhibit on emerging from the liquid is due to their becoming overheated by conduction, more or less according to the depth of the bath (*Ber.* x. 1327).

From observations on the boiling points of solutions of calcium chloride, H. Hammerl (*Wien. Akad. Ber.* [2 Abth.], lxxii. 8) deduces the interpolation equation:

$$t = 0\cdot0519p + 0\cdot011163p^2,$$

in which t denotes the excess of the boiling temperature above that of water, p the percentage of CaCl^2 in the solution:

p	t	
	Calc.	Obs.
14.3	3.0	2.7
28.6	10.6	10.9
41.5	21.3	20.5
51.9	32.8	31.8
58.4	40.5	40.3
64.6	50.1	51.2
70.8	59.8	62.4

whence also may be calculated the following more convenient form of table:

p	5	10	15	20	25	30	35	40	45	50	55	60	65	70
t	0.5	1.6	3.2	5.5	8.3	11.6	15.4	19.9	24.9	30.5	36.6	43.3	50.6	58.4

Boiling of Over-heated Liquids.—It is well known that a liquid heated in a vessel of glass or other material having a smooth surface may often be raised several degrees above its ordinary boiling point without actually boiling, and that the introduction of fragments of glass or other substances will then throw it into sudden and violent ebullition. Experiments on this subject have been made by Gernez (*Ann. Chim. Phys.* [5], iv. 335–401), from which he infers that solid bodies which determine the ebullition of over-heated liquids lose this property when they have previously been strongly heated; and those which do not act chemically on the liquids, no longer give rise to the formation of vapour bubbles after they have been used for some time to keep up the boiling. Bodies which have not been in contact with the air, and contain no air or gas in their interior, are without action on superheated liquids, but bodies which have been rendered inactive by the action of heat, or by prolonged immersion in a boiling liquid, recover their activity after exposure to the air; in fact, the boiling of superheated liquid is set up by contact with an atmosphere of gas. Gernez regards boiling as the evaporation of a liquid at the temperature of the normal boiling point towards the surfaces of gases, which are either introduced into the liquid from without, or developed within it in consequence of the heating of gas-solutions above the limit of supersaturation. An indefinitely small quantity of gas is sufficient to set up the boiling, which may then continue for any length of time, as each bubble of vapour which escapes leaves behind it a very small bubble capable of exciting further ebullition.

Critical observations on the experiments and conclusions of Gernez have been published by C. Tomlinson (*Phil. Mag.* [4], xlix. 432–448; l. 85–100).

Distillation of Liquids not miscible with Water in a current of Steam.—Experiments on this kind of distillation have been made by A. Naumann (*Ber. x.* 1421, 1819, 2014, 2099) on benzene, toluene, oil of turpentine, carbon tetrachloride, nitrobenzene, ethyl bromide, ethyl benzoate, and naphthalene, the first three of which are specifically lighter, the last five heavier than water. The boiler used for the lighter liquids was an upright tubulated receiver, into the lower part of which the steam was passed laterally in such a manner that, during the entire distillation, the orifice of the tube which conveyed the steam was never covered by the condensed water there collected, but was always immersed in the supernatant liquid, which formed a turbid mixture of water-drops with the other liquid. For the heavier liquids, in order to diminish the quantity required, a cylindrical tube, narrowing towards the bottom, was used. The mixture of liquids which distilled over was collected in graduated tubes; and after the water had been completely separated from the other liquid, the volumes of the two were measured, excepting in the case of naphthalene, in which the proportions were determined by weighing.

The following general laws were found to hold good for each of the eight fluid mixtures investigated: (1). A constant boiling point lower than that of the less volatile constituent. (2). A constant ratio of the constituents distilled over. (3). The ratio of the two constituents in the distillate, expressed in the known molecular weights deduced from the normal vapour-densities, is equal to the ratio of the vapour-tensions of the two constituents at the temperature of the mixed vapour. (4). The temperature of the mixed vapour is mostly above that of the liquid mixture.

These regularities are independent of the height of the space above the boiling mixture filled with the mixed vapours, but they presuppose that the layer of liquid

above the point where the vapour enters, shall not, in moderately rapid distillation, sink below 50 mm.

The following table shows the mean values deduced from numerous observations :

Substance	Molecular formula	Specific gravity	Boiling point			Height of barometer (corr.) mm.	Ratio (in molecular weights) of the water to the substance in the distillate $\frac{g}{m} : \frac{G}{M}$	Ratio of the vapour-tension of the water to that of the other liquid at the temperature of the mixed vapour $p : P$
			Of the substance alone (uncorr.)	Of the liquid mixture	Temperature of the mixed vapour			
Benzene	C^6H^6	0·8773	79·5°	68·5°	69·1°	742	0·41	0·42
Toluene	C^7H^8	0·8657	108·5	82·4	84	752	1·27	1·26
Turpentine oil . .	$C^{10}H^{16}$	0·8827	160	93·2	94·8	745·5	6·6	5·83
Carbon Tetrachloride .	CCl^4	1·599	76·1	65·7	66·7	747	0·36	0·36
Nitrobenzene . . .	$C^6H^5NO^2$	1·2060	208	98·6	99	753	38·5	33·3
Ethyl Bromide . . .	C^2H^5Br	1·4069	72	37	37	741	0·064	0·065
Ethyl Benzoate . . .	$C^2H^5.C^7H^5O^2$	1·048	213	98·7	99·1	751	49·91	45·99
Naphthalene . . .	$C^{10}H^8$	—	218	97·4	98·8	750	38·98	36·4

From the law enunciated in (3), and established by the numbers in the last two columns of the preceding table, may be deduced a method of determining molecular weights by distillation or sublimation in indifferent vapours or gases. Let g denote the weight of one constituent of the distillate, m its molecular weight, and p its vapour-tension at the boiling temperature t of the mixture and the barometric pressure b ; also let G denote the weight of the other constituent of the distillate, M its molecular weight, and P its vapour-tension, likewise at the boiling temperature measured in the mixed vapour; then

$$\frac{g}{m} : \frac{G}{M} = p : P;$$

and if the molecular weight M be the quantity sought, we have

$$M = \frac{m G p}{g P}.$$

If one of the bodies is water, $m = 18$; p must be sought in Regnault's table of the tensions of water-vapour (iii. 93; also *Relation des Expériences*, &c. p. 489); g and G are the relative weights in the distillate of water and the body under examination; and $P = b - p$. If a liquid or solid body which does not boil without decomposition, has at any temperatures a vapour-tension of only a few millimeters, there will most probably be found another body, boiling within these same temperatures, in which the body in question does not dissolve, and in whose vapour it can be volatilised, so that its molecular weight can then be determined in the manner above described. This method of determining molecular weights is likely to be especially useful in cases where the ordinary methods are inapplicable.

Evaporation. Experiments on the rate of evaporation of volatile liquids, such as ether and carbon sulphide, in open and in closed vessels have been made by J. Stefan (*Wien. Akad. Ber.* [2 Abth.], lxviii. 385-423). The experiments were made with rather narrow tubes, in order to avoid as far as possible the great lowering of temperature consequent on rapid evaporation in shallow vessels. Experiments on evaporation from open tubes into the air led to the following conclusions. The rate of evaporation of a liquid from an open tube is inversely proportional to the distance between the level of the liquid and the open end of the tube, provided this distance exceeds about 10 mm. It is independent of the diameter of the tube (0·6 to

6 mm. in the experiments quoted). The rate is proportional to the logarithm of a fraction having for its numerator the atmospheric pressure, and for its denominator this pressure diminished by the maximum vapour-tension. For the case in which this tension is equal to the atmospheric pressure, the fraction representing the rate of evaporation becomes infinitely great, and the law then denotes another process, viz. ebullition. These laws may also be deduced from the theoretical discussion of the experiments founded on the mechanical theory of gases.

To study the rate of evaporation in closed tubes, a tube closed at one end was plunged by its open end into ether, whereupon bubbles were given off, somewhat quickly at first, afterwards more slowly, their rate of evolution being regulated by the following simple law: *The times in which equal numbers of successive bubbles are evolved follow the law of the uneven numbers, 1, 3, 5, &c.* If the tube contains hydrogen instead of air, the same number of bubbles is evolved in one-fourth of the time. As the number of bubbles gives a measure of the quantity of vapour formed, it follows, from the fact just stated, that ether evaporates in hydrogen gas four times as quickly as in air under similar circumstances. This result was confirmed by means of an apparatus in which a liquid could be left to evaporate in any given gas, under circumstances similar to those of evaporation in the open air, the ether being then found to evaporate in hydrogen 3.7 times as fast as in air.

When a tube provided with a stop-cock is dipped into ether with the cock open, and the cock is then closed, the level of the liquid within the tube sinks below the outer level, and the depths to which the inner level sinks in given times are proportional to the square roots of these times; or the quantity of vapour evolved in a given time is proportional to the square root of the time. This law agrees with that above stated as to the evolution of bubbles. Both laws, however, are true, not unconditionally for all times, but only for the beginning of the process. They may be regarded as exact until about half the quantity of vapour has entered the tube that is required for complete saturation. They are strictly true, as the theory of these experiments shows, for a tube of infinite length, and no deviation from them is perceptible so long as the partial pressure of the vapour which arrives at the closed end of the tube falls within the errors of observation. A theoretical investigation of the question shows that the evaporation of a liquid in a gaseous mixture leads to an alteration in the proportions of the constituents of that mixture, in consequence of which the more diffusible gas is found in the neighbourhood of the evaporating liquid in greater proportion to the less diffusible than in other parts of the space. If, therefore, a liquid be left to evaporate in a tube filled with detonating gas, the quantity of hydrogen in the neighbourhood of the liquid is relatively greater than in the other parts of the tube. Since now the nature of the gas in which a liquid evaporates has an essential influence on the rate of the evaporation, we ought in strictness, when discussing experiments on evaporation in the air, not to regard the air as a simple gas. But the difference between the behaviour of nitrogen and of oxygen is so small, that in diffusion-processes, the air may be regarded as a simple gas without sensible error.

Evaporation in Gases.—Experiments on the rate of evaporation in different gases have been made by W. Kirchman (*Arch. Pharm.* [3], ix. 423-427). Equal quantities of camphor were introduced into eight glass vessels of the same size and shape, four being filled with air and the other four with carbon dioxide. After all the eight glasses had been exposed for some weeks to the same fluctuations of temperature, those filled with air were found to be covered with thick layers of camphor, while in those filled with carbon dioxide, the camphor remained at the bottom almost intact, the sides of these vessels being merely lined with a thin film of camphor crystals. Hence it appears that the volatilisation of the camphor is sensibly affected by the quality of the gas, just as the manner in which a solid body dissolves in a liquid is essentially affected by the nature of that liquid. Further experiments showed that carbon dioxide is also a relatively less favourable medium of evaporation than air for the terpenes, for chloroform and for carbon disulphide, but, on the contrary, a better medium for ethyl oxide, for methyl, ethyl, and amyl alcohols, and for water. Moreover, dry carbon dioxide was found to be an excellent medium for removing water from freshly distilled volatile oils. Air removes chlorine from chlorine-water even when not saturated; but the strongest chlorine-water is completely deprived of chlorine by passing through it scarcely more than its own volume of carbon dioxide.

The following proportions between the rates of evaporation of liquids in different gases have been observed by G. Baumgartner (*Wien. Akad. Ber.* [2 Abth.], lxxv. 313, 689).

	In Air	In Carbon Dioxide	In Hy- drogen	In Coal- gas
For Ether	1	0·80	3·83	1·50
„ Carbon Disulphide	1	0·81	3·35	1·60
„ Chloroform	1	0·64	3·65	1·69
„ Alcohol	1	—	3·58	1·80

Saturation of Air with Water-vapour, and Desiccation of Air.—From experiments by H. C. Dibbits (*Zeitschr. anal. Chem.* 1876, 121–170), it appears: (1). That air which has been dried by means of strong sulphuric acid becomes completely saturated with water-vapour by passing through water at a maximum rate of 30 litres per hour. (2). Air dried as described may be saturated with water-vapour by being caused to pass over the surface of water, provided that the surface of water exposed be not very small compared with the rapidity of the flow of air. (3). Concentrated sulphuric acid (containing not more than 8·4 per cent. water), dries air at temperatures up to about 25° so thoroughly that 100 litres do not give up to phosphoric anhydride more than 0·0002 gram. (4). If the temperature be higher than 25° or 30°, sulphuric acid does not desiccate air so completely; yet the quantity of water-vapour contained in 1 litre of air dried by means of sulphuric acid at 50° amounted to less than 0·0001 gram.

Phosphoric anhydride may be said to effect an almost absolute desiccation of air, the quantity of aqueous vapour left by it in a litre of air not exceeding an extremely small fraction of a milligram.

The desiccating power of calcium chloride is much affected by temperature. If air dried by passing over this salt at a given temperature be brought into contact with a fresh quantity of the same salt at a lower temperature, a further desiccation takes place; but if the second portion of calcium chloride be maintained at a higher temperature than the first, the air becomes moister. By passing a gas, already dried over calcium chloride, through a system of tubes containing equal weights of calcium chloride, positive or negative alterations in weight may be obtained, according as the different parts of the system possess a higher or lower temperature. If the temperature at the beginning of the system of tubes be the same as that at the end, the algebraic sum of the weight-alterations is always = 0; if these two temperatures differ, the system suffers a positive or negative weight-alteration, in proportion to the difference of temperature between the first and last tubes.

The following table of the weights of water-vapour contained in 1 litre of saturated air is calculated from the vapour-tension determinations of Regnault and of Magnus:—

Temperature	Weight of water-vapour in milligrams		Temperature	Weight of water-vapour in milligrams	
	Magnus	Regnault		Magnus	Regnault
–20°	1·046	1·058	+1°	5·131	5·209

Condensation of Vapour.—The results of experiments by Pasley on the condensation of aqueous vapour mixed with air on cold surfaces are summarised by O. Reynolds (*Proc. Roy. Soc.* xxi. 275) as follows: (1). The presence of a small quantity of air in aqueous vapour, produces considerable retardation in the condensation of the vapour on a cold surface. The condensability of pure vapour appears to depend only on the heat-conducting power of the condensing surface. (2). In conse-

quence of this action of the air, the size of the surface-condenser of a steam-engine must be increased according to the quantity of air mixed with the vapour. (3). By the mixture of air with steam before the latter comes to be used, the condensation may be diminished and the efficiency of the engine thereby impaired. (4). Nearly the greatest possible efficiency is attained, when the pressure of the air amounts to $\frac{1}{10}$ of that of the steam, or when about 2 cubic feet of air at 1 atm. at 15° are present to 1 pound of steam. According to Reynolds, the diminution of condensability of a vapour by admixture of air may be ascribed, as pointed out by Siemens, to the fact that the layer of air continually interposed between the condensing surface and the vapour must be penetrated or displaced by the latter before the condensation can go on.

HEAT OF CHEMICAL COMBINATION.

The principal data of Thermochemistry have been collected and arranged by Berthelot (*Annuaire pour l'An 1877, publié par le Bureau des Longitudes*, pp. 395-442) in the following tables. In the column headed 'Authors' A denotes Alluard; A, Andrews; B, Berthelot; D, Dulong; Ds, Desains; Dt, Ditte; Dev, Deville; F, Favre; G, Grassi; Gh, Graham; H, Hautefeuille; Hs, Hesse; L, Louguinine; P, Person; R, Regnault; T, Thomsen; Tr, Troost; S, Silbermann; W, Woods. Numbers not determined by experiment, but obtained according to analogy by calculation, are distinguished by a star. The numerical data denote kilogram-degrees, or thousands of gram-degrees.

TABLE I.—Formation of the most important Chemical Compounds, the Elements and Compounds being referred to the state in which they exist at 15°.

" Iodide . . .	—	C^2H^3OI	— 1.8
Butyryl Chloride . . .	—	C^4H^7OCl	— 3.8
" Bromide . . .	—	C^4H^7OBr	— 1.9
Valeryl Chloride . . .	—	C^5H^9OCl	— 2.5
" Bromide . . .	—	C^5H^9OBr	— 1.7

The following are thermochemical determinations, chiefly by Berthelot and Thomsen, not included in the preceding table; and re-determinations of certain values contained therein. The heat-unit is the kilogram-degree, excepting where the contrary is stated.

Thermic Constants of Oxidising and Reducing Agents (Thomsen, *Deut. Chem. Ges. Ber.* vi. 233, 1434). The thermochemical determination of the strength of affinity of oxygen in the several stages of oxidation of a body requires an exact knowledge of the action of oxidising and reducing agents: for only a small number of oxygen-compounds can be directly prepared in such a manner that the oxidation can be made the basis of exact calorimetric determinations. In most cases, indeed, the heat has to be estimated by indirect methods, either by oxidation with the aid of oxidising agents, or by subjecting the oxidised compound under examination to the action of reducing agents. With this view, Thomsen has determined the following constants:—

Reaction-constants of Reducing Agents.

Reaction	Q (heat evolved)
(SO ² Aq, Cl ²)	73·907
(Fe ² Cl ³ H ⁴ Aq, Cl ²)	55·523
(2FeSO ⁴ Aq, Cl ²)	48·763
(SnCl ⁴ H ⁴ Aq, Cl ²)	76·019
(SO ² Aq, O)	63·634
(Fe ² Cl ³ H ⁴ Aq, O)	45·250
(2FeSO ⁴ Aq, O)	38·490
(SnCl ⁴ H ⁴ Aq, O)	65·746

The meaning of these numbers is as follows: If one of these reducing agents, *sulphurous acid, ferrous sulphate, ferrous chloride, stannous chloride*, be used to remove oxygen or chlorine from a compound, and if the quantity of heat evolved in this process for every atom of oxygen or molecule of chlorine removed be denoted by R, then the quantity of heat consumed in the decomposition of the compound which furnishes the oxygen or chlorine, is represented by Q—R.

Reaction-constants of Oxidising Agents.

Reaction	Q' = total heat evolved	Number of oxygen atoms given off	Q for 1 oxygen atom
2(Cl, H, Aq) — (H ² , O)	10·273 heat-units	1	10·273 gram-degrees
2(Br, H, Aq) — (H ² , O)	— 11·605	1	— 11·605
2(Br, Aq, H) — (H ² , O)	— 12·683	1	— 12·618
(Cl, H, Aq) — (Cl, O, H, Aq)	9·437	1	9·437
(Mn ² O ³ K ² Aq, 6HClAq)	58·635	5	11·727
(Mn ² O ³ K ² Aq, 3SO ² Aq)	69·485	5	13·897
(Mn ² O ³ K ² Aq, 2HClAq)	55·757	3	18·556
(Mn ² O ³ K ² Aq, SO ² Aq)	59·547	3	19·849
(MnO, SO ² Aq)*	4·969	1	4·969

— (2MnO, O ³ , 2KAq)	28·257	3	9·419
— (2MnO ³ , 2KAq)	— 14·765	5	— 2·953
— (Mn, O)	— 21·511	1	— 21·511
— (2Cr, O ³ , Aq)	— 18·868	3	— 6·299
— (IHAq, O ³)	— 42·542	3	— 14·181
— (H ² O, O, Aq)	+ 23·074	1	+ 23·074

The meaning of these numbers is as follows: If a substance is oxidised by one of the reagents here indicated, viz. *chlorine, bromine, potassium permanganate, manganese*

* K = KHO; $\overline{\text{Mn}}$ = MnH³O³; $\overline{\text{Cr}}$ = CrH³O³.

3rd Sup.

3 R

dioxide, chromic acid, or hydrogen dioxide, the quantity of heat developed by each atom of oxygen absorbed is greater by the value of Q given in the table for the reagent in question, than that which would have been developed if the same oxidation had been effected by oxygen. If the oxidation effected by either of these reagents be equal to R heat-units for 1 atom of oxygen, then the quantity which would be evolved by oxidation with free oxygen is $R-Q$.

Heat of Combustion of Hydrogen. Schüller a. Wartha (*Ber.* xi. 1298), by means of their modified form of Bunsen's ice-calorimeter (p. 926), estimate the quantity of heat evolved by the combustion of 1 gram of hydrogen (at 0° and 760 mm.) at 34.126 heat-units. (Thomsen's number 69 [p. 952] denotes the quantity evolved in the combustion of 2 grams of hydrogen.)

C. v. Than (*Ber.* xi. 947, 1241) has determined the quantity of heat evolved in the combustion of a mixture of 2 vol. H. and 1 vol. O. in closed vessels, by burning a measured quantity of the gas in Bunsen's ice-calorimeter. The number thus found in one experiment was 33.863 heat-units; another, in which additional precautions were taken to ensure the correct measurement of the gas, gave 33.964 units.

Heat of Formation of Ozone. According to Berthelot (*Compt. rend.* lxxxii. 1281), the formation of ozone from oxygen under the influence of the silent electric discharge is attended with an absorption of heat amounting to 29.6 units.

Heat of Combustion of Sulphur. According to Berthelot (*Compt. rend.* lxxxiv. 674):

On account however of the unavoidable formation of SO^3 , the true number must be a little lower than this. The experiment was made with pure octohedral sulphur. The insoluble sulphur extracted from flowers of sulphur would yield the same amount of heat, since its conversion into octohedral sulphur, which takes place at about 18° , is not attended either with evolution or with absorption of heat.

Sulphuric Acid and Sulphates. Berthelot (*loc. cit.*) deduces the heat of formation of these compounds from the following data, which he regards as the most exact yet obtained:

	Heat-units
$S + O^2 = SO^2 \text{ gas}$	69.1 (Berthelot)
$SO^2 \text{ gas} + \text{water} = SO^2 \text{ dissolved}$	7.7 (Favre, Thomsen)
$SO^2 \text{ dissolved} + Cl^2 \text{ gas} + 2H^2O = SO^3.H^2O \text{ dilute}$	73.9 (Thomsen)
$H + Cl = HCl \text{ dilute}$	39.3 (Thomsen)
$H^2 + O = H^2O$	69.0 (mean acc. to several observers)

Hence:

	Heat-units
$SO^2 \text{ dissolved} + O + H^2O + \text{water} = SO^3.H^2O \text{ dilute}$	64.3
$SO^2 \text{ gas} + O + H^2O + \text{water} = SO^3.H^2O \text{ dilute}$	72.0
$S + O^3 + H^2O = SO^3.H^2O \text{ dilute}$	141.0

Further.

$SO^3 + \text{water} = SO^3.H^2O \text{ dilute}$	37.4 (Berthelot)
$SO^3.H^2O \text{ pure} + \text{water} = SO^3.H^2O \text{ dilute}$	17.0 (various)

whence:

$S + O^3 = SO^2 \text{ anhydrous}$	103.6
$SO^2 + O = SO^3$	34.4
$S + O^3 + H^2O = SO^3.H^2O$	124.0
$S + O^1 + H^2 = SO^4H^2$	193.0

Finally, according to various investigators:

$S + O^4 + K^2 = SO^4K^2$	342.2
$S + O^4 + Na^2 = SO^4Na^2$	326.4
$S + O^4 + Pb = SO^4Pb$	214.0
$S + O^4 + Zn = SO^4Zn$	233.4
$S + O^4 + Cu = SO^4Cu$	182.8

For the heat of formation of potassium thiosulphate, Berthelot finds (*Compt. rend.* lxxxii. 400):

Hyposulphurous acid, SO^2H^2 (Berthelot, *ibid.* lxxxiii. 416):

	Heat-units
$\text{S} + \text{H}^2 + \text{O}^2 + \text{water} = \text{SO}^2\text{H}^2 \text{ dilute}$	+ 86.4
$\text{S} + \text{H}^2\text{O}^2 = \text{SO}^2\text{H}^2$ „	39.0
$\text{SO}^2 + \text{H}^2 + \text{water} = \text{SO}^2\text{H}^2$ „	0.6
$\text{H}^2\text{S} \text{ dil.} + \text{O}^2 = \text{SO}^2\text{H}^2$ „	38.6
$2\text{SO}^2\text{H}^2 \text{ dil.} = \text{SO}^4\text{H}^2 \text{ dil.} + \text{SH}^2 \text{ dissolved}$	54.8
$2\text{SO}^2\text{H}^2$ „ „ „ „ „	41.2

This last value explains the greater stability of thiosulphuric acid, $\text{S}^2\text{O}^3\text{H}^2$, inasmuch as the stability of a chemical system increases, under otherwise similar circumstances, with the amount of energy which it has lost.

Heat of Formation of Hydrobromic and Hydriodic Acids (Berthelot, *Compt. rend.* lxxxiv. 677, 678).

For Hydrobromic acid, Berthelot finds—

$\text{H} + \text{Br liquid} = \text{HBr gas}$	9.5
$\text{H} + \text{Br solid} = \text{HBr}$ „	9.4
$\text{H} + \text{Br gas} = \text{HBr}$ „	13.5
$\text{H} + \text{Br liquid} + \text{water} = \text{HBr dissolved}$	29.5
$\text{H} + \text{Br gas} + \text{water} = \text{HBr dilute}$	33.1

For Hydriodic acid:

$\text{H} + \text{I solid} = \text{HI gas}$	- 6.4
$\text{H} + \text{I liquid} = \text{HI}$ „	- 4.5
$\text{H} + \text{I gas} = \text{HI}$ „	- 0.8
$\text{H} + \text{I solid} + \text{water} = \text{HI dilute}$	+ 13.2
$\text{H} + \text{I gas} + \text{water} = \text{HI}$ „	+ 18.8

The numbers for the heats of formation of hydrochloric acid (22.0, p. 252) and of hydrobromic acid are nearly on the ratio of 1 : 2.

Thermochemistry of the Oxygen-acids of Chlorine, Bromine, and Iodine. 1. *Chloric acid and Chlorates* (Berthelot, *Ann. Chim. Phys.* [5], x 327-389).

1. Formation of Chlorates from the Elements:

$\text{Cl} + \text{O}^3 + \text{K} = \text{ClO}^3\text{K solid}$	94.6
$\text{Cl} + \text{O}^3 + \text{Na} = \text{ClO}^3\text{Na}$ „	85.4

Various Reactions:

$3\text{Cl}^2 + 3\text{K}^2\text{O dilute} = 3\text{ClO}^3\text{K dilute} + 3\text{KCl dilute}$	+ 76.2
$3\text{Cl}^2 + 3\text{Na}^2\text{O} „ = 3\text{ClO}^3\text{Na} „ + 3\text{NaCl} „$	+ 75.9
$3\text{Cl}^2 + \frac{3}{2}\text{BaO} „ = 3\text{ClO}^3\text{Ba}^{\frac{1}{2}} „ + \frac{3}{2}\text{BaCl}^2 „$	+ 75.1
$3\text{Cl}^2 + \frac{3}{2}\text{K}^2\text{O} „ = \text{ClO}^3\text{K diss.} + \frac{5}{2}\text{KCl} „$	+ 94.2
$3\text{Cl}^2 + 3\text{Na}^2\text{O} „ = \text{ClO}^3\text{Na} „ + 5\text{NaCl} „$	+ 94.2
$3\text{Cl}^2 + 3\text{BaO} „ = \text{ClO}^3\text{Ba}^{\frac{1}{2}} „ + \frac{5}{2}\text{BaCl}^2 „$	+ 95.0
$3\text{Cl}^2 + 3\text{K}^2\text{O} „ = 6\text{KCl} „ + \text{O}^3 „$	+ 111.0
$3\text{Cl}^2 + 3\text{Na}^2\text{O} „ = 6\text{NaCl} „ + \text{O}^3 „$	+ 110.0
$3\text{Cl}^2 + 3\text{BaO} „ = 3\text{BaCl}^2 „ + \text{O}^3 „$	+ 111.8
$3\text{ClO}^3\text{K dissolved} = \text{ClO}^3\text{K} „ + 2\text{KCl} „$	+ 18.0
$3\text{ClO}^3\text{Na} „ = \text{ClO}^3\text{Na} „ + 2\text{NaCl} „$	+ 18.3
$3\text{ClO}^3\text{Ba}^{\frac{1}{2}} „ = \text{ClO}^3\text{Ba}^{\frac{1}{2}} „ + \text{BaCl}^2 „$	+ 19.9

Successive oxidation:

$\text{Cl}^2 + \text{O} + \text{water} = \text{Cl}^2\text{O dilute}$	- 5.8
$\text{Cl}^2 + \text{O}^5 + \text{water} = \text{Cl}^2\text{O}^5$ „	- 24.0

Heat of conversion of chlorates into chlorides and oxygen:

$\text{KClO}^3 \text{ solid} = \text{KCl solid} + \text{O}^3$	+ 11
$\text{NaClO}^3 „ = \text{NaCl} „ + \text{O}^3$	+ 12.3
$\text{Ba}^{\frac{1}{2}}\text{ClO}^3 „ = \text{Ba}^{\frac{1}{2}}\text{Cl} „ + \text{O}^3$	12.6

Heat of solution of potassium perchlorate:

$\text{ClO}^4\text{K} + 100 \text{ times its weight of water at } 23^\circ$	- 12.13
---	---------

2. Bromic acid (*Compt. rend.* lxxxiv. 679).

	Heat-units
Br ² liquid + O ³ + H ² O + water = Br ² O ³ .H ² O dilute . . .	- 49.6
Br ² gas + O ³ + H ² O + water = Br ² O ³ .H ² O „ . . .	- 42.2
BrO ³ H dilute = HBr dilute + O ³	+ 15.5
BrO ³ K solid = KBr solid + O ³	+ 11.1

Formation of hypobromites with excess of alkali:

Na ² O (1 eq. in 3 litres) + Br ² at 9°.	+ 12.0
K ² O („ 4 „) + Br ² at 11°.	11.9
BaO („ 6 „) + Br ² at 13°.	11.4

Supposing now that dilute hypobromous acid in combining with bases gives out as much heat as hypochlorous acid, namely, 9.5 units; then, for the heat of formation of hypobromous acid, we have:

Br ² liquid + O + water = Br ² O dilute	- 13.4
Br ² gas + O + water = Br ² O „	6.0

3. Iodic acid and Iodates (*Berthelot, Compt. rend.* lxxxiv. 734).

I ² solid + O ³ + water = IO ³ H dilute	+ 45.2
I ² „ + O ³ = I ² O ³ anhydrous	+ 46.8
I ² gas + O ³ = I ² O ³ solid	+ 37.8
I ² solid + O ⁶ + H ² + water = 2IO ³ H dissolved	+ 114.2
I ² „ + O ⁶ + H ² = 2IO ³ H crystallised	+ 119.6
I ² O ³ solid + H ² O solid = 2IO ³ H „	+ 2.26
I ² O ³ „ + 2IO ³ H „ = 2IO ³ H.I ² O ³ „	+ 1.24
IO ³ H dissolved = HI + O ³	- 43.9
IO ³ H cryst. + KOH solid = IO ³ K cryst. + H ² O solid	+ 31.5
IO ³ K „ + IO ³ H „ = IO ³ K.IO ³ H solid	+ 3.1
I solid + O ³ + K = IO ³ K solid	+ 123.9
I gas + O ³ + K = IO ³ K „	+ 128.4
IO ³ K solid = KI „ + O ³	- 44.1
IO ³ K dissolved = KI dissolved + O ³	- 43.4

The heat of formation of potassium iodate is greater than that of the bromate or chlorate.

I gas + O ³ + K = IO ³ K solid	+ 128.4
Cl gas + O ³ + K = ClO ³ K „	+ 94.6
Br gas + O ³ + K = BrO ³ K „	+ 87.6

Hence it appears that the stability of the three salts increases from the bromate to the chlorate and iodate. The greater stability of the iodate is indicated also by a comparison of the heats of decomposition of the three salts:

ClO ³ K = KCl + O ³	+ 11
BrO ³ K = KBr + O ³	+ 11.1
IO ³ K = KI + O ³	- 44.1

A comparison of the fundamental reactions of the three halogens with an alkali gives:

3Cl ² gas + 3K ² O { 3ClOK diss. + 3KCl dissolved	+ 76.2
dilute { ClO ³ K „ + 5KCl „	+ 94.2
6KCl „ + O ³ „	+ 111.0
3Br ² gas + 3K ² O { 3BrOK „ + 3KBr „	+ 57.6
dilute { BrO ³ K „ + 5KBr „	+ 54.0
6KBr „ + O ³ „	+ 74.4
3I ² gas + 3K ² O { 3IOK „ + 3KI „	+ 19.5
dilute { IO ³ K „ + 5KI „	+ 26.4
6KI „ + O ³ „	- 17.6

From this it is seen that the most important chemical conditions in the formation of compounds of oxygen with the halogen-elements are in accordance with the thermic relations.

Heat of Formation and Transformation of Hydroxylamine, or Oxy-ammonia, NH^2O (Berthelot, *Compt. rend.* lxxxiii. 473):

	Heat-units
NH^2O dissolved = $\frac{2}{3}\text{N} + \frac{1}{3}\text{NH}^2$ dissolved + H^2O	+ 57.0
NH^2O " " HCl dilute at 24°	+ 9.2
$\text{NH}^2\text{O}.\text{HCl}$ cryst. + 90 pts. water at 24°	- 3.31
$\text{N} + \text{H}^2 + \text{O}$ " = NH^2O dissolved	+ 23.7*
$\text{N} + \text{H}^2 + \text{O} + \text{HCl}$ dil. = $\text{NH}^2\text{O}.\text{HCl}$ dissolved	+ 39.5
$\text{N} + \text{H}^2 + \text{O} + \text{Cl}$ " = $\text{NH}^2\text{O}.\text{HCl}$ cryst.	+ 75.5
$\text{NO} + \text{H}^2$ = NH^2O dissolved	+ 67.0

For the purely theoretical reactions:

NH^2 dissolved + O = NH^2O dissolved	- 11.4
$\text{NH}^2.\text{HCl}$ solid + O = $\text{NH}^2\text{O}.\text{HCl}$ cryst.	- 15.1

Further:

NH^2O diss. + H^2 = $\text{NH}^2.\text{H}^2\text{O}$ diss.	+ 67.0
NH^2O dil. + $\frac{1}{2}\text{O}$ = $\text{N} + \frac{3}{2}\text{H}^2\text{O}$	+ 79.8
NH^2O " + O = $\text{NO}^2 + \frac{3}{2}\text{H}^2\text{O}$ liquid	+ 70.8
NH^2O " + O^2 = NO^2 dil. + $\frac{3}{2}\text{H}^2\text{O}$	+ 53.9
NH^2O " + O^3 = NO^2 " + $\frac{3}{2}\text{H}^2\text{O}$	+ 72.4
$\text{NH}^2\text{O}.\text{HCl}$ diss. + $\frac{1}{2}\text{K}^2\text{O}$ "	+ 4.44
" " + NH^2 "	+ 3.2

Decomposition of Ammonium Nitrate (Berthelot, *Ann. Chim. Phys.* [5], x. 364).

$\text{NO}^2\text{H}.\text{NH}^2$ solid = $\text{N}^2\text{O} + 2\text{H}^2\text{O}$ liquid	37.3
" fused = $\text{N}^2\text{O} + 2\text{H}^2\text{O}$ gas, about	26.0
" " = $\text{N}^2 + \text{O} + 2\text{H}^2\text{O}$ gas	44.0
" " = $\text{N} + \text{NO} + 2\text{H}^2\text{O}$ gas	1.0
" " = $\frac{2}{3}\text{N} + \frac{1}{3}\text{NO}^2 + 2\text{H}^2\text{O}$ gas	32.0
" " = NO^2H gas + NH^2 gas	- 30.0

Heat of Formation of various Metallic Compounds.* 1. Magnesium, Calcium, Strontium and Barium (Thomsen, *J. pr. Chem.* [2], xvi. 97-124).

Reaction	Magnesium	Calcium	Strontium	Barium
(R, O)	145.86	131.36	130.98	130.38

(R O^2H^2 Aq., 2HCl Aq.)	27.69	27.90	27.63	27.78
(R O^2H^2 Aq., SO^2 Aq.)	31.22	31.14	30.71	36.9

On the Heat of Solution of these salts, see pp. 991, 992.

* In the table (p. 952) the thermal value given for this reaction is 47.4.

2. Nickel and Cobalt compounds (Thomsen, *J. pr. Chem.* [2], xiv. 413). These metals in their dynamical relations stand nearest to iron, the order of affinity being Fe—Co—Ni. The heat of formation of the monoxides, sesquioxides and anhydrous chlorides is shown in the following table:—

R	(R, O, H ² O)	(R ² , O ³ , 3H ² O) [†]	(RCl ³)
Fe . . .	68.28 heat-units	191.13 units	82.05 units
Co . . .	63.40 "	149.30 "	76.48 "
Ni . . .	60.84 "	120.38 "	74.53 "

The analogy of the three metals is shown by their heat of neutralisation, and the evolution of heat on solution of the anhydrous chlorides in water—

R	(RO ² H ² , SO ² Aq.)	(RO ² H ² , 2HClAq.)	(RCl ² , Aq.)
Fe . . .	24.92 units	21.39 units	17.90 units
Co . . .	24.67 "	21.14 "	18.34 "
Ni . . .	26.11 "	22.58 "	19.17 "

The difference between the three is shown by the evolution of heat on formation of the sesquioxides from the monoxides—

R	(2RO ² H ² , O, H ² O) [‡]
Fe . . .	54.57 heat-units
Co . . .	22.5 "
Ni . . .	— 1.3

It is owing to this difference that iron sesquioxide dissolves in dilute sulphuric acid without decomposition, whilst cobalt sesquioxide gives off oxygen, with formation of a cobaltous salt, and in the case of nickel the decomposition is very energetic. For the same reason the acid solutions of nickel and cobalt sulphates are not oxidised in the air. On the other hand, the free monoxides or their ammoniacal solutions behave quite differently—the oxidation of iron monoxide being represented by 54570 heat-units, that of cobalt monoxide by 22500 units, whilst nickel monoxide with the negative quantity of —1300 units remains unaltered.

Nickel and cobalt decompose water—they dissolve in dilute acids with evolution of hydrogen. In this respect they stand between cadmium and tin, as is shown by the evolution of heat on decomposition of dilute hydrochloric acid by these metals thus:—

Zinc . . .	34.20 heat-units.
Iron . . .	21.31 "
Cadmium . . .	17.61 "
Cobalt . . .	16.18 "
Nickel . . .	15.06 "
Tin . . .	2.5 "

The following table gives the thermal values determined for cobalt and nickel in various reactions. Ni and Co = 59. Temperature = 18°:—

Reaction	Evolution of Heat	Explanation
Co, Cl ² . . .	+ 76.48 heat-units.	Anhydrous chloride
Co, O, H ² O . . .	63.4 "	} Monoxide and hydrated oxide from metal,
Co ² , O ³ , 3H ² O . . .	149.3 "	
Co, O ² SO ² , 7H ² O . . .	162.97 "	} oxygen, and water
2CoO ² H ² , O, H ² O . . .	22.5 "	
2Co ² O ² H ² , O, H ² O . . .	— 0.7 "	} Crystallised sulphate
CoO ² H ² , 2HClAq. . .	+ 21.14 "	
CoO ² H ² , SO ² Aq. . .	24.67 "	} Oxidation of monoxide to sesquioxide
CoCl ² , Aq. . .	18.34 "	
CoSO ⁴ , 7H ² O Aq. . .	— 3.57 "	} Further oxidation of sesquioxide
Co.Cl ² , Aq. . .	+ 94.82 "	
Co, O, SO ² Aq. . .	88.07 "	} Heat of neutralisation of monoxide
Ni, Cl ² . . .	74.53 "	
Ni, O, H ² O . . .	60.84 "	} Heat of solution of anhydrous chloride
Ni ² , O ³ , 3H ² O . . .	120.38 "	
Ni ² , O ² , SO ² , 7H ² O . . .	162.53 "	} and crystallised sulphate
2NiO ² H ² , O, H ² O . . .	— 1.3 "	
NiO ² H ² , 2HClAq. . .	+ 22.58 "	} Formation of chloride and sulphate in
NiO ² H ² , SO ² Aq. . .	26.11 "	
NiCl ² , Aq. . .	19.17 "	} aqueous solution
NiSO ⁴ , 7H ² O Aq. . .	— 4.25 "	
Ni, Cl ² , Aq. . .	+ 93.7 "	} Heat of neutralisation
Ni, O, SO ² Aq. . .	86.95 "	

3. Tin Compounds (Thomsen, *loc. cit.*) Sn = 118. Temperature 81°.*Evolution of Heat on Solution of Compounds in Water.*

Reaction	Evolution of Heat	Explanation
$\text{SnCl}_4, \text{Aq.}$	29.92 heat-units.	Anhydrous tetrachloride
$\text{SnCl}_2\text{K}^2, \text{Aq.}$	-3.38 "	Chloride of tin and potassium
$\text{SnCl}_2, \text{Aq.}$	+0.35 "	Anhydrous dichloride

The affinity of tin for both oxygen and chlorine is very great, but more so for the latter than the former body. The formation of the hydrated oxide of tin from the metal, oxygen and water is accompanied by the same evolution of heat as the formation of hydrated monoxide of iron, and of water thus:—

The affinity of tin for oxygen is 2.41 heat-units greater than that of cadmium, but 14.59 less than that of zinc.

Tin readily takes up another atom of oxygen, and the oxidation of the hydrated monoxide into the hydrated dioxide is accompanied by an evolution of 65.4 heat-units.

The heat of neutralisation of the monoxide of tin for hydrochloric acid is 2.77 heat-units, that of the dioxide for soda 9.56 heat-units. Hence tin does not readily decompose water either in weakly acid or in alkaline solutions. The reduction of water by tin and very dilute hydrochloric acid gives only 2.5 heat-units; but the evolution of heat and rapidity of decomposition increase with the degree of concentration of the acid. This is the reason why tin is a suitable reducing agent for many organic bodies, since the oxidation of the tin takes place at the cost of the more easily reducible body. The heat of formation of the anhydrous stannous chloride is almost the same as that of ferrous chloride, mercurous chloride, and lead chloride.

On the other hand the behaviour of these chlorine-compounds to water is very different, the evolution of heat on solution of stannous chloride being +0.35 units, ferrous chloride +17.9 units, lead chloride -6.8 units; that of mercurous chloride is unknown.

A comparison of the higher chlorides of these metals gives—

But as the numbers of chlorine-molecules in the compounds are as 3 : 2 : 1, it follows that the formation of ferric, stannic, and mercuric chlorides is accompanied by an equal evolution of heat for equal quantities of chlorine. The lower chlorides therefore of iron, tin, and mercury are formed with evolution of the same quantity of heat,

amounting in the mean to 81.8 units for each molecule of chlorine, and the higher chlorides also evolve equal quantities of heat, amounting to 63.6 units for each molecule of chlorine. It may therefore be supposed that the union of the chlorine atoms in the higher chloride is of a similar nature, and that the higher chloride is not made up of the lower chloride and chlorine.

The difference of these values viz., $81.8 - 63.6 = 18.2$ units, is the quantity which Thomsen has often pointed to as the thermo-chemical constant.

$$\begin{aligned}\text{Again,} \quad 81.8 &= 9 \times 9.089 \\ 63.6 &= 7 \times 9.086,\end{aligned}$$

thus the absolute evolution of heat for chlorine in the two groups shows the same constant for the half of $18.0 = 2 \times 9.1$.

Whether other metals which have more than one chloride exhibit the same relation is not known, since those of copper only have been investigated.

The evolution of heat for cuprous chloride is 65.75, for cupric chloride 51.63 heat-units for each molecule of chlorine: the absolute evolution of heat is therefore considerably less than in the above cases; but—

$$\begin{aligned}81.8 : 63.6 &= 1.286 : 1 \\ 65.7 : 51.63 &= 1.274 : 1,\end{aligned}$$

and therefore the evolution of heat of cuprous and cupric chloride stands in the same relation as those of the lower and higher chlorides of tin, iron, and mercury.

4. Platinum and Palladium Compounds (Thomsen, *J. pr. Chem.* [2], xv. 435, 473).

(a.) *Heat of Formation of the Haloid Double Salts of Platinum.*

Reaction	Heat evolved	Explanation
Pt, Cl ⁴ , 2KCl . . .	89.5 units	Anhydrous salts corresponding with the chloride and bromide.

$\text{PdO}^2\text{H}^2, 4\text{HClAq}$	14.93 "	

Temperature 18°. Pt. = 198. Pd. = 106.

The haloïd compounds of platinum and palladium form with the hydrogen compounds of chlorine, bromine, and iodine, compounds which are soluble in water, and exhibit the character of bibasic hydracids, *i.e.* they form crystalline soluble salts with the alkalis, alkaline earths, and bases of the magnesium series, and more or less insoluble salts with the oxide of lead, mercury, and silver. The isomorphism of several of these groups indicates similarity of constitution, and the heat of neutralisation for the same base is the same as that of hydrochloric acid. The formulæ of the two series of acids are PtCl^1H^2 and PtCl^1H^2 . Tin, mercury, and gold form similar acids, and if the compounds of fluorine were included, silicon and several other elements would be added to the group. The heat of neutralisation of all these acids agrees with that of hydrochloric acid. These bodies are not known in the anhydrous state, but several of them have been obtained as hydrated crystalline acids, *e.g.* $\text{PtCl}^1\text{H}^4 + 6\text{H}^2\text{O}$, $\text{AuCl}^1\text{H} + 3\text{H}^2\text{O}$, $\text{AuBr}^1\text{H} + 5\text{H}^2\text{O}$, $\text{HgBr}^1\text{H} + 4\text{H}^2\text{O}$. They are all decomposed by heat, and yield normally water, haloïd acids, and a haloïd compound of the metal; but in many cases the temperature rises so high that the metallic compound is partially decomposed. Some of these acids are decomposed by water, while others possess considerable stability.

It appears to be a general rule that the heat of solution of potassium salts is always more strongly negative than that of the corresponding sodium salts, and that the differences of the heats of solution of the corresponding haloïd salts of potassium and sodium are simple multiples of a constant. Thus:

	Units
$\text{K}^2\text{Cl}^2, \text{Aq} - \text{Na}^2\text{Cl}^2, \text{Aq}$	= - 8.88 + 2.36 = - 6.52 = - 2 × 3.26
$\text{K}^2\text{Br}^2, \text{Aq} - \text{Na}^2\text{Br}^2, \text{Aq}$	= - 10.16 + 38 = - 9.78 = - 3 × 3.26
$\text{K}^2\text{I}^2, \text{Aq} - \text{Na}^2\text{I}^2, \text{Aq}$	= - 10.22 - 2.44 = - 12.66 = - 4 × 3.165
$\text{PtCl}^1\text{K}^2, \text{Aq} - \text{PtCl}^1\text{Na}^2, \text{Aq}$	= - 13.76 - 8.54 = - 22.30 = - 7 × 3.186
$\text{PtBr}^1\text{K}^2, \text{Aq} - \text{PtBr}^1\text{Na}^2, \text{Aq}$	= - 12.26 - 9.99 = - 22.25 = - 7 × 3.179

The explanation of this fact is that the sodium salts are not fully saturated compounds like the potassium salts; they have a tendency to combine with water, and this tendency is least with sodium chloride, greatest with the haloïd compounds of sodium and platinum. The formation of potassium-palladium chloride is accompanied by a greater evolution of heat than that of potassium-platinum chloride, while, on the other hand, it is just the reverse in the case of the dichlorides. This would follow from the fact that palladium forms the dichloride, platinum the tetrachloride most readily. The heat evolved in each case is as follows:

	Platinum	Palladium
Dichloride	4517 units	2 × 26.335 units
Tetrachloride	2.4475 "	3 × 26.353 "

More important is the result of the comparison of the difference of evolution of heat in the formation of compounds of two different stages of the same metals. Thus in the passage of the compounds of gold, mercury, palladium, and platinum from a lower to a higher stage by addition of a molecule of chlorine, bromine, and iodine, the evolution of heat is as follows:

	Chlorine	Bromine	Iodine
Mercury	6 × 8.858	4 × 8.822	3 × 8.793
Platinum	5 × 8.866	3 × 8.983	—
Palladium	3 × 8.797	—	—
Gold	2 × 8.505	1 × 8.930	—

A molecule of chlorine, therefore, gives in these allied reactions an unequal evolution of heat in the proportion of 2 : 3 : 5 : 6, bromine of 1 : 3 : 4, &c. The mean constant is the same in all, viz. 8.850 units.

4. Gold-compounds (Thomsen, *J. pr. Chem.* [2], xiii. 348-369). Gold shows allotropic peculiarities according to the kind of solution from which it is precipitated, and the kind of reagent used. Three such modifications have been investigated. When gold is precipitated from a solution of auric chloride by sulphurous acid, it forms a mass which boils together; when precipitated in a similar manner from a solution of the bromide, it forms a very fine dark powder, which retains its pulverulent state even on drying: when reduced from the sub-chloride, sub-bromide, or sub-iodide by sulphurous acid or a hydrogen acid, it has the form of a very fine powder with perfect metallic lustre and a yellow colour. These modifications differ from each other by unequal evolution of heat in similar reactions. The gold which has been precipitated from the chloride by sulphurous acid shows least energy and is taken as the standard of reference. The energy of gold precipitated from the bromide is greater by an amount represented by 3·2 heat-units, while that of gold precipitated from the sub-chloride, the sub-bromide, or sub-iodide is 4·7 units greater for each atom. The last two modifications, therefore, evolve respectively 3·2 and 4·7 units of heat when converted into the first modification.

The following tables give the direct results of the experiments on the thermochemistry of the gold compounds:

Reaction	Evolution of heat	Explanation
(AuCl ³ Aq, HClAq) . . .	4·53 units	Reactions of halogen-acids on the soluble haloid compounds of gold.
(AuBr ³ Aq, HBrAq) . . .	7·7 "	
(AuCl ³ Aq, 3HBrAq) . . .	15·21 "	
(AuBr ³ Aq, 3HClAq) . . .	4·28 "	
(AuCl ³ HAq, 4HBrAq) . . .	13·8 "	
(AuBr ³ HAq, HClAq) . . .	— 51 "	Heat of neutralisation of hydrated oxide for hydrobromic and hydrochloric acids.
(AuO ³ H ³ , 4HBrAq) . . .	36·78 "	
(AuO ³ H ³ , 4HClAq) . . .	22·97 "	
(AuCl ³ Aq, 2SO ² Aq) . . .	83·6 "	Reduction of soluble haloid compounds by sulphurous acid.
(AuBr ³ HAq, 2SO ² Aq) . . .	61·79 "	
(3AuCl, HClAq) . . .	4·98 "	Decomposition of sub-chloride and sub-bromide by the corresponding halogen acid.
(3AuBr, HBrAq) . . .	3·65 "	
(2AuBr, SO ² Aq) . . .	42·76 "	Reduction of sub-bromide and sub-iodide by sulphurous acid.
(2AuI, SO ² Aq) . . .	23·4 "	
(AuCl ³ Aq, 3KIAq) . . .	45·66 "	Neutral chloride decomposed by KI.
(AuBr ³ H, 5H ² O, Aq) . . .	— 11·4 "	Direct determination of heat of solution.
(AuCl ³ Aq) . . .	+ 4·45 "	
(AuBr ³ , Aq) . . .	— 3·71 "	
(AuBr ³ sHBrAq) . . .	+ 3·88 "	Indirect determination of the same for AuBr ³ .

From these data Thomsen calculates the following values of the quantities of heat evolved in the formation of gold-compounds, all the values relating to that modification of gold which is precipitated from a dilute solution of the chloride by sulphurous acid.

Reaction	Evolution of heat	Explanation
(Au, Cl ³) . . .	22·82 heat-units	Heat of formation of anhydrous haloid compounds.
(Au, Br ³) . . .	8·85 "	
(Au, Cl) . . .	5·81 "	
(Au, Br) . . .	— 0·08 "	
(Au, I) . . .	— 5·52 "	Heat of formation of hydrated oxide.
(Au ² , O ³ , H ² O) . . .	— 13·19 "

(Au, Br ³ , Aq) . . .	5·09 "	
(Au, Cl ³ , HClAq) . . .	31·80 "	Heat of formation of solutions of acid haloid compounds.
(Au, Br ³ , HBrAq) . . .	12·79 "	

Heat of Formation of the Carbon-, Boron-, and Silicon-compounds of Iron and Manganese (Troost & Hautefeuille, *Ann. Chim. Phys.* [5], ix. 56-70).

The combination of iron and carbon is attended with absorption of heat, as shown by the fact that when a carbide of iron is chlorinated by treating it with mercuric chloride, the quantity of heat evolved increases with the proportion of carbon present: thus:

1 gram of iron containing only traces of carbon gave	. . .	0.827 heat-units
1 " " 2.8 per cent. " "	. . .	0.879 "
1 " " 4.0 " " "	. . .	0.896 "

The carbide of iron must be regarded therefore not as a true chemical compound, but as a solution of the carbon in the iron.

The formation of manganese carbide, on the other hand, is attended with evolution of heat, as shown by the fact that a specimen containing 4.8 per cent. carbon gave, when treated with mercuric chloride, 1.19 heat-units, whilst another containing 6.8 per cent. carbon gave only 1.01. The carbides of manganese are therefore true chemical compounds; the compound Mn^3C has, indeed, a degree of stability comparable with that of the most stable inorganic compounds. The 'ferro-manganeses' of commerce, Mn^2Fe^3 , $MnFe$, Mn^2Fe , &c., are likewise true chemical compounds, their formation being attended with disengagement of heat.

Silicide of manganese is formed with great evolution of heat. In the combination of silicon with iron, the evolution of heat is next to nothing for the proportion of silicon which is found in metallurgic products.

The heat of formation of crystallised manganese boride, MnB^2 , from its elements amounts to 2.487 heat-units for 1 gram. The quantities of heat evolved in the formation of iron boride, containing 11 and 23 per cent. boron, are respectively 0.517 and 1.611 units for 1 gram.

Phosphide of iron is formed with great evolution of heat. Sulphide of iron is probably formed with scarcely perceptible evolution of heat. The formation of sulphide and phosphide of manganese from the carbide is also attended with great evolution of heat.

Heat evolved in the transformations of Acetylene (Berthelot, *Ann.*

Chim. Phys. [5], ix. 165-174):

C^2H^2 gas + O^2 gas = $2CO^2$ gas + H^2O liquid.	. . .	321.0
C^2H^2 + O^4 = $C^2H^2O^4$, Oxalic acid, solid.	. . .	260.8
C^2H^2 + O + H^2O = $C^2H^4O^2$, Acetic acid, cryst.	. . .	113.5
C^2H^2 + O^4 = CH^2O^2 , Formic acid, cryst. + CO^2 gas.	. . .	253.5
C^2H^2 + H^2 = C^2H^4 , Ethylene.	. . .	56.0
C^2H^2 + N^2 = $2CNH$, Hydrogen Cyanide, gas.	. . .	36.0
$3C^2H^2$ = C^6H^6 , Benzene, liquid.	. . .	nearly 190.0
C^2 , diamond + H^2 = C^2H^2 gas.	. . .	64.0

Heats of Combination of Ethylene (Berthelot, *ibid.* 296, 306):

C^2H^4 gas + Br^2 liquid	= $C^2H^4Br^2$ liquid	. . .	+ 29.3
C^2H^4 " + Br^2 gas	= $C^2H^4Br^2$ " "	. . .	36.5
C^2H^4 " + Br^2 "	= $C^2H^4Br^2$ gas	. . .	about 28.0
C^2H^4 " + H^2SO^4 dilute	= $C^2H^4.H^2O.SO^3$, Isethionic acid, dil.	. . .	16.01
C^2H^4 " + SO^3 solid + water	= $C^2H^4.H^2O.SO^2$, " "	. . .	53.3

Heat of Formation of Ethyl Chloride and Iodide on the assumption that the ethers of ethylene give the same numbers as those of amylene (*infra*) (Berthelot, *ibid.* 348):

C^2H^5O gas + HCl gas = C^2H^5Cl gas + H^2O gas	. . .	- 2.7
C^2H^5O " + HI " = C^2H^5I " + H^2O "	. . .	- 1.3

If the haloid acid alone were gaseous, the value for C^2H^5Cl would be 3.4, and for C^2H^5I , 6.0; if, on the other hand, all the acting substances were dissolved in water, the value for C^2H^5Cl would be -16.6, and for C^2H^5I -16.0, the ethers being insoluble in water.

Heat of Combination of Amylene with the Haloid Acids (Berthelot,

ibid. 292):

C^5H^{10} liquid + HI (sp. gr. 1.98)	. . .	1.7
C^5H^{10} " + HBr (sp. gr. 1.79)	. . .	0.8
C^5H^{10} " + HCl (" 1.20)	. . .	0.95
C^5H^{10} " + HI gas	. . .	17.6
C^5H^{10} " + HBr gas	. . .	15.2
C^5H^{10} " + HCl "	. . .	14.8
C^5H^{10} gas + HI " = $C^5H^{10}.HI$ liquid	. . .	22.9
C^5H^{10} " + HBr " = $C^5H^{10}.HBr$. . .	20.5
C^5H^{10} " + HCl " = $C^5H^{10}.HCl$. . .	20.0

The heat of evaporation of amylene at 12.5° in a current of air was found to be -5.25.

Heat of Conversion of Alcohols into Acid Alcoholic Sulphates (Berthelot, *ibid.* 307). The reactions are :

		I	II
Methyl Alcohol	CH^1O	-5.1	+13.8
Ethyl Alcohol	$\text{C}^2\text{H}^6\text{O}$	4.7	14.7
Propyl Alcohol	$\text{C}^3\text{H}^8\text{O}$	4.05	15.9
Pseudopropyl Alcohol	$\text{C}^3\text{H}^8\text{O}$	3.3	17.1
Isobutyl Alcohol	$\text{C}^4\text{H}^{10}\text{O}$	2.2	17.6
Amyl Alcohol (ferment.)	$\text{C}^5\text{H}^{12}\text{O}$	0.2	19.5
Glycerin *	$\text{C}^3\text{H}^8\text{O}^3$	3.2	15.2

Heat of Formation and of various reactions of Aldehyde (Berthelot, *Ann. Chim. Phys.* [5], ix. 174-180):

$\text{C}^2\text{H}^4\text{O}$ pure + O	=	$\text{C}^2\text{H}^4\text{O}^2$ Acetic acid, liquid	+ 70.1
$\text{C}^2\text{H}^4\text{O}$ „ + O	=	$\text{C}^2\text{H}^4\text{O}^2$ „ solid	+ 67.6
$\text{C}^2\text{H}^4\text{O}$ gas + O	=	$\text{C}^2\text{H}^4\text{O}^2$ „ gas	- 70.0
$\text{C}^2\text{H}^4\text{O}$ liq. + H ²	=	$\text{C}^2\text{H}^6\text{O}$ liq. + 28.0; all gas	+ 32.0
$\text{C}^2\text{H}^4\text{O}$ gas + H ²	=	C^2H^6 gas + ?	+ 37.0
$\text{C}^2\text{H}^4\text{O}$ „	=	$\text{CH}^1 + \text{CO}$	- 5.5
$\text{C}^2\text{H}^4\text{O}$ „	=	$\text{CH}^2 + \text{H}^2\text{O}$	- 45.0

The last two reactions are brought about by heat, therefore by foreign energy.

$\text{C}^2\text{H}^4\text{O} + \text{Cl}^2$	=	$\text{C}^2\text{H}^3\text{ClO} + \text{HCl}$	+ 39.5
$\text{C}^2\text{H}^4\text{O} + \text{Br}^2$	=	$\text{C}^2\text{H}^3\text{BrO} + \text{HBr}$ + 16.0; Br ² gas	+ 23.0
$\text{C}^2\text{H}^4\text{O} + \text{I}^2$	=	$\text{C}^2\text{H}^3\text{IO} + \text{HI}$ - 9.8; I ² „	- 8.0

The negative value for the iodine-compound is in accordance with the impossibility of producing the compound by direct action.

$\text{C}^2\text{H}^4\text{O}$ gas	=	$\text{CH}^1 + \text{CO}^2$	- 5.5
$\text{C}^2\text{H}^4\text{O}$ „	=	$\text{C}^2\text{H}^2 + \text{H}^2\text{O}$	- 45.0
C^2 diamond + H ² + O	=	$\text{C}^2\text{H}^4\text{O}$ liq. + 46.0; gas	+ 40.0
C^2H^4 ethylene + O	=	$\text{C}^2\text{H}^4\text{O}$ gas	+ 48.0
$\text{C}^2\text{H}^6\text{O}$ alcohol, gas	=	$\text{C}^2\text{H}^4\text{O}$ „ + H ² about - 24.0

The evolution of heat in the decomposition of explosive bodies—the water being considered as gaseous—can be calculated only for nitroglycerin, which alone contains sufficient oxygen for its combustion. This, for 1 mol. = 227 grams, amounts to 405·5, and for 1 gram to 1·786 kil.-degrees.

2. *Evolution of Heat in the Perfect Combustion of Explosive Substances by free Oxygen, the water being supposed to be gaseous.*

	Molecule	Heat of combustion	
		1 mol.	1 gram
Ethyl Nitrate	91	305·5	3·357
Nitroglycerin	227	406·5	1·786
Gun-cotton	297	—	1·572
Picric acid	229	668·0	2·919
Potassium Picrate	267	661·0	2·473

If A denotes the heat evolved in the combustion of 1 equivalent (semi-molecule) of the substance containing carbon and hydrogen by free oxygen, and n the number of equivalents of oxygen consumed, the heat evolved when the combustion is effected by various oxidising agents is as follows :

* Berthelot gives for gun-cotton the formula $\text{C}^6\text{H}^{10}\text{O}^2(\text{NO}^3\text{H})^3$, and molecular weight 549, making the heat of formation for 1 mol. 502; but there is an error in the calculation: the molecular weight of $\text{C}^6\text{H}^{10}\text{O}^2(\text{NO}^3\text{H})^3$ is 351, and the corresponding heat-equivalent is 322 (or 273 for mol. wt. 297).

Heat evolved in the Formation and Combustion of Formic and Oxalic Acid (Berthelot, *Compt. rend.* lxxvi. 1433–1441; *Ann. Chim. Phys.* [5], v. 310–318).

For the heat of formation of formic acid from its elements, Berthelot finds:

For the heat of combustion:

For the formation of marsh gas by the dry distillation of barium formate:

For the formation of oxalic acid:

For the combustion of oxalic acid:

Thermochemistry of Acetyl-derivatives (Berthelot a. Louguinine (*Ann. Chim. Phys.* [5], vi. 289–304). The decomposition of acetyl chloride by water:

Since now the heat of solution of gaseous hydrochloric acid in water amounts to 17·4 heat-units, and that of crystallisable liquid acetic acid to 0·4, it follows that

The decomposition of acetyl bromide by water gives

The heat of solution of gaseous HBr is 20·0, therefore

The heat of decomposition of acetyl iodide by water is

The heat of solution of HI is 19·57, therefore

According to these results, the formation of the acid chlorides, bromides, and iodides from the corresponding organic acids and the halogen acids should be attended with absorption of heat. Consequently, these bodies are formed only in presence of a compound, like phosphoric or sulphuric anhydride, the combination of which with water is accompanied by evolution of heat, *e.g.*

Hence for the substitution of the halogen-elements in acetic acid :

It follows from this that the direct substitution of iodine for hydrogen cannot be effected. On the other hand, acetyl iodide and iodated compounds in general are easily attacked by hydriodic acid, with separation of iodine. Acetyl chloride is converted by gaseous hydriodic acid into iodide, and by gaseous hydrobromic acid into bromide, with evolution of 3 kil.-degrees of heat. On the other hand, chlorine expels bromine from acetyl bromide, and iodine from the iodide. Moreover, iodine can be replaced by chlorine, with the aid of silver chloride:

These examples show how thermochemical investigations may serve as guides in the choice of reagents for the preparation of any desired compound.

The decomposition of the *chlorides* and *bromides* of the *fatty acid radicles* by water has also been studied by W. Louguinine. The following values relate to the reaction:

Chloride or Bromide (liquid) + H²O gas = Acid (liquid) + Hydrochloric or Hydrobromic acid (gas):

	Chloride	Bromide
Acetic	17.5	13.8
Butyric (normal)	14.75	12.84
Butyric (iso-)	13.08	13.01
Valeric acid (iso-), from valerin	12.66	12.58
„ „ by oxidation	13.43	12.60

Trimethylacetic chloride gave for:

For the conversion of acetic anhydride into the acid, Berthelot finds (*Compt. rend.* lxxx. 599):

and by subtracting from the difference of these two numbers, viz. 13.92, the heat of solution of acetic acid, there remains for the heat of conversion of C⁴H⁶O³ into C²H⁴O²:

This value is regarded by Berthelot as more exact than the number 12.0 formerly obtained by the very slow action of water on the anhydride.

Heat of Solution and of Chemical Action in the Wet Way.

Influence of Temperature on the Heat of Solution and the Heat of Chemical Action in general. The following general law of the equivalence between heat and chemical change, founded on the principle of the equivalence between heat and mechanical work—in this instance molecular work—and on the general law of the conservation of energy, was enunciated by Berthelot in 1865 (*Ann. Chim. Phys.* [4], vi. 329): *When a system of bodies, simple or compound, existing under given conditions, undergoes physical or chemical alterations which bring it into a new state without the aid of external mechanical actions, the quantity of heat evolved or absorbed during these changes depends exclusively on the initial and final states of the system, and is the same whatever may be the nature and results of the intermediate states.*

Now suppose a system of still uncombined bodies to be raised, by assumption of a number of heat-units, U, without experiencing chemical change, from the temperature *t* to the higher temperature *τ*; then suppose combination to take place, and let the quantity of heat thereby evolved be denoted by Q_τ. Next let the resulting compound, without experiencing any chemical change, be cooled from *τ* to *t* by abstraction of

V units of heat. Lastly, let Q_t be the number of heat-units evolved when the same bodies unite chemically at the temperature t ; then it follows from the general principle just enunciated that:

$$Q_\tau - Q_t = U - V.$$

If the interval of temperature $\tau - t$ be so chosen that neither the uncombined bodies nor any of the products of the reaction suffer a change of aggregation, the preceding equation may be written in this form:

$$Q_\tau - Q_t = (\Sigma c - \Sigma c_1)(\tau - t),$$

where Σc denotes the sum of the specific heats of the atoms of the uncombined bodies, and Σc_1 that of the combined bodies.

In the gaseous state, the quantity of heat evolved in chemical reactions is but little affected by temperature, on account of the slight differences between the specific heats of the gases before and after the reaction. The liquid state is, on the whole, the least favourable to the comparison of the quantities of heat evolved or absorbed in reactions, on account of the rapid alteration of the specific heat of liquids with the temperature, whereas the alterations of the quantities of heat evolved, referred to the solid state, consequent on a change in the initial temperature, mostly fall within the limits of error of observation (Berthelot, *Compt. rend.* lxxviii. 1670).

Evolution of Heat in Solution at various Temperatures, and in the Dilution of Concentrated Solutions.—Let C be the molecular heat of the salt; nH^2O the quantity of water in which 1 mol. of the salt is dissolved; $18n + K$ the specific heat of this solution. Now from the observations of Schüller (1st *Suppl.* 668) it may be inferred that $K < C$ and even < 0 , for the more dilute solutions. Between the temperatures τ and t , the heat-capacity, U , of the constituents alone is equal to $(18n + C)(\tau - t)$, and that of the solution is $V = (18n + K)(\tau - t)$; consequently:

$$U - V = (C - K)(\tau - t),$$

and according to Berthelot's fundamental equation (*supra*):

$$Q_\tau - Q_t = (C - K)(\tau - t).$$

If now $K < C$, as it always is for solutions of an anhydrous salt in a large quantity of water, and if the solution at the temperature t is attended with absorption of heat, the quantity thus absorbed will be greater as the initial temperature τ is lower in comparison with t . On the other hand, the higher the initial temperature, the smaller will be the quantity of heat absorbed until, at a certain temperature, solution will take place without either evolution or absorption of heat. For initial temperatures higher than this, an evolution of heat takes place, increasing in amount as the initial temperature is higher. If, on the contrary, heat is evolved at a certain temperature t , the amount so evolved decreases as the initial temperature is lower, is reduced to nothing at a certain limit, and, on further lowering of the initial temperature, passes into a continually increasing absorption of heat.

For the temperature τ of solution, unattended either by evolution or by absorption of heat, we have the equation:

$$Q_\tau = Q_t + U - V = Q_t + (18n + C)(\tau - t) - (18n + K)(\tau - t) = 0,$$

whence

$$\tau = -\frac{Q_t}{C - K} + t.$$

For example, Berthelot finds that the solution of anhydrous sodium sulphate in water at 21.5° is attended with the evolution of 780 units of heat.

Na_2SO_4 (142 grm.) + $400H^2O$ (7200 grm.) evolves 780 gram-degrees.

From this and the molecular heats of the salt and its solution, the temperature at which dissolution takes place without thermal change may be calculated as follows: For the solid salt, the molecular heat is 32.2, that of the initial system is therefore $7200 + 32.2 = 7232.5$. For the final system, that is to say, the resulting solution, we have:

	Specific heat	Molecular heat	$U - V$	τ
according to Schüller (1)	0.9835	7222	$(72325 - 7222)(\tau - 21.5)$	-52.8
„ Marignac (2)	0.9805	7199	$(72325 - 7199)(\tau - 21.5)$	-2.8
„ Thomsen (3)	0.976	7166	$(72325 - 7166)(\tau - 21.5)$	$+9.8$

(1) 1st. *Suppl.* 668.

(2) 2nd. *Suppl.* 601.

(3) *Ibid.* 599.

The preceding values of τ are calculated from the equation $Q_t = 780 + U - V$

whence, according to Schüller, $\tau = -\frac{780}{10.5} + 21.5 = -52.8^\circ$

„ Marignac, $\tau = -\frac{780}{35.5} + 21.5 = -2.8^\circ$

„ Thomsen, $\tau = -\frac{780}{66.5} + 21.5 = +9.8^\circ$

From direct observations at $+2.5^\circ$, $+3^\circ$, and $+3.9^\circ$, all of which indicated absorption of small quantities of heat, Berthelot infers that the temperature at which no thermal change would take place is about $+7^\circ$, which is intermediate between those deduced from the observations of Marignac and Thomsen. The accuracy of the calculation of τ is diminished by the fact that the divisor results from a small difference between two large experimental numbers, so that small errors in the determination of the latter will exert a considerable influence on the result of the calculation. Moreover, the calculation is based on the assumption that within the observed limits of temperature no change takes place in the heat-capacity either of the solution or of its constituents.

Crystallised potassium carbonate, $K_2CO_3 \cdot 1\frac{1}{2}H_2O$, dissolves at ordinary temperatures with absorption of heat, and calculation shows that within the limits of temperature accessible to experiment, dissolution is attended sometimes with evolution, sometimes with absorption of heat. Berthelot observed the following thermal changes:

The point of no thermal change must be situated near 25° . By similar calculations it is found that the absorption of heat which takes place on dissolution at ordinary temperatures becomes nothing and then passes into evolution of heat:

for KCl in 100 H_2O at about 130°
 „ $NaNO_3$ in 100 H_2O „ 160
 „ KNO_3 in 200 H_2O „ 200

For the dilution of the solution of 1 mol. of a salt in n mol. water by addition of n_1 mol. water, $U = [18(n + n_1) + K](\tau - t)$ and $V = [18(n + n_1) + K_1](\tau - t)$: therefore

$$Q_\tau = Q_t + (K - K_1)(\tau - t).$$

Now as K is always greater than K_1 , the evolution of heat on dilution increases as the initial temperature is greater; consequently an absorption of heat taking place at t° gradually diminishes as the initial temperature increases, then becomes nothing, and passes into a continually increasing evolution of heat. For the temperature of dilution without thermal change, we have the equation

$$Q_\tau = Q_t + (K - K_1)(\tau - t) = 0;$$

whence
$$\tau = \frac{Q_t}{K - K_1} + t$$

(Berthelot, *Compt. rend.* lxxviii. 1722-1730).

By further experiments (*Ann. Chim. Phys.* [5], ix. 43) Berthelot finds that the heat of solution of slightly soluble bodies exhibits the same changes of sign and magnitude as those above noticed in very soluble bodies:

Calcium Hydrate, at about 15°	+	3
Strontium Sulphate, $SrSO_4$, anhydrous	{	at ordinary temperatures.	nearly	0
Calcium Sulphate, $CaSO_4 \cdot 2H_2O$		a little below 15°	positive	
		above 25°	negative	
Lead Chloride	-	6
Potassium Picrate, $C^6H^2(NO^2)_3K$	-	10

Berthelot takes a similar view of the thermal changes which occur in crystallisation, precipitation, coagulation, and the conversion of an amorphous into a crystalline body, and proposes, as a differential method of measuring the specific heats of dilute solutions, the determination of the magnitude $U - V$ by two mixture-experiments to be carried out at temperatures differing from one another by 10 or 15 degrees, the calculation being then performed according to the equation $U - V = (K - K_1)(\tau - t)$.

On the influence of temperature on the Heat of Chemical Combination in the Wet way, see also Thomsen (*Deut. Chem. Ges. Ber.* vii. 1330-1345; *Jahresb. f. Chem.* 1873, 64).

Relations between the Heat of Solution of Salts and the Density of the Vapours evolved from their Solutions.—It has been shown by Kirchhoff (*Pogg. Ann.* xciii, 196) that the thermic effect produced in the dissolution of a solid or liquid body in water is related to the vapour-density of the solution in the manner represented by the formula—

$$dQ = ATVF \frac{d}{dt} \log \left(\frac{F}{t} \right) dm,$$

in which dQ denotes the heat absorbed on addition of the weight dm of the substance at the temperature t ; $A = \frac{1}{425}$, the heat-equivalent of the unit of work; $T = t + 273$ the absolute temperature; F the maximum tension of water-vapour at the same temperature.

The correctness of this theory has been demonstrated by Moutier (*Ann. Chim. Phys.* [4], xxviii, 515–529), by comparison with the experiments of Wüllner (iii, 95) on the vapour-tensions of various salt-solutions at different degrees of concentration, together with those of Person (*Jahresb. f. Chem.* 1851, 57) on the heat of solution of the same salts under similar conditions.

Constitution of Acids and Salts in Solution (Berthelot, *Compt. rend.* lxxxi, 844–849). The relative strength of acids and bases may be estimated by the extent to which their salts are decomposed by increasing quantities of water, as indicated by the accompanying evolution or absorption of heat.

Strong acids and bases, dissolved in separate portions of water and then united in equivalent quantities, form neutral stable salts, which disengage quantities of heat nearly constant for the different acids and bases of this category. This quantity of heat does not seem to vary on the addition of a fresh portion of water, or of a base or acid identical with or differing from those already in combination. From this it may be inferred that water does not tend to separate such bases and acids, at least in any appreciable manner. To such a class belong the chlorides, nitrates, and neutral sulphates of the fixed alkalis.

Weak acids, on the other hand, combining even with strong bases, form salts which are decomposed by water, the decomposition increasing with the amount of water added, and decreasing with the amount of base or acid. The progress of this decomposition is not always the same, but increases sometimes indefinitely, sometimes up to a certain limit, depending on the amount of water added. This is observed in borates, carbonates, alkaline phenates, and even in acetates, butyrates, valerates, &c.

Sometimes the decomposition of a neutral salt takes place almost entirely on the first addition of water, in such a manner that an absorption of heat occurs nearly equal to that disengaged in the initial formation of the alkaline salt; this is the case with the alkaline compounds derived from alcohol, mannite, glycerin, &c. In salts containing weak bases, such as the oxides of the heavy metals, the decomposing action of water shows itself distinctly even in presence of strong acids, and still more in presence of weak acids. The ammonia-salts of strong acids likewise show signs of decomposition by water, and in those of weak acids the decomposition is much more evident. Thus the neutral carbonate and phenate of ammonia are decomposed by water much more readily than the carbonates and phenates of the fixed alkalis; and between dissolved alkali carbonates and the nitrate, chloride, or sulphate of ammonium, double decomposition takes place, resulting in the formation of ammonium carbonate, and the union of the strongest acid with the strongest base, producing the most stable salt.

The following law, founded on thermo-chemical investigations, is laid down by Berthelot (*Bull. Soc. Chim.* [2], xix, 156). *The salt whose formation is attended with the greatest evolution of heat is always produced when the salts at whose expense its formation takes place are present in the solution in a state of partial decomposition. The sum of the reactions determined by the formation of this principal reaction is not however necessarily accompanied by the greatest possible evolution of heat, but may even be attended with absorption of heat.* Thus, for example, potassium carbonate in solution decomposes ammonium sulphate, and is converted entirely or nearly so into potassium sulphate with absorption of 3.2 units of heat. The point to be determined is therefore the stability of the salts in presence of water. This can in many cases be measured by the thermic changes accompanying dissolution and dilution, as in the case of ammonium salts with weak acids, which decompose to an extent increasing with the quantity of water present (*2nd Suppl.* 628, 629, 631).

The decomposition of ammonia-salts containing strong acids, the sulphate for example, which is slight and not sensible to the thermometer, may be recognised by the acid reaction produced, and by the alkalimetric analysis of the distillate.

If, for example, only a few ten-thousandths of the whole are decomposed, the addition of an alkaline carbonate disturbs the equilibrium so far as to produce complete conversion into potassium sulphate and ammonium carbonate, because free sulphuric acid cannot exist in its presence, the formation of potassium sulphate disengaging a greater quantity of heat than that of the carbonate. Ammonium carbonate is also completely decomposed by an equivalent quantity even of dilute sulphuric acid, as shown by the thermic changes which take place (Berthelot, *Jahresb. f. Chem.* 1872, 91). A similar explanation applies to the double decomposition of metallic salts. Thus, in consequence of the partial decomposition of dissolved ferric nitrate or sulphate, the addition of sodium acetate gives rise, according to thermal observations, to almost complete decomposition (*ibid.* 84; 2nd Suppl. 287). Of all the salts whose formation is possible, the one actually produced is that whose formation is attended with the greatest evolution of heat. The same rule determines also the action of acids on dissolved salts (*Jahresb. f. Chem.* 1872, 90; 2nd Suppl. 286). If the salt which evolves most heat is stable in presence of water, its formation will be complete; but if it suffers partial decomposition under the influence of water, its formation will be limited, in proportion to the degree of its stability. The above-mentioned rule, which is applicable to all saline solutions, is regarded by Berthelot as confirmatory of the general thermochemical principle, according to which every chemical change which takes place without external influence results in the formation of that body or those bodies whose production is attended with the greatest evolution of heat.

Redissolution of Precipitates by Acids.—Berthelot finds that the laws which regulate the division of a base between two acids and the formation of soluble salts within a solution (2nd Suppl. 286) are applicable also to insoluble salts, inasmuch as these latter are completely decomposed and dissolved by stronger acids, which act on the base of the salt with greater evolution of heat. Insoluble silver acetate for example is immediately converted by nitric acid into the soluble nitrate:

$\text{NO}^3\text{H dilute} + \text{C}^2\text{H}^3\text{AgO}^2 = \text{NO}^3\text{Ag dilute} + \text{C}^2\text{H}^4\text{O}^2$ dissolved, gives . . . $-3\cdot5$ kil.-deg.

But this absorption of heat is due to the conversion of a solid into a dissolved body: for calculation gives—

$\text{NO}^3\text{H dilute} + \text{C}^2\text{H}^3\text{AgNO}^2 = \text{NO}^3\text{Ag solid} + \text{C}^2\text{H}^4\text{O}^2$ dissolved . . . $+2$ kil.-deg.

and if the two acids were separated by water, the evolution of heat would amount even to 9 kil.-degs. A number of similar cases might be adduced in which a salt insoluble in water is completely dissolved by a monobasic acid. The dissolution of insoluble carbonates by monobasic acids, such as nitric or hydrochloric, in solutions concentrated but containing a quantity of water sufficient to dissolve the carbonic acid, is likewise complete. In dilute solutions the action is attended sometimes with evolution, sometimes with absorption of heat (silver carbonate and nitric acid). Thermic measurements also show that 1 mol. precipitated calcium tartrate, $\text{C}^4\text{H}^4\text{CaO}^6$, must be completely decomposed by 2 mols. hydrochloric acid. A similar reaction takes place between barium citrate and dilute hydrochloric acid, and between barium tartrate or citrate and dilute sulphuric acid (*Compt. rend.* lxxvii. 393).

Solution of Mixed Salts.—The thermic relations in the solution of mixed salts in water, and the accompanying double decompositions have been investigated by A. Winkelmänn (*Pogg. Ann.* cxlix. 492–521). The general result may be stated in the following propositions: (1). In salts which do not suffer mutual decomposition when dissolved together, the law observed by Person (*Ann. Chim. Phys.* [3], xxxiii. 448) that the quantity of heat absorbed in the dissolution of a mixture of salts is equal to the sum of the quantities absorbed in the dissolution of the individual salts—is nearly true, and the more nearly as the solutions are less concentrated. The specific heat of the solution of such a saline mixture is also nearly equal to the mean specific heat of equally concentrated solutions of the individual salts, of which the mixed solution may be supposed to be ultimately constituted. (2). The form of the compounds in which acids and bases are introduced into the solution is not always a matter of indifference, inasmuch as the state of equilibrium which is ultimately established in the solution may depend upon that form. Instances of this are afforded by ammonium nitrate and sodium chloride on the one hand, and sodium nitrate and ammonium chloride on the other. The following comparison shows the deviation from Person's first law, which may take place in mixtures of salts which do not undergo mutual decomposition when dissolved in water. The mixture of these salts in equally concentrated solutions is usually attended with a rise of temperature, as observed by Marignac (2nd Suppl. 635); Winkelmänn however, as also Marignac, has noticed some cases in which a fall of temperature is produced, thus—

Rise of temperature for—

KCl and NaCl.
KCl and KNO₃.
NaCl and NaNO₃.
KCl and NH₄Cl.
NH₄Cl and NH₄NO₃.

Fall of temperature for—

NaCl and NH₄Cl.
NaNO₃ and NH₄NO₃.

For the combinations in the first group, therefore, the quantity of heat calculated according to Person's first law, as required for the solution of a mixture of salts, is greater than the quantity actually used up, while for those in the second group it is less. But in both cases the differences between the observed and the calculated quantities are so small that for low degrees of concentration they fall altogether within the limits of observational error.

Heat of Combination and Specific Heat of Liquid Mixtures.—Winkelmänn (*Pogg. Ann.* cl. 592-619; cli. 512) has determined these data for mixtures of alcohol and benzin,* of alcohol and carbon disulphide, and of benzin and carbon disulphide, in the first case at three, in the other two at two different temperatures. The densities and the specific heats of the individual constituents were as follows:

Alcohol.

Sp. gr. at 16.03° = 0.7946.

Sp. heat $K_t = 0.5721 + 0.001443t + 0.0000122t^2$, between 3.82 and 28.18°.

Benzin.

Sp. gr. at 16.50° = 0.6986.

Sp. heat $K_t = 0.5244 + 0.000220t$, between 3.32° and 19.06°.

Carbon Disulphide.

Sp. gr. at 16.06° = 1.2665.

Sp. heat $K_t = 0.2575 + 0.000182t$, between 4.47° and 18.62°.

The mixing of alcohol and benzin, alcohol and CS₂, benzin and CS₂, is attended with a fall of temperature, and the amount of heat absorbed on mixing 1 gram. of either constituent with varying quantities of the other, increases with the quantity of the latter constituent. In this case, therefore, the same law holds good that is observed in the solution of salts at comparatively low temperatures, namely, that the quantity of heat absorbed in the act of solution increases with the quantity of water used. A comparison of the quantities of heat required for the formation of a given weight of a mixture from different proportions of its constituents, always exhibits a maximum for a mixture of equal parts of the two. From this point, in the three mixtures above mentioned, the quantities of heat consumed diminish most quickly on the side where the mixture contains a predominating quantity of that constituent which has the greater specific heat. The mixtures of alcohol and water form, in respect of their thermal relations, a peculiar group, in which, on the contrary, more heat is evolved on mixing 1 gram of alcohol with a larger quantity than with a smaller quantity of water.

The following table exhibits the specific heats and heats of mixing of mixtures of alcohol and water, as determined on the one hand by Winkelmann, and on the other by Dupré a. Page (*Phil. Mag.* [4], xxxviii. 153; see also 2nd Suppl. 474). Series I. and III. show the quantities of heat evolved in the formation of 5 grams of the mixture referred to the initial temperature 17°; series II. and IV. the specific heats of the mixtures for the interval of temperature 17.4° to 20.5°.

Alcohol in 10 pts. of mixture	Dupré a. Page		Winkelmann	
	I	II	III	IV
1	26.68	1.0353	25.90	1.0302
2	43.95	1.0436	42.70	1.0474
3	47.98	1.0260	47.23	1.0337
4	44.86	0.9680	42.60	0.9872
5	35.58	0.9063	35.02	0.9243
6	27.26	0.8433	26.72	0.8662
7	18.82	0.7844	19.05	0.8060
8	12.48	0.7169	12.06	0.7389
9	7.70	0.6576	6.54	0.6746

The somewhat considerable differences between these numbers follow a regular order in the specific heats, but in the heats of mixture they are quite irregular.

On the specific heats of mixtures of alcohol with water, carbon disulphide, chloro-
* 'Benzin,' also called 'ligroin,' is a constituent of petroleum; b. p. 60°-80°; not to be confounded with benzene.

form and benzin, see also Schüller (2nd Suppl. 477), where, however, benzin (from petroleum) is erroneously called 'benzene.'

Heat of Combination referred to the Solid State. Berthelot (*Compt. rend.* lxxvii. 24-32) considers that in estimating the quantities of heat evolved in the reaction between dissolved bases and acids, sufficient account has not been taken of the double decompositions occurring in solutions. Such decompositions indeed cannot be foreseen, except by calculation of the thermal action which would take place between the bodies if they were separated from the water, together with the investigation of the special action of the solvent upon each. He has, therefore, referred the quantities of heat evolved to the solid and crystalline state, the calculated values for which alter but little with the temperature, in consequence of the smallness of the alteration in the specific heat. For the calculations in question it is necessary to know, not only the quantities of heat evolved in the reactions between the dissolved bodies, but likewise the heat of solution of these bodies. With this view Berthelot has determined the heats of solution of the following compounds:

HEAT OF SOLUTION OF SALTS. 1 PT. SALT DISSOLVED IN 50-100 PTS. WATER.

1. Monobasic Salts.

Formates		Acetates		Benzoates, Picrates, &c.

* This number 0.76 agrees very well with those found by Graham, 0.76, and by Favre 0.75, but differs greatly from that of Thomsen, (p. 988) viz. 0.06, which is probably due to an error of observation.

Formation of Crystallised Hydrates.—The heats of formation of these hydrates, given in the following table, are easily computed from the numbers above tabulated. The numbers for the hydrates of acids and bases exhibit no simple relation to each other, but they are much larger than those for the hydrates of salts containing water of crystallisation, which likewise do not bear any simple relation to one another. Sodium acetate, for example, loses the whole of its water of crystallisation in a vacuum, whilst the combination of each molecule of water is attended with the evolution of 1.46 heat-units; cupric acetate, on the other hand, which gives off nine times less heat, viz. 0.16 heat-units, does not part with its water in a vacuum.

The heats of formation of bibasic salts exceed those of equivalent quantities of the corresponding monobasic salts, and those of the sulphates exceed those of the organic salts. The differences between the heats of the salts of the alkalis and alkaline earths are all of the same order of magnitude. All such regularities, however, are true only for the anhydrous salts. Solubility or insolubility has but little influence on the result, as may be seen by comparison of the sulphates with the formates or acetates.

Relations between the Heats of Solution in the preceding Table.—The potassium and sodium salts of the same acid often exhibit nearly constant differences: -3.1 for the chlorides; -3.7 for the nitrates; -3.6 for the picrates; -3.4×2 for the sulphates. Between the sodium and ammonium salts, the differences are: 2.9 for the chlorides, 2.5 for the nitrates, 1.7×2 for the sulphates, 2.3 for the picrates. Between the formates of potassium and sodium, the difference is only -0.4 ; between the acetates -0.8 ; between the oxalates -0.2×2 , &c. On the other hand, the anhydrous acetates of potassium, sodium, calcium, barium, and lead all exceed the corresponding formates by about 4.

Development of Heat and Changes of Volume attending the Solution of Anhydrous Salts (Favre a. Valson, *Compt. rend.* lxxvii. 802-809). In the following table, which is a sequel to those already given (*2nd Suppl.* 292-303), P denotes the weight in grams of the equivalent of the salt; D the density of the solid anhydrous salt; $V = \frac{P}{D}$ the volume of 1 eq.; d the density of the normal solution, containing 1 eq. of the salt in a litre; v the increase of volume, calculated therefrom, of 1 litre of water by dissolution of 1 eq. of the salt; $C = (V - v) \times 75.76$ kilogram-degrees of heat (see *2nd Suppl.* 302); C' the heat evolved in the dissolution of the salt, as determined by the mercury-calorimeter: $C - C'$ denotes, therefore, the amount of internal work expressed in kil.-degrees of heat:

Change of Volume and Development of Heat in the Solution of Anhydrous Salts.

Salt	P	D	$V = \frac{P}{D}$	d	v	$V - v$	$\frac{V - v}{v}$	C	C'	C - C'

Thermo-neutrality and Neutrality of Density. The term *thermo-neutrality* is employed by Favre a. Valson (*Compt. rend.* lxxvii. 907) to express the fact that the quantity of heat evolved or absorbed when a salt is dissolved in water already containing equivalent quantities of other salts, is, for the most part, the same that it would be if the former salt were dissolved in pure water. When, for example, 1 eq. of sodium nitrate is dissolved in water containing 1 eq. potassium chloride and 1 eq. ammonium sulphate, an absorption of heat occurs, amounting to 4.702 kilogram-degrees; and the quantity absorbed on dissolving the same quantity of sodium-nitrate in pure water is 4.842, differing from the former by only 0.140; the amount of heat-absorption in the two cases may therefore be regarded as the same: in other words, the condition of thermo-neutrality is satisfied.

Neutrality of density has a similar meaning with regard to the density of the resulting solution, which is, in fact, an arithmetical mean between the densities of the solutions formed by dissolving each salt separately in the same quantity of water. This may be illustrated by the following example, in which the letters P, D, &c. have the same signification as in the table on p. 984.

	P	D	V	\bar{d}	v	$V - v$	$\frac{V - v}{V}$
			c.c.		c.c.	c.c.	
NO ³ Na	85	2.241	37.9	1.0540	29.4	8.5	0.22
ClK	74.5	1.976	37.8	1.0444	29.0	8.8	0.23
$\frac{\text{SO}^4(\text{NH}^4)^2}{2}$	66	1.766	37.4	1.0378	27.3	10.1	0.27
Mean	75.2	1.994	37.7	1.0454	28.6	9.1	0.24
Mixture	75.2	1.994	37.7	1.0445	29.4	8.3	0.22

In like manner the dissolution of 1 eq. cupric sulphate in pure water gives rise to the same thermic change as in water already containing 1 eq. potassium sulphate. Moreover, the precipitation of potassio-cupric sulphate by barium chloride produces the same evolution of heat as the precipitation of the two constituent salts. Hence it would appear that double salts, like potassio-cupric sulphate, cannot exist in solution, but are split up in the act of dissolving into their constituent salts, and then conform to the law of thermo-neutrality (*compare 2nd Suppl.* 293). Potassium sulphate and copper sulphate, dissolved together in equivalent proportions, also yield a solution in which the law of density-neutrality is satisfied, as shown by the following numbers:

	P	D	V	\bar{d}	v	$V - v$	$\frac{V - v}{V}$
			c.c.		c.c.	c.c.	
$\frac{\text{SO}^4\text{K}^2}{2}$	87	2.653	32.8	1.0662	19.6	13.2	0.40
$\frac{\text{SO}^4\text{Cu}}{2}$	80	2.707	21.5	1.0777	2.1	19.4	0.90
Mean	83.5	3.180	27.1	1.0720	10.8	16.3	0.60
Mixtures	83.5	3.180	27.1	1.0717	11.1	16.0	0.59

Potassio-cupric sulphate and other neutral double salts appear, therefore, to yield solutions in which each of the constituent salts is in the same state as if it existed alone in the liquid. With *acid salts*, however, which in the crystallised state are true double salts, the case is different. Hydropotassic sulphate and its constituent salts, for example, when precipitated by barium chloride, yield the following quantities of heat:

		Kilogram-degrees
Dissolved alone, $\frac{\text{SO}^4\text{K}^2}{2}$, gives		2.879
" $\frac{\text{SO}^4\text{Cu}}{2}$ "		4.766
	Sum .	7.645
Dissolved acid salt, SO ⁴ KH, gives.		8.450
	Difference .	0.805

The density-relations are shown in the following table :

	P	D	V	d	v	$V - v$	$\frac{V - v}{V}$
$\frac{\text{SO}^4\text{K}^2}{2}$	87	2.653	32.8	1.0662	19.6	13.2	0.40
$\frac{\text{SO}^4\text{Cu}}{2}$	49	1.848	26.5	1.0300	18.5	8.0	0.30
Mean	68	2.250	29.7	1.0481	19.0	10.6	0.35
Mixture	68	2.250	29.7	1.0455	21.5	8.2	0.27

Those salts which do not satisfy the law of thermo-neutrality when their dilute solutions are mixed together, are likewise found not to exhibit neutrality of density, thus :

				Kil.-degrees
$\frac{\text{Na}^2\text{O}}{2}$ dilute	+	$\frac{\text{CO}^2}{2}$ gas	= $\frac{\text{Na}^2\text{CO}^3}{2}$ dilute . .	12.940
NH^3 dissolved	+	$\frac{\text{SO}^4\text{H}^2}{2}$ dissolved	= $\frac{(\text{NH}^4)^2\text{SO}^4}{2}$ dilute . .	14.888
				Sum
NH^3 dilute	+	$\frac{\text{CO}^2}{2}$ gas	= $\frac{(\text{NH}^4)^2\text{CO}^3}{2}$ dilute . .	8.473
$\frac{\text{Na}^2\text{O}}{2}$ dissolved	+	$\frac{\text{SO}^4\text{H}^2}{2}$ dissolved	= $\frac{\text{Na}^2\text{SO}^4}{2}$ dilute . .	16.301
				Sum
Difference of the two sums				3.054
Heat of solution of $\frac{\text{Na}^2\text{CO}^3}{2}$ in pure water				-7.840
„	„	in water + $\frac{(\text{NH}^4)^2\text{SO}^4}{2}$		-10.700
Difference				2.860

The two differences agree nearly with one another, and there is no thermo-neutrality. With regard to the relations of density of these salts, the following results have been obtained :

	P	D	V	d	v	$V - v$	$\frac{V - v}{V}$
$\frac{\text{CO}^3\text{Na}^2}{2}$	53	2.420	21.9	1.0519	1.0	20.9	0.96
$\frac{\text{SO}^4(\text{NH}^4)^2}{2}$	66	1.776	37.4	1.0378	27.3	10.1	0.27
Mean	59.5	2.093	29.6	1.0448	14.1	15.5	0.61
Mixture	59.5	2.093	29.6	1.0391	19.7	9.9	0.33
$\frac{(\text{NH}^4)^2\text{CO}^3}{2}$	48	—	—	1.0178	29.7	—	—
$\frac{\text{Na}^2\text{SO}^4}{2}$	71	2.681	26.5	1.0606	9.8	16.7	0.63
Mean	59.5	—	—	1.03992	19.7	16.7	—

The values of d , v , &c. for the mixture differ considerably from the first means, but agree nearly with the second, showing that the salts Na^2CO^3 and $(\text{NH}^4)^2\text{SO}^4$ have been converted in the mixture into Na^2SO^4 and $(\text{NH}^4)^2\text{CO}^3$. Similar results have been obtained by Favre & Valson with sodium borate and ammonium sulphate. (See also Berthelot, *Compt. rend.* lxxvii. 971; *Jahresh. f. Chem.* 1873, 104.) Favre

a. Valson point out the agreement of their results with those of Berthelot on the constitution of salts in solution (*Compt. rend.* lxxiv. 48, 119; lxxv. 207, 263; *Ann. Chim. Phys.* [4], xxvi. 433; 2nd Suppl. 285), and to those of Thomsen on the action of dilute sulphuric acid on solution of potassium sulphate (*Pogg. Ann.* cxxxviii. 497; *Jahresb.* 1869, 115).

Heat of Solution of Various Classes of Compounds.

Thomsen (*Deut. Chem. Ges. Ber.* vi. 710-717) has collected together in the following table the results of his experiments on the heat evolved or absorbed in the dissolution of various salts and other bodies in water. The values are calculated for the molecule, *i.e.* for the weight represented by the formula. The quantity of water used to dissolve each substance is stated according to the number of water-molecules contained in the solution for each molecule of the substance dissolved.

Substance	Formula	Quantity of water in mols.	Thermic effect per mol. of substance

Most salts, whether anhydrous or hydrated, dissolve in water with absorption of heat; some however, even when united with their maximum amount of crystallisation-water, dissolve with evolution of heat; such is the case with the sulphates of manganese, cadmium, yttrium, lanthanum, and beryllium, the acetates of copper and cerium, and with hypophosphite of barium.

In the amount of heat absorbed in the act of solution there is often an agreement between salts of corresponding formulæ: thus the sulphates of magnesium, zinc, nickel, and iron containing 7 mols. water give nearly equal values. To this rule, however, there are conspicuous exceptions; *e.g.* barium nitrate dissolves in water with much greater absorption of heat than the corresponding lead salt, whereas the acetates of the same bases exhibit the opposite relation.

• The nitrates and sulphates of the alkali-metals exhibit, for equal numbers of molecules, nearly equal differences of latent heat of solution, *e. g.*—

	R	K	Na	NH ⁺
	R ² N ² O ⁶	— 17040	— 10120	— 12640
	R ² SO ⁴	— 6380	— 60	— 2370
	Difference	— 10660	— 10060	— 10270

Nearly equal differences of latent heat are also found between the nitrates and chlorides of potassium and sodium, but in the ammonia-compounds the difference has a very different value :

	R	K	Na	NH ⁺
	RNO ³	— 8520	— 5060	— 6320
	RCl	— 4440	— 1180	— 3888
	Difference	— 4080	— 3880	— 2440

The latent heats of solution of the chlorides, bromides, and iodides of potassium, sodium, and ammonium, likewise do not exhibit any corresponding differences.

Of all salts, the potassium salts exhibit the greatest amount of latent heat for equal numbers of molecules; but the latent heat of sodium salts is much smaller if they contain a considerable amount of water.

All the crystallised acids which have been examined dissolve with absorption of heat, and the same is the case with selenious anhydride. In some, *e. g.* boric acid and the organic acids, the absorption is very considerable. On the contrary, all the liquid acids examined dissolve in water with evolution of heat, which is very great for sulphuric acid, very small for acetic acid.

The latent heat of solution of salts increases with the quantity of water present, so that aqueous solutions of salts, the dissolution of which is attended with absorption of heat, likewise absorb heat on dilution with water. Thus it appears from the numbers above given that a solution of sodium sulphate containing 50 molecules of water absorbs, on dilution with 50, 150, 350, and 550 molecules of water, the following quantities of heat

<i>n</i>	(Na ² SO ⁴ .50H ² O. <i>n</i> H ² O)
50	— 0·67 kilogram-degrees
150	— 1·09 "
350	— 1·30 "
550	— 1·35 "

Here the absorption of heat in the dilution of the liquid approximates to a maximum which is more clearly seen from the numbers which exhibit the absorption of heat in such solutions when they are mixed with quantities of water equal to those which they already contain, *e. g.*

<i>n</i>	(Na ² SO ⁴ . <i>n</i> H ² O. <i>n</i> H ² O)
5	— 0·67 kilogram-degrees
100	— 0·42 "
200	— 0·21 "
400	— 0·6 "

A somewhat different relation is exhibited in the absorption of heat, which takes place when a solution of sodium silicate is diluted with water. Experiment gave the following results :

<i>n</i>	(Na ² O.3SiO ² . <i>n</i> H ² O. <i>n</i> H ² O)
37·5	— 0·88 kilogram-degrees
75	— 0·92 "
150	— 0·94 "
300	— 1·17 "
600	— 1·34 "

Hence it appears that, whereas for sodium sulphate the absorption of heat which takes place on diluting the solution with a quantity of water equal to that which it already contains becomes smaller as the quantity of water increases, the contrary is the case with the silicate, so that a solution of the latter containing 300 mols. water exhibits, on dilution with another 300 mols., an absorption of heat $1\frac{1}{3}$ times as great as that which is exhibited by a solution containing only $\frac{1}{3}$ of that quantity of water. In the case of sodium silicate the absorption of heat is very considerable. A solution, which for each mol. Na²O contains 3 mols. SiO² and 37·5 mols. water, exhibits, on dilution with 562·5 mols. water, an absorption of heat amounting to 5·27 kilogram-degrees. This result is probably due to a partial decomposition of the silicate by the action of the water.

In the latent heat of many hydrated salts, the latent heat of the water, *i. e.* of ice, may be recognised. When a salt capable of uniting with water in several proportions

is dissolved in water, the evolution of heat, reckoned absolutely, becomes smaller as the quantity of water contained in the salt is greater. Thus, for example, anhydrous sodium sulphate gives -60 gram-degrees, but the salt containing 10 mols. water gives -18.76 ; cupric sulphate with 1 mol. water gives $+8.72$; the same salt with 5 mols. water gives -2.75 . This difference may arise from two causes; first, the affinity of the salt for the water may not be satisfied in the less hydrated salt, and consequently there may arise an evolution of heat corresponding with the affinity; secondly, the greater absorption of heat which attends the dissolution of the more highly hydrated salt may be due to the passage of a larger quantity of water from the solid to the liquid state. If the affinity between the salt and the water is very small, the effect is due almost entirely to the latter cause. The latent heat of ice at 0° amounts to 1.442 kilogram-degrees; but if the dissolution of the salt takes place at 20° , this amount must be increased by 20 times the difference between the molecular heat of water and that of ice, or about 0.18 kilogram-degree, so that the heat of solution of 1 mol. water (ice) at 20° amounts to about -1.62 kilogram-degrees.

Manganous sulphate crystallises with 4 and 5 mols. water; the affinity of the fifth water-molecule is very small; the difference of the heats of solution amounts, according to the numbers above given, to $.04 - 1.77 = -1.73$ kilogram-degrees.

For sodium phosphate and sodium ammonium phosphate, the heats of solution are as follows:

For $\text{NaNaHPO}_4 + 12\text{H}_2\text{O}$:	-22.92 kilogram-degrees
For $\text{Na}(\text{NH}_4)\text{HPO}_4 + 4\text{H}_2\text{O}$:	-10.75 "
Difference for $\text{Na} - \text{NH}_4 + 8\text{H}_2\text{O}$:	-12.17 "

Now the difference for the nitrates is $+1.26$; for the sulphates $+\frac{1}{2} 2.31 = +1.155$; mean $+1.208$: hence the latent heat for 8 mols. water is $-12.17 - 1.208 = -13.378$; or for 1 mol. water -1.672 .

A similar magnitude is distinctly recognisable in the heat of solution of sodium carbonate with $10\text{H}_2\text{O}$: for $-1.649 = -0.1649 \times 10$. In sodium sulphate also there is a similar difference between the anhydrous and the hydrated salt, viz. $-18.7 = -1.87 \times 10$.

Heat of Solution of Chlorine-, Bromine-, and Iodine-compounds
(Thomsen, *J. pr. Chem.* [2], xvi. 323-341; *Deut. Chem. Ges. Ber.* x. 1017-1023). The following table exhibits the results of the whole of Thomsen's experiments on the heat of solution of the halogen-compounds of the metals. The numbers are calculated for a temperature of 18° . As it is very difficult and sometimes impossible to bring the amount of water in a hydrated compound into exact agreement with the number of molecules in the formula, inasmuch as some compounds are very deliquescent, and others lose water in drying, the proportion of water (in molecules) as directly determined by analysis is given in the last column.

The anhydrous chlorides, bromides, and iodides dissolve in water either with evolution or with absorption of heat, aluminium chloride showing the greatest evolution, and thallium chloride the greatest absorption.

The anhydrous chlorides, bromides, and iodides, which dissolve in water with evolution of heat, form crystalline compounds with water.—To this group belong the haloid compounds of Li, Ba, Sr, Ca, Mg, Al, Zn, Mn, Fe, Co, Ni, Cu, Sn. The heat of solution of the anhydrous chloride and bromide of cadmium is positive, and both bodies combine with water; cadmium iodide, on the other hand, has a negative value, and this body does not combine with water at ordinary temperatures. The heat of solution of the anhydrous chloride of gold, AuCl_3 , is positive; that of the bromide, AuBr_3 , negative; the former combines with water to produce the compound $\text{AuCl}_3 \cdot 2\text{H}_2\text{O}$: the latter forms no hydrate. Sodium iodide shows a positive value, and crystallises in combination with water; the value for the bromide is almost nil, and the hydrate is easily decomposed; that of the chloride is negative, and it combines with water at a very low temperature only.

The hydrated chlorides, bromides, and iodides generally absorb heat on solution in water, but the following are exceptions: $\text{MgCl}_2 + 6\text{H}_2\text{O}$, $\text{MnCl}_2 + 4\text{H}_2\text{O}$, $\text{FeCl}_2 + 4\text{H}_2\text{O}$, $\text{CdCl}_2 + 2\text{H}_2\text{O}$, and $\text{CuCl}_2 + 2\text{H}_2\text{O}$. It is not unlikely that compounds of these bodies with a larger proportion of water are possible.

The heat of formation of hydrates is positive, the evolution of heat being due, partly to the latent heat of water, and partly to the affinity of the haloid compound for water, and its value depends on the number of molecules of water taken up.

The magnitude of the heat of solution of the anhydrous haloid compounds appears to be subject to several laws.—In the case of the metals of the alkaline earths, the heat of solution increases with the increasing atomic weight of the electronegative constituent, the chloride evolving least, the iodide most heat. At the same time the heat of solution rises regularly from barium to magnesium, *i.e.* with the decreasing atomic weight of the electro-positive constituent.

The group of the alkali-metals shows a similar behaviour; but potassium, and probably thallium, form compounds in which the value decreases with the electronegative element, and this is probably connected with the fact that these two metals do not form hydrated haloid compounds.

A comparison of the two groups exhibits some remarkable relations: thus the difference of the heat of solution

between BaCl_2 and Ti^2Cl^2	= 22·27
„ SrCl_2 „ K^2Cl^2	= 20·02
„ CaCl_2 „ Na^2Cl^2	= 19·77
„ MgCl_2 „ Li^2Cl^2	= 19·04

The compounds of the formula R^2Cl^2 also show that the heat of solution for equivalent quantities is greater in proportion as the atomic weight of the electro-positive constituent is less.

The heat of solution of the haloid compounds of the heavy metals exhibits the reverse of the above cases: for the quantity is greatest for the chlorides, and least for the iodides.

Heats of Solution of Alkaline Chlorides and Nitrates. Winkelmann (*Pogg. Ann.* cxlix. 1–32) has determined the heats of solution of the chlorides and nitrates of potassium, sodium, and ammonium at the temperatures 0° and 50° , and the specific heats of the resulting solutions. In the following table, k denotes the specific heat; λ_0 and λ_{50} the quantities of heat required to dissolve 1 gram of the salt at the respective temperatures; p the percentage in grams of salt contained in the solution.

Sodium Chloride.

$$\begin{aligned} k &= 0.99608 - 0.01079 p + 0.000137 p^2. \\ \lambda_0 &= 32.1 - 1.837 p + 0.0687 p^2, \text{ up to } p = 11.2. \\ \lambda_0 &= 28.62 - 0.8475 p + 0.00791 p^2, \text{ from } p = 11.2 \text{ to } p = 32.04. \\ \lambda_{50} &= 6.41 - 0.07 p, \text{ from } p = 3.09 \text{ to } p = 26.03. \end{aligned}$$

Sodium Nitrate.

$$\begin{aligned} k &= 1.0015 - 0.01066 p + 0.000161 p^2, \text{ from } p = 3.03 \text{ to } p = 19.19. \\ k &= 0.9410 - 0.004 p, \text{ from } p = 25.03 \text{ to } p = 40.06. \\ k &= 0.8703 - 0.002233 p, \text{ from } p = 40.06 \text{ to } p = 70.09. \\ \lambda_0 &= 64.4 - 0.728 p, \text{ from } p = 3.03 \text{ to } p = 23.6. \\ \lambda_0 &= 58.1 - 0.5221 p + 0.002644 p^2, \text{ from } p = 23.6 \text{ to } p = 70.0. \\ \lambda_{50} &= 51.1 - 0.3037 p, \text{ from } p = 3.03 \text{ to } p = 31.3. \\ \lambda_{50} &= 45.1 - 0.123 p, \text{ from } p = 31.3 \text{ to } p = 70. \end{aligned}$$

Potassium Chloride.

$$\begin{aligned} k &= 0.9965 - 0.011491 p + 0.0001086 p^2, \text{ from } p = 3.04 \text{ to } p = 29.4. \\ \lambda_0 &= 69.48 - 0.75 p, \text{ from } p = 3.04 \text{ to } p = 9.6. \\ \lambda_0 &= 65.4 - 0.34 p, \text{ from } p = 9.6 \text{ to } p = 29.4. \\ \lambda_{50} &= 45.3 - 0.1 p, \text{ from } p = 3.0 \text{ to } p = 29.4. \end{aligned}$$

Potassium Nitrate.

$$\begin{aligned} k &= 0.9979 - 0.01039 p + 0.000143 p^2, \text{ from } p = 3.05 \text{ to } p = 19.80. \\ \lambda_0 &= 95.9 - 2.123 p, \text{ from } p = 3.05 \text{ to } p = 5.6. \\ \lambda_0 &= 85.64 - 0.161 p - 0.0246 p^2, \text{ from } p = 5.62 \text{ to } p = 19.8. \\ \lambda_{50} &= 73.66 - 0.42 p, \text{ from } p = 3.0 \text{ to } p = 19.8. \end{aligned}$$

Ammonium Chloride.

$$\begin{aligned} k &= 0.9962 - 0.01114 p - 0.000132 p^2, \text{ from } p = 3.03 \text{ to } p = 25. \\ \lambda_0 &= 85.66 - 0.357 p - 0.0192 p^2, \text{ from } p = 3.0303 \text{ to } p = 9.98. \\ \lambda_0 &= 78.26 + 0.387 p - 0.0287 p^2, \text{ from } p = 9.98 \text{ to } p = 25. \\ \lambda_{50} &= 55.1 + 0.1 p, \text{ from } p = 3.03 \text{ to } p = 25. \end{aligned}$$

Ammonium Nitrate.

$$\begin{aligned} k &= 0.9835 - 0.00618 p, \text{ from } p = 3.04 \text{ to } p = 20. \\ k &= 0.7925 + 0.008555 p - 0.0002575 p^2, \text{ from } p = 20 \text{ to } p = 40. \\ \lambda_0 &= 92.25 - 1.737 p + 0.04025 p^2, \text{ from } p = 3.04 \text{ to } p = 20. \\ \lambda_0 &= 89.1 - 0.985 p + 0.0105 p^2, \text{ from } p = 20 \text{ to } p = 40. \end{aligned}$$

The values of the specific heats of nitrate and chloride of ammonium are not so well established as the rest.

Winkelmann's determinations do not exhibit any general simple relation between the heat of solution and the quantity of water required to dissolve the salt.

Cold produced by Solution of Ammonium Nitrate in Water (J. Tollinger, *Wien. Akad. Ber.* [2 Abth.] lxxii. 535-577). The specific heat of a solution of 1 mol. of the salt in 100 mols. water, or of 1 part by weight of the salt in 22.5 parts by weight of water, is 0.95955 between 20° and 27°, or nearly 0.962 for ordinary temperature. Thomsen found 0.962; Winkelmann 0.956. The general expression for the molecular heat of 1 mol. of the salt in m mol. water is—

$$S_m = \frac{736 + 354.8 m + 18 m^2}{20 + m};$$

or more simply for $m < 8$, $S_m = 29.6 + 17.7m$; for $m > 8$, $S_m = 20 + 17.8m$. The specific heat of the solid salt is, according to previous determinations by Tollinger, 0.129 (*ibid.* lxi. 319; *Jahresb. f. Chem.* 1870, 112). The estimation of the heat of solution at different temperatures* led, for the unit of weight, and for the molecule (80) to the equations:

$$w_t = 84.23 - 0.408 t \text{ and } W_t = 6738 - 32.6 t.$$

The quantity of heat absorbed in the solution of 1 mol. of the salt in m mol. water at the temperature t is represented by the general equation—

$$W_{mt} = \frac{25342 + 7091 m}{9 + m} - t \frac{39.6 m - 48}{20 + m}.$$

For the point of solidification τ , the determinations above given lead to the following equations:

$$\tau = -0.338 p - 0.0015 p^2, \text{ or } \tau = -\frac{149 + 0.5 m}{2.7 + m},$$

in which p denotes the percentage of salt and m , as before, the number of molecules of H_2O to 1 mol. NH_4NO_3 .

With respect to the solubility of the salt, the investigations relating to the determination of the point of saturation give the equations—

$$S = -88.5 + 1.64 p; \text{ and } S = \frac{335.5 - 88.5 m}{4.41 + m}.$$

The attainable minimum of temperature is limited by the points of solidification and

* Compare Winkelmann, *supra*, and Thomsen, p. 987 of this Supplement.

saturation, therefore by τ and Δ , for both of which, according to the formulæ above given, $m = 5.82$. Substituting this value, we find

$$\tau = \Delta = -17.5^{\circ}.$$

The most favourable proportion of a mixture for cooling a body down to a given temperature corresponds with that degree of concentration which just gives the saturation at the desired final temperature. For the practical application of mixtures of water or snow with ammonium nitrate as frigorific mixtures, Tollinger has calculated two tables according to the points of view above indicated. When snow is used, the molecular heat of fusion = 1440 gram-degrees, and the molecular heat, 34, of ice, likewise enter into the calculation.

Heat of Solution and Dilution of Nitric Acid. The following table contains the results of two series of experiments by Thomsen (*Deut. Chem. Ges. Ber.* vi. 697), in the first of which a hydrate of nitric acid containing α -molecules of water was mixed with the quantity of water required to make up 100 molecules, that is to say with 100 α -molecules of water; in the second series the acid was each time mixed with a quantity of water equal to that which it already contained, that is to say, with α -molecules α .

α	$[\text{NO}^3\text{H}.\alpha\text{H}^2\text{O}, (100-\alpha)\text{H}^2\text{O}]$	α	$\text{NO}^3\text{H}.\alpha\text{H}^2\text{O}, \alpha\text{H}^2\text{O}$
0.175	6.650 kil.-deg.	0.3125	1.014 kil.-deg.
0.5	5.458 "	0.625	1.393 "
1.0	4.171 "	1.25	1.556 "
1.5	3.292 "	2.5	1.378 "
2.5	2.146 "		
3.0	1.720 "		
5.0	0.758 "		

From these values Thomsen draws the following conclusions: When a hydrated nitric acid $\text{NO}^3\text{H}.\alpha\text{H}^2\text{O}$ is mixed with a quantity of water equal to that which it already contains, the evolution of heat at first increases with α till α becomes equal to 1.244, at which point the quantity of heat evolved attains its maximum value, viz. 1.556 kilogram-degrees. When the acid becomes weaker, that is, when $\alpha > 1.234$, the evolution of heat diminishes, and when the acid contains 20 mols. water it changes to absorption; in other words, the thermic effect becomes negative. The absorption of heat on mixing the acid with water goes on till the acid contains 40 molecules of water, but on continuing the dilution, evolution of heat again takes place. The minimum of heat-evolution on mixing aqueous nitric or sulphuric acid with a quantity of water equal to that which it already contains, takes place at that degree of dilution of the acid at which the molecular heat (or calorimetric equivalent) of the acid is equal to that of the water contained in it. For hydrochloric acid this last statement does not hold good, because in solutions of this acid the calorimetric equivalent of the acid is always less than that of the water with which it is associated.

The following values, true for the temperature 9.7° , are deduced by interpolation from the results of experiments by Berthelot (*Compt. rend.* lxxviii. 769-777).

Formula of the original acid, $\text{NO}^3\text{H} + \alpha\text{H}^2\text{O}$	Evolution of Heat on dilution to $\text{NO}^3\text{H} + 200\text{H}^2\text{O}$
NO^3H	7.15 kil.-degrees.
$\text{NO}^3\text{H} + 0.5\text{H}^2\text{O}$	5.15 "
1.0	3.84 "
1.5	3.02 "
2	2.32 "
3	1.42 "
4	0.79 "
5	0.42 "
6	0.20 "
7	0.06 "
7.5	0 "
8	-0.04 "
10	-0.09 "
15	-0.24 "
20	-0.18 "
40	-0.09 "
100 H^2O	-0.03 "

From these results, Berthelot infers the existence of the hydrate $\text{NO}^3\text{H}\cdot 2\text{H}^2\text{O}$. He regards as incorrect the statement of Thomsen that the absorption of heat which takes place on diluting the acid with water changes to evolution of heat at certain degrees of hydration. The influence of temperature is deducible from the formula $Q_r = Q_d + U - V$, and while $\text{NO}^3\text{H} + n\text{H}^2\text{O}$ is increasing to $\text{NO}^3\text{H} + 200\text{H}^2\text{O}$, n is less than 200, and consequently U greater than V , so that the heat of dilution increases continually with the temperature. The experiments of Hesse, Thomsen, and Berthelot on the specific heats of these solutions, give for

$$\begin{aligned} n &= 0: U - V = 0.040 (\tau - t); & n &= 10: U - V = 0.0181 (\tau - t) \\ n &= 20: U - V = 0.0116 (\tau - t); & n &= 40: U - V = 0.0051 (\tau - t) \\ n &= 80: U - V = 0.001 (\tau - t). \end{aligned}$$

The molecular volumes of nitric acid solutions are represented approximately by the formula

$$V = 18n + 29 + \frac{39}{n + 3.2}$$

Thermic Effects of the Reaction of Sulphuric Acid with Water.

Thomsen (*Ber.* vi. 496) regards the greater number of the experiments hitherto made by himself and others (*2nd Suppl.* 633) on the evolution of heat attending the mixing of sulphuric acid with water, as deficient in accuracy, and has therefore undertaken new experiments, in which, for all determinations of large numbers, he used 49 grams of strong sulphuric acid, SO^4H^2 , or about a hundred times the quantity employed by Favre & Silbermann. Two series of experiments were made, as in the case of nitric acid, a hydrate containing $\alpha\text{H}^2\text{O}$ being diluted in the first series with $(100-\alpha)\text{H}^2\text{O}$; and in the second with $\alpha\text{H}^2\text{O}$. All the hydrates were analysed with the greatest care, so as to preclude as far as possible an error of 1 per thousand in their numbers of water-molecules. The following table exhibits the results.

α	$\text{SO}^4\alpha\text{H}^2\text{O}, (100-\alpha)\text{H}^2\text{O}$	α	$\text{SO}^4\alpha\text{H}^2\text{O}, \alpha\text{H}^2\text{O}$
1	16.850 kil.-degrees	50	174 kil.-degrees
2	10.578 "	100	206 "
3	7.486 "	200	248 "
4	5.742 "	400	328 "
6	3.768 "	800	216 "
10	1.910 "		
20	.692 "		
30	.174 "		

From these values Thomsen calculates the quantities of heat evolved on mixing 1 mol. sulphuric acid, SO^4H^2 , with n molecules of water. The results are given in the following table:—

n	Heat evolved in the formation of $\text{SH}^2\text{O}^4\cdot n\text{H}^2\text{O}$	n	Heat evolved in the formation of $\text{SO}^4\text{H}^2\cdot n\text{H}^2\text{O}$
1	6.272 kil.-degrees	49	16.676 kil.-degrees
2	9.364 "	99	16.850 "
3	11.108 "	199	17.056 "
5	13.082 "	399	17.304 "
9	14.940 "	799	17.632 "
19	16.248 "	1599	17.848 "

Faundler (*Wien. Acad. Ber.* [2 Abth.], lxxi. 155-178) has repeated his measurements of the heat evolved on mixing sulphuric acid with water, with results approaching very nearly to those formerly obtained (*2nd Suppl.* 634). Denoting by n the number of water-molecules added to sulphuric acid SO^4H^2 , the quantities of heat evolved in the formation of the several hydrates from 1 gram of SO^4H^2 may be approximately represented within the limits $n=1$ and $n=5$ by the formula

$$W_n = \frac{n}{n + 1.588} \cdot 17.92.$$

The rise of temperature t produced in the formation of the several hydrates is shown in the following table:

n	t	t corrected	n	t	t corrected
0.5	89.0°	82°	4	138.7°	133°
1	134.2	127	5	125.1	121
1.5	151.2	145	6	111.9	109
2	158.4	152	7	99.3	98
2.5	155.4	149	8	91.2	89
3	153.3	145	9	83.8	81
3.5	145.9	140	10	77.0	76

The calculation of t is based on the specific heat of the hydrates at ordinary temperatures, that of t corrected, on the specific heat as it increases with the temperature between 0° and 159°.

The greatest rise of temperature amounts to 159°, and is obtained on mixing 1 mol. SO^4H^2 with 1.84 mol. H^2O , or 1 part by weight of SO^4H^2 with 0.338 part water.

Berthelot (*Compt. rend.* lxxviii. 716) has investigated the thermic relations of the crystalline hydrate of sulphuric acid, $\text{SO}^4\text{H}^2.\text{H}^2\text{O}$, with the following results:

$\text{SO}^4\text{H}^2.\text{H}^2\text{O}$ solid + 400 H^2O evolves	Kil.-degrees
$\text{SO}^4\text{H}^2.\text{H}^2\text{O}$ liquid + 400 H^2O	0.712
Whence the heat of fusion of $\text{SO}^4\text{H}^2.\text{H}^2\text{O}$	10.80
SO^4H^2 liquid + H^2O liquid = $\text{SO}^4\text{H}^2.\text{H}^2\text{O}$ liquid, 16920—10800	= 0.368*
SO^4H^2 solid + H^2O solid = $\text{SO}^4\text{H}^2.\text{H}^2\text{O}$ solid, 16060—7120—1440	= 0.612
	= 0.750

The existence of the hydrate $\text{SO}^4\text{H}^2.\text{H}^2\text{O}$ may be inferred, according to Berthelot, from its thermic relations. For, as appears from the experiments of Favre and Quillard (*2nd Suppl.* 633), on mixing 1 mol. SO^4H^2 successively with $\frac{1}{2}$, $\frac{1}{4}$ &c. mol. water, the quantities of heat evolved are proportional to the quantities of water added up to 1 mol. H^2O , whereas above that limit they decrease rapidly. The variations in the heat-capacities and vapour-tensions tend also to the same conclusion.

Thomsen, on the other hand (*Ber.* vii. 772), regards the existence of definite hydrates in the aqueous solutions of acids as not satisfactorily established. With regard to the hydrate of sulphuric acid, $\text{SO}^4\text{H}^2.\text{H}^2\text{O}$, the proportionality maintained by Berthelot of the quantities of heat evolved on mixing 1 mol. SO^4H^2 with fractions of a molecule of water is not borne out by the experiments of Favre and Quillard above cited, or by his own. With regard also to the hydrate of nitric acid, $\text{NO}^3\text{H}^2.2\text{H}^2\text{O}$, Berthelot's determination of the quantities of heat evolved on mixing nitric acid with water are not convincing, and on the other hand, Thomsen's own experiments show a continuous evolution of heat up to 5 H^2O , and therefore give no indication whatever of the existence of a hydrate $\text{NO}^3\text{H}^2.2\text{H}^2\text{O}$.

Thermic Changes attending the Solution of Chlorine in Water, and the Oxidation of various Salts by Chlorine. Berthelot (*Compt. rend.* lxxvi. 1514—1522; *Ann. Chim. Phys.* [5], v. 318—356) finds that the heat of solution of chlorine in water varies between 1.64 and 3.77 kil.-degrees, and considers that the variation is due, not to the existence of two allotropic states of the gaseous chlorine, but to the circumstance that the chlorine is sometimes simply dissolved by the water, and sometimes acts chemically on it, the action being exerted both on the hydrogen and on the oxygen. The decomposition of water by chlorine, with evolution of free oxygen ($\text{Cl}^2 + \text{H}^2\text{O} = 2\text{HCl} + \text{O}^2$) should evolve 10 kilogram-degrees of heat. The formation of hydrochloric acid and the oxides of chlorine appears to be induced by the presence of a small quantity of a foreign body, perhaps a trace of hypochlorous acid.

Similar irregularities are observed in the oxidation of mercurous chloride, stannous chloride, and ferrous sulphate by the agency of chlorine. Thus, in the action of chlorine-water on calomel, the heat-evolved varies, for 35.5 grams of chlorine, between +16.3 and +22.8 kilogram-degrees; in the action on neutral stannous chloride between +36.5 and +39.6, becoming constant however and equal to +32.2 in presence of a certain quantity of hydrochloric acid; on neutral ferrous sulphate, between 20.44 and 23.87, becoming constant and = 26.65 in presence of a molecule of sulphuric

* This number is considerably greater than the heat of fusion of the pure acid, SO^4H^2 , viz. 0.86, and greater even than the sum of the heats of fusion of the acid and water, viz. 0.86+1.44 = 2.3.

acid, SO^4H^2 , and rising to 27.39 in presence of $2\text{SO}^4\text{H}^2$. These thermal variations may be explained on the assumption that, in the oxidation of the preceding salts, the chlorine first decomposes the water and produces oxides of chlorine, with evolution of a smaller amount of heat for an equal weight of chlorine. These oxides of chlorine however disappear in course of time, and bring about the same final condition, *e.g.* the formation of stannic chloride, SnCl_4 , but so slowly that the heat thereby evolved is not indicated by the thermometer. In presence of a large excess of dilute hydrochloric acid, the quantity of heat evolved becomes nearly constant, *e.g.* in the case of stannous chloride = 38.5 kil.-deg. for 35.5 grm. chlorine. The action of chlorine on alkaline oxides gives constant quantities of heat:

For Cl^2 and K^2O	+	25.4
" Cl^2 " Na^2O	+	25.3
" Cl^2 " BaO	+	25.0

On the other hand

Cl_2O dilute + K^2O dilute gives + 19.2.

Therefore

Cl_2 gas + O^2 gas + water gives + 5.8.

In view of the irregularities above noticed, Berthelot is of opinion that calorimetric determinations, like those of Thomsen (p. 961), depending on oxidising actions under the influence of chlorine, are not to be depended upon. Free hypochlorous acid cannot be used for a similar purpose excepting in cases where the oxidation is very quickly completed. *Potassium permanganate* also cannot be safely used for thermo-chemical investigations. On the whole, the use of indirect oxidation and reduction in thermo-chemistry requires very great caution.

Thermic changes accompanying the action of the Haloid Acids in Aqueous Solution on the Oxides of Potassium, Mercury, and Silver; also the mutual displacement of these Acids from their Salts (Berthelot, *Compt. rend.* lxxvii. 308):

					Kil.-deg.
2HCl (in 4 litres)	+ K^2O (in 4 litres)	.	.	.	+ 27.18
2HBr "	" + K^2O "	.	.	.	+ 27.60
2HI "	" + K^2O "	.	.	.	+ 27.16
HI (in 2 litres)	+ KCl (in 2 litres)	.	.	.	+ 0.04 { diff.
HCl "	" + KI "	.	.	.	+ 0.10 } - 0.06
HCl gas + water (800H ² O)	+ 17.43		KCl solid + water	.	- 4.19
HBr "	" + 20.00		KBr " "	.	- 5.45
HI "	" + 19.57		KI " "	.	- 5.32
HgCl ² (in 12 l.)	+ K^2O (in 4 l.)	.	.	.	+ 8.34
HgCl ² (in 16 l.)	" "	.	.	.	+ 8.18
HgCl ² (solid)	+ water (40 pts.)	.	.	.	- 3.04

whence $\text{HgO} + 2\text{HCl}$ (dilute) = HgCl^2 dissolved . . . + 18.92
 " " = " solid . . . + 21.96

HgCl^2 (in 8 l.) + 2KI (in 8 l.) = HgI^2 (ppd.) + 2KCl (diss.) . . . + 41.02

If the quantity of mercuric iodide dissolved be taken into account, the last number becomes 41.32, whence:

$\text{HgO} + 2\text{HI}$ dilute = HgI^2 solid	+ 60.24
NO^3Ag (in 6 l.) + KCl (in 2 l.)	+ 15.67
$2\text{NO}^3\text{H}$ dilute + K^2O dilute	+ 27.66
$2\text{NO}^3\text{Ag}$ (in 4 l.) + K^2O (in 4 l.)	+ 17.32
whence $2\text{NO}^3\text{H}$ dilute + Ag^2O precipitated	+ 10.34
2HCl	+ 41.20
2HCl gas + " " = $2\text{AgCl} + \text{H}^2\text{O}$ gas	+ 56.8

The last figure, however, is only approximately correct, inasmuch as the physical state of silver chloride, as shown by Stas, varies with the conditions of precipitation and more especially of drying; the same is true for silver oxide.

NO^3Ag (in 6 l.) + KBr (in 2 l.)	+ 20.30
whence 2HBr dilute + Ag^2O = 2AgBr precipitated	+ 50.28
2HBr gas + " " = " + H^2O gas	+ 71.0 (approx.)
NO^3Ag (in 6 l.) + KI (in 4 l.)	+ 26.90
whence 2HI dilute + Ag^2O = 2AgI precipitated	+ 63.64
" gas + " " " + H^2O gas	+ 83.6 (approx.)

A comparison of these numbers shows that the mutual displacement of the halogens does not in general produce any thermal effects which can be regarded as constant, or at all events as multiples, of a common constant. An approximately constant relation exists, however, for the salts of the alkali-metals, and for the acid chlorides, bromides, and iodides of certain non-metallic elements, and of certain organic compounds analogous in constitution to the haloïd acids.

The partition of an alkaline base, potash for example, between two haloïd acids, cannot be predicted on thermochemical grounds, since the quantities of heat evolved in the formation of the alkaline chlorides, bromides, and iodides are equal. In this case opposite reactions may take place accordingly as the solution is evaporated or precipitated. An excess of hydriodic acid expels the other two acids almost completely on evaporation; and hydrochloric acid is almost wholly expelled by an excess of hydrobromic acid; but the displacements are not complete when the acids are present in equivalent quantities. On the contrary, hydrochloric acid, even in considerable excess, displaces only a fraction of an equivalent of hydrobromic acid. A strong solution of hydrochloric acid added to a saturated solution of potassium iodide produces a crystalline precipitate of potassium chloride, containing only traces of iodine. Berthelot considers that in this case the hydrochloric acid first divides the base with the hydriodic acid, and that the anhydrous hydrochloric acid, which, according to Berthelot, is always present in concentrated solutions, lays hold of the water which holds the potassium chloride in solution, and precipitates the latter.

Berthelot has also observed the following reaction: $\frac{\text{HgCl}^2}{2}$ (1 eq. in 4 l.) + KI (1 eq. in 4 l.) develops 13.67 and 13.61 kil.-deg. of heat instead of 20.6: consequently III dissolved + $\frac{\text{HgO}}{2}$ precipitated gives 23.0. Between the formation of solid mercuric chloride and that of the solid iodide by means of the dissolved haloïd acids, there is, therefore, a thermal difference of 12.1, whereas for potassium iodide and chloride it amounts to only 1.1, and rises for silver iodide to 11.2, which number would fall back to 8.4 if the observation were made at the first moment of precipitation. The formation of mercuric iodide surpasses, therefore, in a thermal point of view, that of all other known iodides.

Formation of Cyanides (Berthelot, *Compt. rend.* lxxvii. 338). See also 2nd Suppl. 662:

	Heat-units
2HCy (in 4 l.) + HgO (suspended in 20 l.)	+ 30.96
HgCy solid + water (40 pts.) = solution	- 1.50
HCy gas, liquefied by pressure	+ 5.70
HCy liquid + water (large quantity)	+ 6.40

whence:

2HCy dissolved + HgO = HgCy ² solid	+ 34.0
2HCy liquid + HgO = HgCy ² „	+ 34.8
2HCy gas + HgO = HgCy ² „ + H ² O gas	+ 36.6

The formation of dissolved mercuric cyanide develops +12.06 more than that of mercuric chloride, and consequently mercuric chloride in dilute solution is completely decomposed by hydrocyanic acid. Experiment gave:

HgCy ² (in 32 l.) + 2HCy (in 4 l.)	+ 0.0	N - N ₁ * = 11.8
HgCl ² „ + 2HCy „	+ 11.8	calc. = 12.0

On the contrary, dissolved potassium cyanide is completely decomposed by dilute hydrochloric acid.

2HCy dissolved + K ² O dilute	+ 5.92	N ₁ - N = 12.0
2HCl „ + „	+ 27.18	

Strong hydrochloric acid, on the other hand, decomposes mercuric cyanide, the decomposition being due, according to Berthelot, to the action of the anhydrous hydrogen chloride, which is either contained in the solution, or produced under the influence of heat, and exhibits, for 1 mol., an amount of energy exceeding that of the hydrated acid by 6 or 7 heat-units. Gaseous hydrogen chloride expels gaseous hydrogen cyanide from mercuric cyanide at ordinary temperature with evolution of 5.2 heat-units for 1 mol. of the acid.

Berthelot has also observed the following developments of heat:

2KCy (in 16 l.) + HgCl ² (in 8 l.)	+ 33.4
2KCl „ + HgCy ² „	0

* N stands for heat of neutralisation (2nd Suppl. 628).

By calculation, $(N - N_1) - (N' - N'_1) = 13.6 - 3.0 - (9.5 - 15.5) = +16.6$ for 1 mol. acid, and for the above 2 mols., $2 \times 16.6 = 32.2$.

The following is a marked exception to the law of the mononeutrality of salts (p. 985), a double cyanide being formed, and the dissolution being attended with considerable evolution of heat:

HgI ² solid	+ 2KCy (in 32 l.)	+ 9.4
	+ 2KCy	+ 9.4
									<hr/>
Total heat of solution									18.8

This formation of double cyanides is shown still more clearly by the following experiment:

HgCy ² (in 32 l.)	+ 2KCy (in 8 l.)	+ 11.6
------------------------------	------------------	---	---	---	---	---	---	--------

Dilute hydrochloric acid added to the preceding liquid forms KCl and HCy:

Preceding liquid	+ HCl (in 2 l.)	+ 5.2
	+ 2HCl	6—

The following experiments were made with silver cyanide:

(1) NO ³ Ag (in 16 l.)	+ HCy (in 4 l.)	+ 15.72
from which								
2HCy dissolved	+ Ag ² O = 2AgCy precipitated	+ 41.8
(2) NO ³ Ag (in 16 l.)	+ KCy (in 4 l.)	+ 26.57
whence								
2HCy dissolved	+ Ag ² O = 2AgCy precipitated	+ 41.8

Consequently

2HCy liquid	+ Ag ² O precipitated	=	2AgCy	+ H ² O liquid	.	.	.	42.6
„ gas	+	„	=	„	+	„	.	54.6
„ „	+	„	=	„	+	„	.	44.4

Further, the formation of a double cyanide gave:

KCy (in 4 l.)	+ AgCy precipitated	+ water (20 l.)	.	.	.	5.6
---------------	---------------------	-----------------	---	---	---	-----

Heat of Solution of the Alkalis and Alkaline Earths (Berthelot, *Compt. rend.* lxxvi. 1041, 1106). KHO (56.1 grams) in dissolving in 260 molecules of water gives out 12.46 kil.-degrees of heat; commercial pure potash containing KHO + 0.88H²O gave off only 4.60; the pure crystallised hydrate KHO.2H²O gave —0.03. The quantities of heat evolved in the dilution of potash-solution, KHO.*n*H²O, may be represented by the formula $A = \frac{23}{n^2}$, as far as *n* = 11; above that limit, the term

$-\frac{23}{10n}$ must be appended; for values of *n* above 32 the formula is reduced to this latter term, and on further dilution heat is invariably absorbed.

The heat of solution of NaHO amounts to +9.78 kil.-degrees; for NaHO + 0.76H²O to +7.31. The heat evolved on dilution of soda-solutions, NaHO.*n*H²O, is represented by the formula $A = \frac{23}{n^2}$, as far as *n* = 5.6; for values of *n* between 5.6 and 18.4

a correction of —0.60 must be made, and above 18.4 a further correction of $-\frac{23}{2n}$. The molecular volumes of soda-solutions decrease gradually, the limit of this contraction not being reached even at 200H²O. The volume of dilute soda-solutions is smaller than that of the water which they contain.

Ammonia, NH³, in dissolving, evolves 8.82 kil.-degrees. The quantity of heat given off in the dilution NH³.*n*H²O with 200 H²O is represented by the formula $A = \frac{1.27}{n}$. One volume of water at —16° dissolves 1270 vols. NH³. The molecular volume of the solution NH³ + *n*H²O is expressed generally by the formula $V = 18n + 24 - \frac{1.2}{n}$.

The quantities of heat evolved in the formation of the hydrates of CaO, BaO, and SrO, and the heats of solution of these hydrates, were deduced from the heat of solution in dilute hydrochloric acid.

Kil.-deg. Kil.-deg. Kil.-deg.
 $\text{CaO} + \text{H}^2\text{O}$. . +15.10; $\text{BaO} + \text{H}^2\text{O}$. . +17.62; $\text{SrO} + \text{H}^2\text{O}$. . +17.20.

The dissolution of the anhydrous bases in water gives rise to the following quantities of heat:

CaO conc. solution . .	+18.10;	dilute solution . .	+19.00
BaO „ „ . .	+27.88;	„ „ . .	+28.12
SrO „ „ . .	+26.80;	„ „ . .	+26.8

Hence may be deduced for the heats of solution of the three hydrates the numbers +3.0, +10.26, +9.64. In the formation of the hydrates $\text{BaH}^2\text{O}^2.9\text{H}^2\text{O}$ and $\text{SrH}^2\text{O}^2.9\text{H}^2\text{O}$, 24.32 and 24.72 kil.-degrees of heat are evolved; in the dissolution of the same hydrates in water, 14.06 and 15.08 kil.-degrees are absorbed.

From the values above given Berthelot infers the existence of several hydrates of potash and soda, probably contained in the solution partly in the state of dissociation.

Heat of Neutralisation of the Alkalis, Alkaline Earths, and Organic Bases (Thomsen, *J. pr. Chem.* [2], xiii. 241-270). The heats of neutralisation of the alkalis, including thallium hydrate, and of the alkaline earths, exhibit great irregularities when these bodies are dissolved as anhydrous oxides or as hydroxides; but all these anomalies disappear when the heat of neutralisation of the aqueous solutions is examined, and the resulting compounds remain in solution. In this case the quantity of heat evolved in the neutralisation of 2 equivalents of base is for hydrochloric acid 27.5 and for sulphuric acid 31.3 kil.-degrees. These values are the true heats of neutralisation of the bases mentioned. The same heat of neutralisation is exhibited by organic bases analogous in constitution to potassium hydroxide, *e.g.* the hydroxides of tetramethylammonium, triethylsulphine and platodiamine. The heat of neutralisation of ammonia, on the other hand, is considerably smaller: for sulphuric acid 28.15, and for hydrochloric acid 24.54; and it is not altered by the substitution of alcohol-radicles, $\text{C}^n\text{H}^{2n+1}$, for hydrogen; thus for triethylamine it is for sulphuric acid 28.34, and for hydrochloric acid 25.04. The aromatic amines, however, exhibit a much smaller heat of neutralisation; for 2 mols. aniline and toluidine, it amounts to 15 kil.-degrees for hydrochloric and 16 for sulphuric acid. Hydroxylamine also gives with hydrochloric acid only 18.5 kil.-degrees. In oxygenised organic bases the heats of neutralisation of the type is likewise lowered; thus methylquinine hydroxide gives with hydrochloric acid about 20, whereas tetramethylammonium hydroxide gives 27.5; triethylstibine oxide gave with 1 mol. sulphuric acid only 3.65 kil.-degrees. Still greater is the difference when the oxygenated radicles are true acid radicles, as in the amides; for 1 mol. urea the heat of neutralisation is only 0.13.

Heat of Solution of Alcohols in 100-120 times their weight of Water (Berthelot, *Ann. Chim. Phys.* [5], ix. 307).

Methyl Alcohol	2	Isobutyl Alcohol	2.88
Ethyl Alcohol	2.5	Amyl Alcohol (ferment.) . .	2.80
Propyl Alcohol	3.05	Glycerin	1.51
Pseudopropyl Alcohol . .	3.45		

Heat of Solution and Neutralisation of Ethyl-sulphuric Acid (Berthelot, *Compt. rend.* lxxvii. 246).

$\text{C}^2\text{H}^4(\text{H}^2\text{SO}^4)$ dil. + $\frac{1}{2}\text{Na}^2\text{O}$ dil.	+13.7
$\text{C}^2\text{H}^4(\text{H}^2\text{SO}^4)$ „ + $\frac{1}{2}\text{BaO}$ „	+13.9
Heat of Solution	
$\text{C}^2\text{H}^4(\text{HNaSO}^4.\text{H}^2\text{O})$ crystallised	- 3.14
$\text{C}^2\text{H}^4(\text{HNaSO}^4)$ anhyd. (dried in cold vacuum)	- 1.02
$\text{C}^2\text{H}^4(\text{HBa}^{\frac{3}{2}}\text{SO}^4)\text{H}^2\text{O}$ crystallised	- 2.13
$\text{C}^2\text{H}^4(\text{HBa}^{\frac{3}{2}}\text{SO}^4)$ anhyd. (dried in cold vacuum)	- 0.35

Heat of Solution of Alkaline Acetates. According to Berthelot (*Compt. rend.* lxxvii. 975) the acetates of potassium and sodium, whether dehydrated by fusion or by exposure in a vacuum at ordinary temperatures, evolve the same quantities of heat on dissolving in water, and the resulting solutions likewise exhibit the same rise of temperature when treated with hydrochloric acid. Reischauer some years ago observed that fused sodium acetate when exposed to the air takes up 14 mols. water and deliquesces to a supersaturated solution, but that the same salt when dehydrated over sulphuric acid in a vacuum takes up only 3 mols. water without essential alteration of appearance. Berthelot attributes this difference to the fact that the dehydration of the salt in a vacuum takes place very slowly, and the slightest trace of the hydrated salt enclosed in the mass will prevent the formation of a supersaturated solution, which in all probability contains chiefly the anhydrous salt.

* The evolution of heat in the formation of the sodium and potassium salts of acetic and trichloroacetic acids has been determined by Louguinine (*Bull. Soc. Chim.* [2], xx. 342), with the view of studying the influence of the introduction of a halogen-atom into the acid molecule. The alkali-solutions employed were of the strength of 0.75 per cent., and did not decompose the trichloroacetic acid. The quantities of heat evolved on solution were as follows:

	Kil.-degrees
Solution of Acetic acid (m. p. 16.5°; b. p. 118°) in water	0.369
„ Trichloroacetic acid „	2.9
Solution of Acetic acid in Caustic Potash	13.499
„ Trichloroacetic acid „	14.235
Solution of Acetic acid in Caustic Soda	13.468
„ Trichloroacetic acid „	14.166

Hence it appears that the quantities of heat evolved in the formation of these salts is determined, not only by the type and constitution of the acid, but also by the nature of the elements of which it is formed.

Thermal Changes attending the Solution and Crystallisation of Sodium Butyrate and the Allotropic modifications of Elements (Berthelot, *Compt. rend.* lxxx. 512). This salt, in the crystallised as well as in the anhydrous state, gives out heat in dissolving:

	Kil.-degrees
C ⁴ H ⁷ NaO ² , dried at 100°	+ 4.27
„ dried in a cold vacuum	+ 4.21
C ⁴ H ⁷ NaO ² . $\frac{1}{3}$ H ² O	+ 3.66
C ⁴ H ⁷ NaO ² . $\frac{3}{5}$ H ² O	+ 3.44

The formation of the crystallised hydrates from water and the anhydrous salt gives out the following quantities of heat:

C ⁴ H ⁷ NaO ² + $\frac{1}{3}$ H ² O (liquid) = C ⁴ H ⁷ NaO ² . $\frac{1}{3}$ H ² O	+ 0.58
C ⁴ H ⁷ NaO ² . $\frac{1}{3}$ H ² O + $\frac{2}{5}$ H ² O (liquid) = C ⁴ H ⁷ NaO ² . $\frac{3}{5}$ H ² O	+ 0.22

The development of heat for the first semi-molecule of water is much greater than for the other five taken together, showing that the first hydrate is not simply a mixture of the anhydrous butyrate with the highest hydrate. Deducting from these numbers the heat of fusion of water, namely 0.715 kil.-degree for each semi-molecule, the following results are obtained:

C ⁴ H ⁷ NaO ² + $\frac{1}{3}$ H ² O (solid) = C ⁴ H ⁷ NaO ² . $\frac{1}{3}$ H ² O	- 0.135
C ⁴ H ⁷ NaO ² . $\frac{1}{3}$ H ² O + $\frac{2}{5}$ H ² O „ = C ⁴ H ⁷ NaO ² . $\frac{3}{5}$ H ² O	- 3.35
C ⁴ H ⁷ NaO ² + 3H ² O „ = C ⁴ H ⁷ NaO ² .3H ² O	- 3.49

The combination of solid water with solid sodium butyrate to a crystallised hydrate is therefore accompanied by a considerable absorption of heat, showing that the change of state consequent on the mere lowering of the temperature below 0°, changes the thermic sign of the combination, which, moreover, takes place directly.

Similar changes of thermic sign occur in the allotropic modifications of elements. The conversion of octohedral sulphur into solid insoluble sulphur is attended with evolution of heat, when it takes place below 18°, with no thermal change when it takes place at about 18°, and with absorption of heat above 18° to about the melting point 113°, probably also in the fluid state up to about 160°. At 160°, on the other hand, the ordinary liquid is converted into insoluble liquid sulphur, and this change is attended with evolution of heat. These changes are accompanied by unequal alteration of the specific heat of the two modifications of sulphur with the temperature. The formation and stability of the insoluble sulphur depend upon the sign of the thermal change which accompanies the reaction: at and above 160°, and below 18°, it is stable, because its formation is attended with evolution of heat; between 18°, and its melting point 113°, and probably also in the liquid state up to 160°, it undergoes spontaneous alteration attended with absorption of heat.

In consequence of the change of condition of an element with rise of temperature, a compound which at a certain temperature is unstable or explosive may become stable at a higher temperature. The formation of hydrogen selenide from its elements in their ordinary state, that is to say, from red or metallic selenium, is attended, according to Hautefeuille (*Compt. rend.* lxxviii. 1554; *Jahresh. f. Chem.* 1869, 103), with absorption of heat:

But the same combination must develop 2 units of heat if the specific heat and heat

of vaporisation of the selenium be taken into account. Hence the stability of hydrogen selenide must increase as its temperature rises; and this will account for the observation of Ditte (2nd *Suppl.*, 1079) that the quantity of hydrogen selenide formed by direct combination of its elements is a function of the temperature.

Solution of Amorphous Bodies. Duvernoy (*Chem. Centr.* 1874, 428, 440) finds that the solution of bodies which have no distinct crystalline structure, and approach more or less to the amorphous state, such as gum, resins, plant-extracts, &c., is, in many cases, attended with evolution of heat, or where no conspicuous change of temperature can be observed, there is, at all events, no diminution. This is shown by the following observations, in which the temperature of the solvent ranged from 15° to 20°:

Substance	Solvent	Rise of temperature
Gum Arabic	Water	1°-1.5°
Dextrin	"	1.6°
Malt Extract, dry	"	1.5°-2°
Caramel	"	1.5°
Liquorice juice	"	1.5°
Myrrh	"	1.5°-2°
Catechu	"	0.5°-0.8°
Kino	Alcohol	2.5°
Sandarac	"	1.5°-2°
Guaiac	"	1.5°-2°
Benzoin	"	1°-2°
Jalap-resin	"	1°
Shellac	"	1°
Dragon's-blood	"	1° and above
Catechu	"	0.8°-1°

Pulverised loaf-sugar or sugar-candy, dissolved in a certain quantity of distilled water, produced a fall of temperature of 2° to 3°; but when fused amorphous sugar, the so-called barley-sugar, was pulverised and dissolved in a small quantity of water at 15°, the thermometer during the dissolution rose to 18° and higher.

G. Fleury (*Compt. rend.* lxxxi. 196) observes that on mixing a solution of 60 grams of sugar in 30 g. of water with 500 g. of dilute hydrochloric acid containing 389 of hydrogen chloride, a rise of temperature from 49.5° to 52.1° takes place, which he attributes to inversion of the sugar.

Freezing Mixtures (Berthelot, *Compt. rend.* lxxviii. 1173). The three following processes take place in freezing mixtures, either singly or simultaneously. 1. Conversion of a liquid or solid body into gas (evaporation of ether or sulphur dioxide; reaction of a bicarbonate with an acid). 2. Liquefaction of a solid body by mixture with a liquid (solution of salts), or by mixture with another solid body (crystallised sulphur trioxide and snow, calcium chloride and snow, &c.) 3. Chemical reaction within a liquid, attended with the formation of substances, the solution of which absorbs more heat than that of their components (dissolved alkaline acetates and dissolved tartaric acid, according to Berthelot's experiments) or better by the formation of bodies which are decomposed by water, such as the salts of weak acids (ammonium carbonate formed by mixing an alkaline carbonate with sulphate or nitrate of ammonia), acid salts, &c.

Whichever of these three reactions may be employed, the fall of temperature $t - t_0$ may be calculated from the equation:

$$t - t_0 = \frac{Q_t}{\sum pc},$$

in which Q_t represents the heat absorbed; p, p, \dots the weights of the products; and c, c, \dots their specific heats. This temperature varies with the initial temperature t_0 , but attains its limit with the solidifying point of the mixture, on which account it is impossible to lower the temperature beyond a certain degree.

The change of temperature which takes place on mixing snow with the crystallised hydrate of sulphuric acid, $\text{SH}_2\text{O}^4 \cdot \text{H}^2\text{O}$, is the sum (algebraical) of three reactions, viz. the fusion of the hydrate and of the snow, which is attended with absorption of heat, and the combination of the two resulting liquids, which gives rise to evolution of heat:

Fusion of $\text{SH}_2\text{O}^4 \cdot \text{H}^2\text{O}$ gives	Kil.-degree	
17H ² O	- 3.68	
Combination of $\text{SH}_2\text{O}^4 \cdot \text{H}^2\text{O}$ with 17H ² O	- 24.31	
	+ 9.8	- 18.03

This is the quantity of heat absorbed for 422 grams of the mixture. To calculate therefrom the depression of temperature, this quantity of heat must be divided by the heat-capacity of the resulting mixture for a rise of temperature of 1° , that is to say, by the product of the weight and specific heat of the mixture. This gives:

$$t - t_1 = \frac{-18.03}{422 \times 0.813} = -0.0526 \text{ kilogram-degree.}$$

The degree of cold obtainable by such mixtures is greater in proportion as the components have been previously cooled to a lower temperature. The limit is determined exclusively by the solidifying point of the aqueous sulphuric acid produced, which lies extremely low. But all degrees of cold hitherto experimentally obtained with freezing mixtures fall short of the theoretical amounts, because heat is absorbed from the sides of the vessel, and the lowering of the temperature is diminished by radiation; chiefly, however, because a portion of the ice remains unmelted.

The following table of the frigorific values of various mixtures of sulphuric acid and snow has been drawn up by Pfaundler (*Wien. Akad. Ber.* [2 Abth.], lxxi. 509-537), from his own observations on the evolution of heat in mixing the several hydrates of sulphuric acid with water (p. 896); the molecular heats of the hydrates of sulphuric acid; the solidifying temperature of sulphuric acid at different degrees of concentration (*ibid.* 351-391); and the latent heat of fusion of snow 79.4 , and its specific heat 0.5 determined by Bunsen:

Applicable to Mixtures of $\text{SO}_4\text{H}^2 + 2.874\text{H}^2\text{O}$ with excess of Snow. Initial Temperature of the Materials 0° .

Number of mol. snow to 1 mol. acid <i>s</i>	Number of mol. snow dissolved at the commencement <i>n - 2.874</i>	Temperature of the resulting mixture <i>t</i>	Final temperature of the mixture after solution of the snow <i>\tau</i>	Frigorific value of the mixture per mol. for temp. <i>\tau</i> <i>q</i>
9.126	9.126	-37°	-37°	0 kil.-deg.
10.5	9.3	36	30.2	2.5
11.5	9.5	35	25	4
13	9.7	34	21.5	7
15	10	33	17.8	10

50	13.2	22	3.9	61
58	13.9	21	3.4	72
66	14.4	20	3.1	83
76	15.0	19	2.8	97.6
87	15.7	18	2.5	114
98	16.3	17	2.3	130
109	17.1	16	2.1	145

To cool a body down to τ , it is most advantageous to mix the hydrate $\text{SO}_4\text{H}^2 + 2.874\text{H}^2\text{O}$ with snow in such proportion that, after the snow has been melted, the mixture may have the solidifying temperature τ° . It will then, at the beginning, have a lower temperature t° . To raise the temperature from t° to τ° , a proportionally very large quantity of heat will have to be taken up by the mixture; but from τ upwards a much smaller quantity of heat will be sufficient to raise the temperature by a given amount. Now the quantity of heat which the mixture must absorb to raise its temperature from t° to τ° is the frigorific value for the temperature τ (for 1 mol. of acid used).

Cryohydrates (F. Guthrie, *Chem. News*, xxx. 237; *Phil. Mag.* [4], xlix. 1-20, 206-218, 266-276; [5], i. 49-60; abstr. *Chem. Soc. Jour.* 1875, 333, 530; 1876, i. 336; ii. 169 1877, i. 36). Every salt soluble in water is capable of uniting with

water in definite proportion to form a solid hydrate having a distinct crystalline form, melting point and solidifying point. Those hydrates which form only at temperatures below 0° are called by Guthrie 'cryohydrates.' Thus sodium chloride unites with 10.5 (? 10) mol. water, forming a hydrate which solidifies at -23° ; ammonium chloride combines with $12\text{H}_2\text{O}$, forming a compound which solidifies at -15° .

The temperature at which a cryohydrate forms is the same as that which is produced on mixing the corresponding salt with ice, and among similar salts, that which unites with the smallest number of water-molecules to form a cryohydrate is likewise that which produces the greatest degree of cold when used to form a freezing mixture. The following table exhibits the results of experiment with several salts. The numbers in column (2) show the lowest temperature producible by mixing a salt with ice; those in (4) show the molecular proportion between the anhydrous salt and the water of the cryohydrate (water-value, aquavalent):

Formula of salt	Temperature of freezing mixture of salt and ice	Solidifying temperature of cryohydrate	Molecular ratio	Percentage of anhydrous salt in the portion of cryohydrate last solidified	Percentage of anhydrous salt in the portion of cryohydrate solidified just before the last

The solidifying point of a mixture of two salts containing the same base or the same acid, lies between those of the constituent salts; so likewise does the temperature of the mixture when used as a cryogen. When salts with different bases and acids are mixed, partial decomposition takes place, resulting in the formation of two new salts. Thus a saturated solution of a mixture of KNO³ and Na²SO⁴ solidifies at -5° , as a mixture of NaNO³ and K²SO⁴, whereas NaNO³ alone solidifies at -17° .

The following table contains the results of experiments with several mixtures of salts. The solutions were evaporated to incipient crystallisation, then cooled down till the salts appeared dry, and the temperature required for the formation of the cryohydrate was noted. The temperature of the mixture, as cryogen, in the last column, is the lowest that was observed on mixing the salt with snow or pounded ice in various proportions:

HCl wt. p. c.	H ₂ O wt. p. c.	Temp. of formation of solid body	Constitution	(NH ₄) ₂ SO ₄ wt. p. c.	H ₂ O wt. p. c.	Temp. of formation of solid body	Constitution

Experiments on the separation of Ice from solutions of mixed salts led to the following results:

Solutions containing 20 per cent. Solid Bodies:

AgNO ³	NH ⁴ NO ³	H ² O
20 g.	10 g.	120 g. gave ice at -4.3°
20	20	160 „ 5.0
20	30	200 „ 5.5
10	20	120 „ 5.8

Solutions containing 30 per cent. Solid Bodies:

30 g.	15 g.	105 g. gave ice at -6.8°
30	30	140 „ 8.0
20	30	116.6 „ 8.9
20	40	140 „ 9.1

These values agree nearly with those calculated on the supposition that the influence of each constituent of the mixture is proportional to its mass.

In aqueous solutions of organic colloïds, such as gum-arabic, white of egg, gelatin, and mixtures of the same, the separation of ice begins at 0° , and complete solidification takes place at a temperature not lower than -0.5° . No cryohydrates appear to be formed, and in the solidified masses, ice and colloid can be distinguished side by side. Consequently gum arabic, for example, is inactive as a cryogen, inasmuch as when it is mixed in the form of powder at 0° with ice, the temperature remains unaltered.

DECOMPOSITION BY HEAT—DISSOCIATION—THERMOLYSIS.

The following theory of Dissociation is proposed by A. Horstmann (*Liebigs Annalen*, clxx. 192–210). Sir William Thomson has pointed out, as a consequence of the dynamical theory of heat, that the entire universe is being gradually brought, by the sum total of natural forces, to a state in which all physical energy will be in the form of heat, and that heat so diffused that all matter will be at the same temperature (see HEAT, iii. 135). This conclusion has been put into mathematical form by Clausius (*Pogg. Ann.* cxv. 400), who has worked out a magnitude called 'Entropy,' which, in all the changes taking place in the universe, is continually increased, but cannot be diminished by any known natural force. The limiting state above mentioned will therefore be attained when the entropy has reached its greatest possible value, and under these conditions no further changes can take place excepting those in which the entropy remains constant, as for example in the movements of the smallest particles of a body of constant temperature, in which those movements are restricted within given spaces, and their changes of velocity within fixed limits.

In dissociation-phenomena, according to Horstmann, the limiting state is brought about in a similar manner, and is attained when the entropy has become as great as it can be under the conditions of the reaction. The problem is therefore solved when we know by what circumstances and in what manner the entropy is altered during the changes under consideration. Consider, for example, the resolution of a gaseous body into gaseous constituents under a constant volume. The entropy is (1) diminished by the consumption of heat in chemical work; (2) increased by the separation from one another of the atoms of the decomposed molecules; (3) increased by the increase of distance between the still undecomposed molecules, which nevertheless must still uniformly fill the same space; (4) and (5) diminished by the increase in the number of molecules of the two products of the decomposition, and the diminution of the distances between these molecules. The entropy will therefore attain its maximum value when the greatest possible number of molecules has been decomposed, with the smallest possible expenditure of heat, and when moreover the molecules of the three gases have been moved as far apart from one another as possible. This, however, can in general happen only when the decomposition is incomplete, whence it follows that a portion of the original compound will always remain undecomposed.

Horstmann has also deduced from his theory the following conclusions, which he has verified by experiments on ammonium carbamate (*Deut. Chem. Ges. Ber.* ix. 1625):

1. The dissociation of a solid body, like chloride or carbamate of ammonium, whose constituents are all gaseous, is smaller in amount in presence of one of the products of decomposition than when the decomposition takes place in a vacuum.

2. The decrease in dissociation becomes greater as the pressure of that product of the action which remains in excess increases; the laws regulating this decrease in dissociation may be formulated mathematically.

3. The tension-decrease of each constituent of the compound is equal for the same pressure, provided that the molecule of the compound contains equal numbers of molecules of each constituent (sal-ammoniac, for instance).

4. If, on the other hand, more molecules of one constituent are present in the compound than of the other (ammonium carbamate, &c.), then the amount of influence exerted by each constituent is different from that of the others, dissociation being decreased to a greater extent by the presence of that constituent the largest number of molecules of which are present in the compound.

5. Dissociation is decreased by the same constituent in the same proportion at all temperatures, as soon as the pressure exerted by the constituent which is in excess stands to the dissociation-tension in a vacuum in the proportion corresponding with the temperature of the experiment.

The experiments on ammonium carbamate were made, without artificial heating, at temperatures between 17° and 22°, at which, according to Naumann (*2nd Suppl.* 252), the dissociation-tension of ammonium carbamate in a vacuum is between 50 and 70 mm. When the pressure of an excess of carbon dioxide amounted to about double the dissociation-tension of ammonium carbamate in a vacuum, this tension was reduced to about 40 per cent., and with a sixfold pressure of carbon dioxide at about 400 mm., it was reduced to about 20 per cent. of its original value. In presence of an excess of ammonia, the dissociation-tension had sunk to about 40 per cent. of its original value, before the pressure of the ammonia in excess amounted to three-fourths of the corresponding tension in the vacuum; with a double pressure, the tension was only 10 per cent., and with a six-fold pressure only 2 or 3 per cent. of its original value, scarcely amounting to 2 mm.

Indifferent gases, such as atmospheric air, produce no perceptible alteration in the dissociation-tension of ammonium carbamate.

On the Theory of Dissociation, see also F. Mohr (*2nd Suppl.* 636-638).

Decomposition of Phosphorus Pentachloride. The vapour-density of this compound, as determined by Dumas' method, is 3.69 (iv. 512), that is to say, about half what it should be for a condensation to 2 volumes:

$$\frac{31 + 5 \cdot 35.5}{2} \times 0.0693 = 7.2. \quad \text{This result indicates a resolution of the vapour of } \text{PCl}_5$$

by heat into PCl_3 and Cl_2 ; and in fact it appears from experiments by Wurtz (*Deut. Chem. Ges. Ber.* ii. 162; *Compt. rend.* lxxvi. 601) that when the pentachloride is volatilised at low temperatures, and the vapour mixed with air, the density of the vapour comes out nearly equal to the normal value 7.2. The numbers thus obtained were however all somewhat below this normal value, whence Wurtz infers that some amount of dissociation must have taken place, even at the comparatively low temperatures at which the experiments were conducted; and to prevent this or diminish its amount, further experiments were made in which the vapour of the pentachloride was allowed to diffuse into a space already saturated with the vapour of one of its decomposition-products, viz. the trichloride. Out of twelve determinations thus made, seven gave numbers agreeing nearly with the normal density, four approximated thereto more or less, and only one showed a sensible excess above it, probably in consequence of peculiar circumstances in the experiment. These results show that the normal vapour-density of phosphorus pentachloride is that of an undecomposed atomic compound.

On the Dissociation of Sulphur Tetrachloride, see *2nd Suppl.* 115; of Gaseous Hydrogen Iodide, p. 428 of this Supplement; of Chloral Hydrate, p. 440 of the same.

On an apparatus for exhibiting the Dissociation of Iodine Trichloride, see Brecken (*Deut. Chem. Ges. Ber.* viii. 489; *Jahresb. f. Chem.* 1875, 151).

Decomposition of Mercuric Oxide. Experiments on the decomposition by heat of pure mercuric oxide (freed from mercurous oxide by ignition with ammonium nitrate) have been made by J. Myers (*Deut. Chem. Ges. Ber.* vi. 11). The oxide was heated in a glass tube connected with a Geissler's pump, whereby the tube could be exhausted, and the pressure of the gas evolved on heating the oxide could be measured. At 150° the tension of the gas soon reaches 2 mm. of mercury, and remains constant when the heating is continued at that temperature for an hour, also when the heat is increased to 240°; at 293° it does not exceed 2.5 mm., and at 350° it amounts to 8 mm. But above this temperature, the tension of the evolved oxygen has no superior limit, but increases continuously, though slowly, with the

duration of the experiment, amounting to 16 mm. after five hours' heating at 400° , and to 343 mm. after $7\frac{1}{2}$ hours' at 560° . Hence Myers infers that up to a certain temperature (about 3.0°) the dissociation of mercuric oxide by heat is normal, the number of molecules decomposed in a given time at any constant temperature being equal to the number of those which reunite by coming in contact, so that a state of equilibrium or maximum tension is attained (see Pfaundler, *Pogg. Ann.* cxxxi. 54); but that above this temperature the tension has no superior limit, because the separate molecules have attained a rapidity of movement greater than that which is compatible with their recombination. The decomposition of mercuric oxide by heat exhibits the further anomaly that the tension of the liberated gas does not diminish on cooling, whether the cooling be slow or rapid.

Debray (*Compt. rend.* lxxvii. 123) objects to the conclusions drawn by Myers from the experiments above mentioned, on the ground that the vapour of mercury being constantly removed by condensation in the cooler portions of the apparatus, the conditions for the attainment of a maximum tension of decomposition did not exist, and points out that in order to study the real phenomena of decomposition, it would be necessary to heat the substance in an apparatus of uniform temperature in every part. Operating in this manner, Debray finds that when a sealed tube containing mercury and oxygen is heated to 440° , the oxygen is almost entirely absorbed, and that even on rapidly cooling the tube, the combination completes itself before a temperature can be reached at which the elements would be without action on one another. This difference of result is evidently due to the fact that in Myers's experiments the tension of the mercury vapour was very low compared with that of the oxygen. That an apparent maximum tension was obtained at temperatures below 350° was probably due to the very slow rate at which decomposition proceeds at those lower temperatures.

Decomposition of Carbonates. Joulin (*Bull. Soc. Chim.* [2], xix. 345) has examined the dissociation of metallic carbonates by heating them in a glass tube connected with a pressure-gauge and a mercurial pump. The salt was dried at a low temperature in an atmosphere of carbon dioxide, and the tube, having been exhausted, was then heated by immersing it in an oil-bath.

Manganese carbonate began to decompose at 70° . At 150° the tension of the carbon dioxide attained a certain value, 215 mm., which remained constant for that temperature; when the salt was allowed to cool, recombination took place, and the tension reverted slowly to its initial value. Above 200° the decomposition was nearly complete, and the elastic force of the gas increased constantly to two atmospheres; the carbonate became brown, and little or no reabsorption took place on cooling.

When the carbonate was heated to 100° , 150° , and 200° , then allowed to cool, and the temperature raised a second time to 100° , the extreme tension was less than one-half of the tension attained when the salt was heated for the first time to 100° , and a third heating produced no sensible alteration of the lower tension. Since no exhaustion was effected during the three operations, this result is probably due to some molecular change in the carbonate, which renders it more stable, and consequently more able to resist decomposition at low temperatures. This explanation is also strengthened by the fact that when the temperature of the bath was quickly raised, the elastic force of the gas attained a value, 489 mm., more than double of that at which it remained constant after a lengthened heating, viz. 215 mm.; a circumstance which seems to imply that the molecules are not, in the first instance, in that condition of stable equilibrium which they finally acquire when the temperature has passed a certain degree, and remained uniform for a considerable time.

The results of the experiments with silver carbonate were somewhat different from those with manganese carbonate, inasmuch as the decomposition of the carbonate and of the resulting oxide proceeded simultaneously at temperatures above 200° . Below this, the extreme tension was sensibly inferior to that of manganese carbonate under the same conditions, and the salt altogether underwent decomposition with greater facility. The decomposition was complete at 225° .

Experiments with lead carbonate (native cerussite) showed that the tension of the carbon dioxide, which at 150° was below 30 mm., rose to 75 mm. at 250° , and increased rapidly up to 300° —at which complete decomposition took place—attaining in $2\frac{1}{2}$ hours a force of two atmospheres.

These experiments show that metallic carbonates are very easily decomposable, and indicate the necessity of great precautions in their preparation and drying previous to analysis.

On the Dissociation of the Acid Carbonates of Ammonium, Potassium, and Sodium in aqueous solution, see p. 409.

Decomposition of Hydrated Salts. G. Wiedemann (*J. pr. Chem.* [2], ix. 338) has examined the dissociation phenomena of several hydrated salts by introducing them into the vacuum of a barometer-tube, and measuring the depression of the mercury produced by the pressure of the evolved aqueous vapour. Before making an observation, the temperature was kept constant for about half-an-hour, in order to ensure a uniform distribution of heat through the slowly-conducting mass of the crystal. After about ten minutes, however, the level of the mercury was found to alter but very slowly. In spite of the precaution just mentioned, the results were often irregular, the tensions observed at low temperatures often differing but little from those of pure water-vapour. To obtain constant results it was necessary, before introducing the crystals into the tube, to dry them over sulphuric acid in rarefied air till they showed traces of efflorescence on the surface.

From numerous experiments on the sulphates of magnesium, zinc, cobalt, nickel, and iron (ferrous), it appears that the results obtained with any given salt, though they may differ slightly from one another at comparatively low temperatures, agree well at temperatures above 30°-35°. Moreover, the tension of the water of crystallisation is independent of the total amount of salt present, and of the space which the vapour has to fill, provided that the quantity of water which can escape from the surface of the salt is sufficient to saturate that space with vapour under the conditions of the experiment.

Hydrated salts begin to lose water at low temperatures, the vapour then showing a small degree of elasticity; as the temperature rises, the amount of water given off and the elasticity of the vapour likewise increase. Different salts exhibit different vapour-tensions at the same temperature. At 70° ferrous sulphate shows the highest vapour-tension, then follow in order the sulphates of cobalt, nickel, magnesium, and zinc. At temperatures above the melting points of these salts the tensions of their vapours increase with rise of temperature faster than below their melting points, but no sudden increase occurs at the melting point.

If p and P be the elasticities of the vapours of pure water and of crystalline water respectively, and if the densities of these vapours vary at every temperature as the elasticities; if also G be the weight of a given volume (1 cubic meter) of saturated water-vapour at the temperature t , and g be the weight of an equal volume of vapour from the crystals, then—

$$g = G \cdot \frac{p}{P}.$$

In the following table the values of G and g are calculated in grams:—

	Water	Magnesium sulphate	Zinc sulphate	Ferrous sulphate	Cobalt sulphate	Nickel sulphate
t	G	g	g	g	g	g
25	22.7	18.0	14.5	15.6	17.2	11.3
30	30.1	25.3	19.1	19.9	22.9	25.3
35	39.3	33.0	28.2	28.1	33.2	33.0
40	50.9	43.6	40.3	37.1	43.6	43.6
45	65.3	54.9	52.4	50.3	56.7	57.2
50	82.9	59.5	56.8	58.1	61.4	63.1
55	104.6	88.1	80.1	90.1	93.9	92.1
60	130.6	107.5	100.9	114.1	117.1	115.0
65	162.0	130.0	121.7	140.8	145.6	143.0
70	199.4	160.0	145.4	175.9	177.1	175.3
75	243.7	195.1	(186.6)	222.1	213.2	211.0
80	295.9	229.8	(230.3)	267.9	255.4	252.2

To calculate the amounts by weight of crystallised salt which must give up its water in order to fill 1 cubic meter with vapour (supposing the salt to be completely dehydrated), the values of g must be multiplied by the numbers 1.97, 2.29, 2.22, 2.24 and 2.24 respectively.

A. Naumann (*Deut. Chem. Ges. Ber.* vii. 1573-1583) is of opinion that Wiedemann's conclusions, as also those of Debray (*1st Suppl.* 425), with respect to the tension of the vapours emitted in the decomposition of hydrated salts, are incorrect, probably because the observations at each particular temperature were not continued long enough. The main result of his own observations is that the vapour-tension actually exhibited by a hydrated salt during decomposition at any particular temperature is not constant. On theoretical grounds, indeed, a hydrated salt of constant and uniform

composition throughout might be expected to give off at any fixed temperature a vapour of constant tension. Practically, however, this perfect uniformity of composition in the salt cannot be preserved or even attained, because the water given off on heating is continually being reabsorbed by the dehydrated portions of the salt, whence arises a continual alteration in the condition of the salt, and consequently in the tension of the vapour given off from it.

These changes in the state of a hydrated salt under the influence of heat are well seen in the case of cupric sulphate, on account of the change of colour consequent on the dehydration. A crystal of this salt placed in the vacuum of Hofmann's vapour-density apparatus (*1st Suppl.* 1127), and exposed to the temperature of boiling alcohol, turns white, if of sufficient size compared with the vacuum-space, on particular spots, especially where it touches the glass or the mercury, these parts being heated sooner than the rest. As the tension gradually increases, these white spots extend, and others appear on previously unattacked parts of the surface. But even after an hour's heating the tension still goes on increasing, though very slowly, whilst the white of the portions first attacked passes through dirty-white to greenish-white, and at the same time the crystal is attacked to a greater depth. Sometimes particular faces of the crystal remain quite blue, and if the experiment be repeated after previous slow cooling—whereby the attacked parts are restored to their blue colour—just those faces which had previously remained unattacked are the first to exhibit the white spots. The darkening of the previously attacked portions from reabsorption of water, while the vapour-tension goes on increasing, shows that partially dehydrated cupric sulphate has a lower vapour-tension than the fully hydrated salt, and that no equilibrium of tension can be attained, till, by partial dehydration of still undecomposed portions of the crystal and reabsorption of water by the first and most completely dehydrated portions, the entire crystal has attained a uniform composition, for which the salt will require to be kept at the same temperature for weeks or perhaps even for months. If the crystal is proportionately small, but still of a size considerably greater than is required to saturate the available space with water-vapour at the given temperature, its whole surface is very quickly attacked, but gradually becomes darker again as the vapour-tension increases. After an hour's heating, the increase of the tension becomes so slow as to lead to the idea that a state of equilibrium is about to be established. That this however is not the case might be shown by careful observation of the tension at a temperature kept constant for a considerable time (which however would be difficult), or by a slight lowering of the temperature, which would be found to produce, not a decrease, but after some time an increase of the vapour-tension, showing that at the previously existing higher temperature the state of equilibrium had not been attained.

The vapour-tensions attained after equal times in different experiments made at the same temperature do not agree, and they are likewise different when the experiment is repeated with the same quantity of the salt. The greatest alteration of form and structure takes place when the water is reabsorbed after cooling. On repeating the experiment at the same temperature, a vapour-tension equal to that previously observed is first attained, but more quickly, and afterwards a higher tension. If the cooling be so conducted that the water cannot be precipitated in the upper part of the vacuum, and then be taken up again by the crystal, with formation of numerous elevations and depressions, but may be enclosed between the surface of the tube and the rising mercury, and thereby prevented from acting on the crystal, the latter undergoes less alteration and exhibits more equal vapour-tensions on repeated heating. Even at the ordinary temperature of a room, transparent crystals, well defined all round, and with sharp edges and smooth faces, exhibited a lower tension than those which were less well-defined or had fracture-surfaces. In certain series of experiments also, on cooling down from a higher to the ordinary temperature, the vapour-tension never returned to the lower amount exhibited by a crystal which had never been raised above the ordinary temperature and thereby essentially altered in structure and composition (Naumann). On the other hand, Wiedemann (*Pogg. Ann.* clii. 612) maintains that cupric sulphate belongs to that class of hydrates in which the influence of the air adhering to the crystals, and of the water enclosed in them, is such as to render it almost impossible to obtain concordant results in any experiments made to determine their vapour-tensions.

Precht a. Kraut (*Liebig's Annalen*, clxxviii. 129–149) are of opinion that in the experiments of Debray (*1st Suppl.* 425), and in those of Wiedemann and Naumann above noticed, sufficient attention has not been paid to two circumstances which have great influence on the course of the dissociation, viz. the quantity of the salt present, and the magnitude of the space to be filled by the vapour.* From their own experi-

* According to Wiedemann, these conditions have no influence on the result, provided the salt present contains sufficient water to saturate the space with vapour (p. 1012).

ments, made with a modified form of Hofmann's vapour-density apparatus, on *gypsum*, *cadmium sulphate*, $3\text{CdSO}_4 \cdot 8\text{H}_2\text{O}$, *ferrous sulphate*, $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, *ammonio-ferrous sulphate*, $(\text{NH}_4)^2\text{Fe}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, *ammonia-alum* and *potash-alum*, they conclude that, at a given temperature in a limited vacuum, the vapour-tension of a hydrated salt is a function of its quantity, increasing with the quantity, and approximating to a limit which would probably be reached only when the quantity of the salt was infinite. If, on the other hand, the temperature and the quantity of the salt are fixed, the attainable tension will be determined by the extent of the vacuous space, a small vacuum determining a comparatively high, and a large vacuum a comparatively low tension. Silicates, such as diopase, $\text{CuSiO}_3 \cdot \text{H}_2\text{O}$, *chrysocolla*, $\text{Zn}^2\text{SiO}_4 \cdot \text{H}_2\text{O}$, and *okenite*, $\text{CaSiO}_3 \cdot \text{SiO}_2 \cdot 2\text{H}_2\text{O}$, give off their water only at temperatures which are too high to allow of observations in a vacuum. These silicates, heated in a stream of dry air, began, for the most part, to give off their water at 100° , but the loss did not in any case amount to 1 mol. or even to a simple fraction thereof; at 300° more water was given off, but in no case was it possible to recognise distinct differences, from which it would be inferred that these silicates contained water in different modes of combination.

The decomposition of hydrates by heat has also been studied by J. B. Hannay (*Chem. Soc. Jour.* 1877, ii. 381-395) and by W. Ramsay (*ibid.* 395-399). Hannay has determined the loss of weight which various hydrates sustain in successive equal intervals of time when they are heated to different temperatures in a current of air. In general a hydrate parts with its water more or less quickly up to a certain point, after which the rate of dehydration becomes suddenly less and continues uniform up to another definite point, and so on. These sudden alterations in the rate of dehydration point to the formation of lower hydrates, which give off their water less quickly. Thus *magnesium sulphate*, $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, lost at 100° in four minutes 8.36 p. water, whereby it was reduced to $\text{MgSO}_4 \cdot 6\text{H}_2\text{O}$. The dehydration went on at a nearly uniform but slower rate, till about 29 or 30 p. water had gone off in forty-five minutes, leaving the trihydrate, $\text{MgSO}_4 \cdot 3\text{H}_2\text{O}$. The weight then diminished more slowly till the dihydrate, $\text{MgSO}_4 \cdot 2\text{H}_2\text{O}$, was left, after which it became extremely slow, till the remaining salt had the composition $\text{MgSO}_4 \cdot \text{H}_2\text{O}$. Similar results were obtained with *sodium sulphate*, *zinc sulphate*, *calcium chloride*, and *strontium chloride*.*

Ramsay has made similar experiments on the amorphous hydrates of alumina and ferric oxide, from which it appears that the variation in the rate of dehydration of hydrated alumina from $\text{Al}_2\text{O}_3 \cdot 4\text{H}_2\text{O}$ downwards is perfectly continuous, the curve which represents it not exhibiting any sudden break at the points corresponding with $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$, $\text{Al}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$, and $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$. The same also is the case with the hydrates of ferric oxide, with the exception of $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, at which there is a sudden break of continuity in the rate of dehydration. Hence Ramsay infers that, if there are really four or five definite hydrates of alumina or ferric oxide, their vapour-tensions must differ but very slightly one from the other; and he regards it as probable either that the hydrates $\text{Al}_2\text{O}_3 \cdot 4\text{H}_2\text{O}$, $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$, $\text{Fe}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$, &c. do not exist as definite compounds (except $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$), or else that there are a great number of hydrates of alumina and of ferric oxide, whose vapour-tensions differ from one another but very slightly, so that the smallest rise or fall of temperature is sufficient to convert a higher into a lower hydrate, and the contrary. *Lead oxide*, on the other hand, forms two definite hydrates, $3\text{PbO} \cdot \text{H}_2\text{O}$ and $2\text{PbO} \cdot \text{H}_2\text{O}$.

The vapour-tensions occurring in the dissociation of salts containing water of crystallisation have been investigated by A. H. Pareau (*Ann. Phys. Chem.* [2], i. 39-63) in the case of $\text{SrCl}_2 + 6\text{H}_2\text{O}$, $\text{CuSO}_4 + 5\text{H}_2\text{O}$, $\text{U}^2(\text{SO}_4)_3 + 3\text{H}_2\text{O}$, and $\text{BaCl}_2 + 2\text{H}_2\text{O}$. In the investigations relating to this subject described in the preceding pages and in 1st Suppl. 425, the state of decomposition of a compound was modified by the introduction of different quantities of the substance into a vacuum. Pareau, on the other hand, examines the tension of dissociation by introducing into the vacuum a constant quantity of a crystalline powder in different states of dehydration. For this purpose the vapour is pumped out by a method similar to that which was applied to the carbon dioxide in Debray's experiments on *calcspar* (1st Suppl. 425). Up to 60° , the mode of variation of the tensions of salts containing water of crystallisation is the same as that for pure water, the curves all running parallel to Regnault's tension-curve for aqueous vapour. Moreover, the tension of dissociation is not a function of the state of decomposition of the salt. It is true that when the water is gradually withdrawn from the salt, the tension alters at a certain temperature, but this alteration is sudden. It is possible, therefore, that the salts investigated may exist in different states of equilibrium with their water of crystallisation. The results of these experiments are

* The papers above referred to contain numerous tables, and diagrams of curves, showing the rates of decomposition of the several salts at different temperatures.

at variance with Pfaundler's theory, and with the mathematical developments of Horstmann (p. 1009). Finally, Pareau draws attention to the following facts: The curves deduced from his observations follow one another according to the number of molecules of crystallisation-water, whereas Wiedemann's curves, which all relate to salts with $7H_2O$, cut one another and lie close together. The tensions of strontium chloride and uranium sulphate agree together when both salts contain only $1\frac{1}{2}$ mol. water; and those of copper sulphate and uranium sulphate agree when both salts contain 3 mol. water. These results might find their explanation in the somewhat bold hypothesis that the dissociation-tensions of salts containing water of crystallisation depend only on the temperature and on the number of molecules of crystallisation water, and are independent of the nature of the salt.

Decomposition of Crystallised Potash-alum.—A. Naumann (*Deut. Chem. Ges. Ber.* x. 456) finds that this salt, when heated to 100° in a sealed tube, gradually decomposes after fusion, its water of crystallisation being separated, and a solid body being deposited, probably consisting of the anhydrous alum; and at the same time there is formed in the liquid, with the aid of the water set free, a basic compound of alumina, potash, sulphuric acid, and water, analogous to that which, according to former observations of Naumann, is produced in aqueous solutions of alum heated to 100° (see p. 66 of this Supplement). The decomposition of alum in closed vessels takes place also to a small amount even at 78° , at which temperature the crystallised alum still retains its form, but not at 34° .

On the Dissociation of Chrome-alum in Aqueous Solution, see p. 68.

Decomposition of Ammoniacal Salts in Aqueous Solution at low Temperatures.—A. R. Leeds (*Sill. Am. J.* [3], vii. 197) has examined the circumstances of these decompositions, by observing the reaction of the vapour emitted from the solution at various temperatures, mostly between 17° and 20° . The reagent employed was alizarin-paper, which, in contact with an alkali or with a solution in which an alkaline reaction is developed, immediately changes from yellow to red. The following are the results:—

Salts	Parts in 100°	Reaction of Liquid	Temperature	Reaction of Vapour
Ammonium Chloride	10.60	slightly acid	37°	strongly alkaline
	5.30	"	38.5	alkaline
	2.65	"	39.3	slightly alkaline
	1.325	"	39.2	"
Ammonium Sulphate	45.62	acid	50.5	alkaline
	22.81	"	51	slightly alkaline
	11.40	"	50.5	"
Ammonium Oxalate	{ saturated at 75°	strongly alkaline	— 1	strongly alkaline
Ammonium Acetate	{ saturated at 17°	acid	55	alkaline

The point of sensible dissociation doubtless depends on the circumstances of the experiment, and on the delicacy of the apparatus and reagents employed. The temperatures above given must therefore be regarded, not as absolute, but as relative and valuable only as indicative of the comparative dissociability of these salts in aqueous solution.

Decomposition of Calcium Chloride in Aqueous Solution.—A boiling solution of this salt begins to give off hydrochloric acid, as indicated by the acid reaction of the condensed vapours, when its boiling point rises to 148° , indicating a degree of concentration corresponding with the formula, $CaCl_2 + 4H_2O$. When the solution is distilled in a retort, the acid reaction does not show itself till the boiling point rises to 160° , evidently because the portions of hydrochloric acid first given off dissolve in the water which condenses on the upper part of the retort, and are carried back with it into the liquid (Dibbits, *Archives néerlandaises*, viii. 295).

RADIANT HEAT.

Diathermancy. 1. Of Rock Salt. From experiments by H. Buff (*Pogg. Ann.* clviii. 177–213), it appears that rock salt absorbs a considerable portion of the heat which falls upon it. The complete diathermancy attributed to it by Melloni is

only apparent, the fact being that rock salt absorbs only the heat rays that are absorbed by atmospheric air. Now in Melloni's experiments the heat which fell upon the rock salt had already traversed a stratum of air, so that it no longer contained any rays that could be absorbed by the salt. See also J. B. Harrison (*Phil. Mag.* [5], iii. 424).

2. Of Metals and Paper.—Aymonnet (*Compt. rend.* lxxxiv. 259) concludes from experiments on the diathermancy of these bodies, viewed in connection with the observations of Wiedemann a. Franz (v. 71) on the rapidity with which the equilibrium of temperature is restored in bars: (1). That metals and paper are not athermanous. (2). That they are more diathermanous for the dark heat-rays emitted from metallic bodies below 100° than for luminous heat-rays, or those which are emitted just below redness. (3). That their absorbing power is less than that of water. (4). That it is possible to discover a mathematical relation between the absorbing power of a body and its conducting power.

On the *Reflection of Heat from Metals*, see Knoblauch (*Ann. Phys. Chem.* [2], i. 1-13).

3. Of Vapours. The absorbing powers of the following vapours for heat from different sources have been investigated by G. L. Hoorweg (*Pogg. Ann.* clv. 385-402).

Leslie's Cube	Absorption	Heated Copper plate coated with Lamp-black	Absorption	Hot Brick	Absorption
Water-vapour	1.7	Water-vapour	2	Water-vapour	2.3
Carbon Disulphide	2.1	Carbon Disulphide	5	Carbon Disulphide	—
Alcohol	17	Ethyl Sulphide	19.7	Alcohol	26
Methyl Alcohol	18	Alcohol	21	Ethyl Sulphide	27.5
Ethyl Sulphide	18	Methyl Alcohol	23	Ethyl Formate	28.6
Ethyl Formate	22.1	Ethyl Formate	23.2	Ethyl Acetate	32.6
Ethyl Acetate	26.5	Ethyl Acetate	27	Methyl Alcohol	37
Total (emitted)	100	Total (emitted)	100	Total (emitted)	100

Hoorweg's experiments likewise show that in vapours—as long known with respect to solids and liquids—each successive stratum transmits a larger proportion of rays than the preceding.

Influence of Length of the Ascending Air-current.

	9 cm.	Air-column of: 50 cm.	100 cm.
Water-vapour	imperceptible	1.6	2
Alcohol „	9	17	21

The disagreement between the results of Tyndall and of Magnus with regard to the absorption of heat-rays by moist air is attributed by Hoorweg to the fact that Tyndall overestimated the amount of absorption, in consequence of neglecting or underestimating that which was due to the vapour condensed on the glass plates with which his tube was closed, while Magnus, on the contrary, underestimated it in consequence of using too short a tube.

According to H. Buff (*Pogg. Ann.* clviii. 177) the diathermancy of hydrogen gas is very nearly equal to that of a vacuum. Dry air absorbs from 50 to 60 per cent. of the heat-rays, which penetrate it from a source of heat raised to the boiling point of water. The absorptive power of moist air exceeds that of dry air by several units per cent., but not nearly to the extent maintained by some physicists.

4. *Absorptive power of Elementary Bodies in Solution.*—From observations on the absorption of heat-rays by solutions, Aymonnet infers (*Compt. rend.* lxxxiii. 97) that the heat-absorbing power of all the elementary bodies referred to their atomic weights is the same, provided (1) that they are dissolved in the same liquid; (2) that they are constituents of bodies of analogous chemical constitution.

5. *Influence of Temperature on Absorptive Power.*—According to Aymonnet (*Compt. rend.* lxxxii. 153), reduction of temperature diminishes the diathermancy of flint glass, but increases that of a solution of iodine in chloroform.

6. *Distribution of Heat in the Spectrum of the Electric Light.*—By experiments with a battery of 50-100 large Bunsen's elements, Desains finds that when the rays of the electric lamp are passed through a column of water 3 to 4 cm. long, the heat-intensity of the dark part of the spectrum is considerably diminished, while the heat of the luminous part remains nearly unaltered, amounting, as in the solar spectrum (1st *Suppl.* 689), to about a third of the total quantity in the spectrum. The electric spectrum in fact agrees nearly with the solar spectrum in all respects, excepting that it is somewhat less extended, especially towards the violet end (*Compt. rend.* lxxxiv. 285).

CONDUCTION OF HEAT.

1. **In Solids.** *Isothermal surfaces in Crystals* (v. 73).—Sénarmont's method of determining the isothermal surfaces of crystals, which consists in coating a thin slice of the crystal with wax, heating the surface strongly at one point, and measuring the ellipse formed round this point by the melting wax (*Ann. Chim. Phys.* [3], xxi. 457), has been modified by W. C. Röntgen (*Pogg. Ann.* cli. 603) as follows: A well-cleaned plate of the crystal, e.g. a plate of quartz cut parallel to the axis, is breathed upon rather strongly in such a manner that the moisture may cover it in a thin uniform film, not in drops. If now a pointed metal rod strongly heated in a flame be set perpendicularly on the centre of the plate, the film of moisture will evaporate round the point in a well-defined ellipse. The experiment may be interrupted when the figure has attained any desired dimensions, and the figure fixed by quickly strewing lycopodium on the surface, and tapping cautiously on the plate so as to make the lycopodium stick only on those parts from which the moisture has not been evaporated. The elliptic figure thus left is so sharply defined that its dimensions may be measured with great exactness. In two square plates of quartz cut parallel to the axis, the ratio of the elliptic axes was found by this method to vary between the numbers 1.274 and 1.323.

C. Pape (*Ann. Phys. Chem.* [2], i. 126-147) has examined, by a modification of Sénarmont's method, the form of the isothermal surfaces in triclinic cupric sulphate. The mean values of the axes of the isothermal surface, regarded as an ellipsoid, were found to be $a : b : c = 0.939 : 0.860 : 1$; a being coincident with the crystallographic axis A , and the other two being situated in the plane of the two crystallographic axes B and C , and forming with them the angle $16^\circ 27'$, the axis b lying between $+B$ and $+C$.

According to Jannettaz (*Compt. rend.* lxxv. 1501) the axis of greatest heat-conduction in uniaxial crystals is parallel to the direction of easiest cleavage; if the crystal exhibits several directions of cleavage, the axis of easiest conduction is parallel to the direction of the greater of the two projections, one parallel and the other perpendicular to the principal axis.

For tourmaline, apatite, and pyromorphite, this rule is undecided, on account of the indistinctness of their cleavage; calcspar and emerald form exceptions to it; and these two minerals further show the peculiarity of contracting when heated, the one in the direction normal to the axis, the other parallel to it. The rule applies also to biaxial crystals, in which in fact it was first noticed by Jannettaz.

In rocks, e.g. granite, gneiss, talc-slate, mica-slate, and serpentine, heat is conducted with the greatest facility along those surfaces, planes, and lines between which there is the smallest amount of cohesion (Jannettaz, *Compt. rend.* lxxviii. 1202; *Jahresb. f. Chem.* 1874, 73).

In Soils. A. v. Littrow (*Wien. Akad. Ber.* [2 Abth.], lxxi. 99-151) has compared the heat-conductivities of different soils by placing the bulbs of thermometers at distances of 6, 12, 12 and 24 cm. from a source of heat, in a caoutchouc cylinder filled with the soil. In the case of dry soils the readings were taken at intervals of ten minutes; with wet ones every hour. The results obtained were—(1). The mechanical condition of the soil exerts the greatest influence on its conducting power; the finer the state of division the less being the conductivity of the soil. Presence of organic matter considerably lessens the conducting power. (2). The petrographical and chemical composition of the soil is of small importance compared with its mechanical condition, but lime and magnesia seem to lower the conductivity. (3). All kinds of soil conduct heat better when wet than when dry, since the air in their pores is replaced by the better conductor—water. (4). The conducting power of wet soil is greater than that of water, from which it follows (5) that the materials which form the soil are in themselves better conductors than water. (6). The conducting power of dry soils lies between that of water and that of air, while the conducting power of wet soils is greater than that of water; so that the conductivity of water is between the two.

In Metals. From the experiments of Decharme (*Compt. rend.* lxxxii. 731, 815), the rate at which heat travels along a bar of iron is, at any point, inversely proportional to the square of the distance of that point from the source of heat. According to Naccari a. Bellati (*Cimento* [3], i. 72, 107), the heat-conductivity of iron is not affected by magnetisation.

According to Horwig (*Pogg. Ann.* cii. 177) the heat-conductivity of mercury between the temperatures of 40° and 160° is perfectly constant.

In Ebonite. J. Stefan (*Wien. Akad. Ber.* [2 Abth.], lxxiv. 438-462), from experiments on the heat-conductivity of ebonite, has calculated the quotient k obtained

by dividing this magnitude by the specific heat referred to the unit of volume, one series of experiments giving $k = 0.00928$, and another series $k = 0.00938$, these numbers having reference to the centimeter as the unit of length, and the second as the unit of time. On the magnitude k depends the rapidity with which differences of temperature in the interior of a body become equalised, and therefore also the rapidity with which a body cools down when exposed to a uniform temperature all round, as when it is immersed in ice. As this property of bodies is seldom noticed, Stefan has given the values of k for several substances, in order to show the place of ebonite among them:

Hydrogen gas	$k = 1.81$
Copper	0.81
Air	0.26
Iron	0.18
Ice	0.011
Glass	0.0034
Water	0.0015
Ebonite	0.00093

From k , the heat-conducting power K is calculated by the formula $K = kcs$, in which c is the specific heat and s the specific gravity of the body. For ebonite, Stefan found $c = 0.23$, $s = 1.22$; therefore $cs = 0.2806$, and $K = 0.00026$. According to their heat-conducting powers, therefore, the eight bodies above mentioned range themselves in the following order:

Copper	$K = 1$
Iron	0.17
Ice	0.0057
Glass	0.0016
Water	0.0015
Hydrogen gas	0.00039
Ebonite	0.00026
Air	0.000055

On the conducting powers of different kinds of glass for heat and for electricity, see ELECTRICITY (p. 722).

Heat-conduction in Liquids. The order of conductivity of a few liquids for heat and electricity, was determined in 1868 by Paalzow (*Pogg. Ann.* cxxxiv. 613) with the results shown in the following table, the best conductors in each column being placed first:

Conducting power for:

<i>Heat.</i>	<i>Electricity.</i>
Mercury.	Mercury.
Water.	Sulphuric acid (sp. gr. 1.25).
Cupric Sulphate (conc.)	Sodium Chloride
Sulphuric acid (sp. gr. 1.25).	Zinc Sulphate
Zinc Sulphate (conc.)	Cupric Sulphate
Sodium Chloride (conc.)	Water.

Experiments on the relative heat-conductivities of a considerable number of liquids were made about the same time by F. Guthrie, from which he concluded that of all known liquids (except mercury) water is the best conductor of heat, and certain others, *e.g.* ethylene bromide, amyl iodide, and ethyl iodide the worst (see *1st Suppl.* 692).

Absolute values of the heat-conducting powers of water and a few other liquids have been obtained by Lundquist (*Pogg. Ann.* cliii. 481), whose results confirm the statement of Paalzow that the conducting powers of liquids for heat and electricity are not proportional to one another, and that the conducting power of liquids for heat varies much less than their conducting powers for electricity.

The following table exhibits the heat-conductivities of certain liquids referred to the centimeter and second as units of length and time, calculated by A. Winkelmann (*Pogg. Ann.* cliii. 481-498) from observations on the rate of cooling of the liquids enclosed in cylindrical vessels. The specific gravities and specific heats are also given:

	Heat-conductivity	Spec. gravity	Spec. heat
Water	0·001540	1	1
Sodium Chloride solution, 33·33 per cent.	0·002675	1·187	0·773
Potassium Chloride solution, 20 per cent.	0·001912	1·110	0·808
Alcohol	0·001506	0·795	0·600
Carbon Disulphide	0·002003	1·268	0·250
Glycerin	0·000748	1·220	0·612

According to E. Sacher (*Dingl. pol. J.* cxxiv. 343) the conduction of heat in liquids whose density decreases from below upwards takes place very slowly in the downward direction. The experiments were made by carefully pouring five layers of alcohol, sp. gr. 0·98 to 0·82, one upon the other. The same result was obtained by cooling experiments.

Heat-conduction in Gases. The following values are given by A. Winkelmann (*Pogg. Ann.* clvii. 497-555 and clix. 177-191):

	Experiment	Theory
Air	1	1
Carbon Dioxide	0·60	0·86
Ethylene	0·79	1·13
Methane	1·23	1·76
Nitrogen Dioxide	0·88	0·96
Nitrogen Monoxide	0·69	0·91

Also the proportions of the heat-conductivity of hydrogen to those of the following gases (each taken as unity) at 7·5°:

Water-vapour	8·88
Alcohol-vapour	11·07
CS ² -vapour	18·08
Ammonia	6·93
Ether-vapour	11·22

The alteration of conducting power with the temperature is expressed by the ratio of the heat-conductivity of a gas at τ° to that at 0° , namely, by $(1 + \bar{\gamma}\tau) : 1$. The observations gave the following values of the temperature-coefficients $\bar{\gamma}$, on the assumption of a constant specific heat for mercury, or $\bar{\gamma}$, on the supposition that the specific heat of mercury decreases with rise of temperature. The coefficients $\bar{\gamma}$ correspond with the value 0·00277, which was found for air and hydrogen:

	$\bar{\gamma}$	$\bar{\gamma}$
Ethylene	0·006110	0·005751
Nitrogen Monoxide	4468	4149
Water-vapour	4712	4388
Alcohol-vapour	6517	6147
CS ² -vapour	6078	5717
Ammonia	5475	5128
Ether-vapour	7400	7012
Carbon Dioxide	5300	4970

On the Mechanical Theory of Heat, see THERMODYNAMICS.

HEBRONITE. This name is proposed by v. Kobell (*J. pr. Chem.* [2], vii. 45), instead of *Montebrosite*, for the hydrated aluminium fluorophosphate occurring at Montebros (Creuse), and at Hebron in the State of Maine (U. S.) (2nd Suppl. 972). A specimen of hebronite from Auburn in Maine gave by analysis:

P ² O ⁵	Al ² O ³	Li	Na	F	H ² O	Sp. gr.
49·00	37·00	3·44	0·79	5·50	4·50 = 100·23	3·06

HELECODEA. On the microscopic appearances and behaviour with reagents of the fibres of *Helecodea* or *Billbergia Leopoldii*, and certain other plants of the Bromeliaceous order, see p. 349 of this Supplement.

HELENIN. This substance, obtained from the root of elecampane (*Inula Hellenium*), and hitherto regarded, on the authority of Gerhardt, as a distinct bitter principle, C²¹H³²O³ (iii. 138), appears from the experiments of J. Kaller (*Deut. Chem. Ges. Ber.* vi. 1506) to be a mixture of two different substances. In fact, when helenin (m. p. 72°), prepared according to Gerhardt's directions, is heated to 50° or 60° in a current of air, a body melting at 64° sublimes, and the melting point of the residue rises above 72°; the former of these substances (inula-camphor) likewise passes over when Gerhardt's helenin is distilled with water.

To obtain pure helenin, the root is exhausted with hot alcohol, and the needle-shaped crystals thereby obtained, which at first melt at 72°, are repeatedly crystallised till their melting point rises to 109°–110°. Helenin thus purified forms colourless inodorous needles, having a faint taste, nearly insoluble in water, easily soluble in alcohol, and having a composition represented by the empirical formula $C^{10}H^{16}O$. All attempts to determine the molecular formula by the preparation of bromo-, nitro-derivatives, &c., were unsuccessful.

Inula-camphor, the second constituent of crude helenin, remains in the alcoholic mother-liquors, and is difficult to obtain in the pure state. A preparation not quite pure gave, on distillation with phosphorus pentasulphide, a hydrocarbon (Gerhardt's *helenene*) having the formula of cymene, $C^{10}H^{14}$. Inula-camphor, probably $C^{10}H^{16}O$, may be obtained pure, though only in small quantity, by distilling elecampane-root with water, as above mentioned; when thus prepared, it forms prismatic needles having an odour like that of peppermint, and a burning aromatic taste.

HELIANTHUS. The chemical composition of the sunflower (*Helianthus annuus*) has been examined by G. C. Wittstein (*Arch. Pharm.* [3], viii. 289). The plant deprived of its seed loses on drying 72.25 per cent. water; the dry residue yields 1.9 per cent. ash; the air-dried seed 4.173 per cent. ash. Different sorts of the seed contain from 41 to 60 per cent. husk, and 40 to 50 per cent. kernel; the kernels yield, by extraction, from 40 to 50.5 per cent. of a fatty oil. The ash of the plant and of its seed have the following composition: *a.* Plant; *b.* Seed.

	K	Na	K ² O	Na ² O	CaO	MgO	Al ² O ³	Fe ² O ³	Cl	SO ²	P ² O ⁵	SiO ²	CO ²
<i>a.</i>	3.68	1.09	44.01	—	9.85	5.29	9.28	0.17	5.00	1.34	0.97	0.69	21.63 = 100
<i>b.</i>	—	1.40	14.48	4.71	6.81	10.96	0.23	1.43	2.16	2.00	31.85	10.81	13.07 = 100

The involucre of the sunflower (grown in Algeria) contains, according to M. Chardon (*Pharm. J. Trans.* [3], iv. 322), a transparent, colourless, resinous mass smelling like the resin of *Pinus maritima*, soluble in alcohol, and drying up, when exposed to the air in thin layers, to a hard brittle mass. This substance does not reduce Fehling's solution at the boiling heat; when slowly heated, it gives off a volatile oil, and leaves a residue resembling colophony.

HEMIALBUMIN. See PROTEIDS.

HEMIPINIC ACID, $C^{10}H^{10}O^6 = C^6H^2\{OCH^3\}_2(CO^2H)^2$, *Dimethyl-phthalic acid*. See NARCOTINE-DERIVATIVES.

HEMIPROTEIN. See PROTEIDS.

HENWOODITE. A mineral occurring in blue or bluish-green radiate spherules on the pyrolusite of the West Phoenix Mine, Cornwall. Streak white, with a bluish-green tinge. Sp. gr. 2.67. Composition:

Al ² O ³	P ² O ⁵	SiO ²	CaO	CuO	Fe ² O ³	Li ² O	Loss
18.24	48.94	1.37	0.54	7.10	2.74	17.10	3.97 = 100

(J. H. Collins, *Jahrb. f. Min.* 1876, 411).

HEPTANE, C^7H^{16} . See PARAFFINS.

HEPTIC ACID, $C^{21}H^{32}O^7 = 3C^7H^{10}O^2.H^2O$ (Domargay, *Compt. rend.* lxxxvi. 1135). An acid, formed, together with methyl-isobutylglyceric acid, $C^4H^{10}O^4$, $C^3H^7(CH^3)(C^4H^9)O^4$, and other products, by the action of alcoholic potash on ethyllic bromoisobutylacetate, $C^{10}H^{17}BrO^3 = CH^3.CO.CBr(C^4H^9).COOC^2H^5$:

To prepare these compounds, isobutylacetylacetic ether, mixed with its own weight of ice, is treated with successive small portions of bromine, care being taken that the temperature does not rise above -5°. When all the bromine has been added, the liquid is allowed to get warm, and soon becomes colourless; it is then poured in small portions into excess of strong alcoholic potash. From the liquid free from alcohol, hydrochloric acid separates an oil which, when purified and fractionally distilled, yields isocaproic (isobutylacetic) acid (see HEXOIC ACID), whilst isobutylmethylglyceric acid remains in the flask in the form of a mobile liquid, changed for the most part by heating into gummy anhydrides, a small portion, however, distilling with the aqueous vapour.

Heptic, oxyheptic, and glycollic acids may be extracted by ether from the water from which the preceding acids have been distilled, and are separated by crystallisation from water and chloroform, in which heptic acid alone is soluble. Heptic acid forms flat needles, having a satiny lustre, and melting at 151° to a colourless liquid, which boils and decomposes at a higher temperature. It is slightly soluble in cold water, colours ferric chloride pale brown, and decomposes carbonates only on heating. Its composition is represented by the formula $3C^7H^{10}O^2 + H^2O$, and that of its barium salt by $C^7H^9BaO^7$; it would seem, therefore, that the acid should have the formula $C^7H^9O^7$. Closer examination shows, however, that it is only in its less energetic reactions that the triple molecule forms a single group, whilst bromine, phosphorus pentachloride, &c. break up this group.

The study of oxyheptic acid, $C^7H^{10}O^3$, confirms this view of the composition of heptic acid. This body is easily formed by the action of alcoholic potash on ethylic dibromisobutylmethylglycerate. After crystallisation from boiling water, it forms pearly scales, melting at 185° , and having the composition $3C^7H^{10}O^3.H^2O$. Pentachloride of phosphorus converts it into a chloride, $C^7H^9OCl^2$, boiling, with decomposition, at 21° . Ammonia converts this chloride into the corresponding amide, melting and decomposing at 251° . Alcohol converts the chloride into the ether $C^7H^9O^2.OC^2H^5$, boiling at 129° – 130° , under a pressure of 10 c.m.; at 230° – 240° , with decomposition, under ordinary pressure. If ammonia be added to the solution of the chloride in a large quantity of alcohol, another amide, $C^7H^9O^2.NH^2$, is obtained on evaporation, in slender needles melting at 87° .

HEPTINE, $C^7H^{12} = CH^3.CH^2.CH^2.CH^2.CH^2.C \equiv CH$ (also, but incorrectly, named *Heptylidene* and *Enanthylidene*). A hydrocarbon, homologous with acetylene or ethine, C^2H^2 ; discovered by Limpriht, who obtained it by the action of sodium on monochlorheptylene, $C^7H^{13}Cl$, and, together with heptylene, by the action of sodium ethylate or alcoholic potash on heptylene chloride, $C^7H^{14}Cl^2$ (iii. 148); afterwards more fully examined by Rubien (1st Suppl. 696). Bruylants (*Ber.* viii. 406) prepares it by the action of potassium hydroxide on the chloride or bromide, $C^7H^{14}Cl^2$ or $C^7H^{14}Br^2$, obtained by treating α -nthaldehyde with PCl^5 or PBr^5 . It boils at 100° – 110° , and reacts with ammoniacal copper and silver solutions like acetylene.

When the bromide $C^7H^{14}Br^2$ is used for the preparation, a *brake-spirit*, $C^7H^{12}Br$, is obtained as a bye-product, in the form of a colourless pungent liquid boiling at 165° .

HEPTOIC ACIDS, $C^7H^{14}O^2 = C^6H^{13}.COOH$. The properties of normal heptoic or α -nanthylic acid, $CH^3.(CH^2)^5.COOH$, prepared by oxidation of α -nthal with nitric or chromic acid, and by oxidation of normal heptyl alcohol from heptane, have been described by Grimshaw a. Schorlemmer (2nd Suppl. 869). The same acid has been more recently studied by Mehliis (*Liebig's Annalen*, clxxxv. 358–372), who prepares it by oxidising α -nthal with nitric acid, and by Lieben a. Janacek (*ibid.* clxxxvii. 126–152), who obtain it by saponification of the cyanide $C^6H^{13}.CN$, prepared from normal hexyl alcohol.

Ammonium heptoate is easily soluble in water, alcohol, and ether, and non-crystalline. The *normal potassium salt*, $C^7H^{13}KO^2$, was obtained by Mehliis as a white silky non-crystalline mass; by Grimshaw a. Schorlemmer as a transparent jelly. The *sodium salt*, $C^7H^{13}NaO^2$, separates in needles or as a jelly, according to the rate of cooling (G. and S.) The *zinc, lead, and copper salts* have been already described (2nd Suppl. 870).

The following derivatives of normal heptoic or α -nanthylic acid are also described by Mehliis (*loc. cit.*)

Enanthonitril, or *Hexyl Cyanide*, $C^7H^{13}N = C^6H^{13}.CN$, is formed, together with α -nanthamide, by heating α -nanthylic acid with potassium thiocyanate (Letts's reaction):

Other reactions, however, go on at the same time, by which the yield of these products is greatly reduced.

Enanthonitril is a clear, colourless, neutral liquid, insoluble in water but soluble in alcohol and ether. It boils at 175° – 178° . Sp. gr. = 0.895 at 22° . It is decomposed by boiling with potash, yielding potassium α -nanthylate and ammonia. It quickly alters when exposed to the air.

Enanthamide, $C^7H^{15}NO = C^7H^{13}O.NH^2$, is formed simultaneously with the nitril; also by the action of ammonia on α -nanthylic anhydride. When pure, it is easily soluble in water, alcohol, and ether. It crystallises from water in iridescent laminae

and from alcohol in pointed needles melting at 94°–95°. By boiling with water or with alkalis it is resolved into cœnanthylic acid and ammonia.

Cœnanthylic anhydride, $(C^7H^{12}O)^2O$, obtained by distilling the acid with phosphorus pentachloride and heating the resulting cœnanthylic chloride with potassium cœnanthylate, is a thick colourless liquid having a neutral reaction, and boiling at 268°–271° without decomposition. Sp. gr. 0.932 at 21°. Reacts with ammonia to form the amide.

Isoheptoic Acid is produced by oxidation of isoheptyl alcohol (p. 1025), and may therefore be constituted according to either of the following formulæ:

The isoprimary alcohol obtained by Grimshaw from ethyl-amyl (2nd Suppl. 642) yielded by oxidation an acid which boiled at 210°–213°; and the isoheptyl alcohol which Schorlemmer obtained from diethyldimethylmethane yielded by oxidation an acid boiling at 209°–213°. The barium, calcium, and silver salts of these two acids also closely resembled one another in their properties (see table on next page). It is possible, however, that one of the acids in question may be constituted according to the first, and the other according to the second of the formulæ above given.

Diethyl-methylacetic Acid, $C(C^2H^5)^2(CH^3).CO^2H$, has been examined by E. Idanow (*Bull. Soc. Chim.* [2], xxvi. 450), who prepares it by acting on zinc-ethyl with acetyl chloride, converting the resulting diethyl-methyl-carbinyl iodide into the corresponding iodide; heating this compound for six to eight days with potassium cyanide; and digesting the crude diethyl-methyl-carbinyl cyanide at 120°–140° with fuming hydrochloric acid. The product thus obtained is distilled, mixed with caustic soda, and evaporated to dryness; the residue is treated with alcohol, which dissolves out the organic salt; and this, when decomposed by sulphuric acid, yields the free diethyl-methylacetic acid in the form of a colourless oily liquid nearly insoluble in water, and having a faint, not unpleasant odour. After drying over dehydrated sodium sulphate and phosphoric anhydride, it boils at 207°–208°, and does not solidify at –20°. Its *normal potassium salt*, $(C^2H^5)^2(CH^3)C.CO^2K$, is very soluble and non-crystalline; the *acid salt*, $C^7H^{13}KO^2.C^7H^{14}O^2$, separates on cooling in stellate groups of needles. The *lead salt* is a white precipitate, slightly soluble in cold water, the solution becoming turbid when heated.

The following table (p. 1023) exhibits a comparative view of the properties of normal heptoic acid prepared in the several ways above mentioned, also of isoheptoic acid and diethyl-dimethylacetic acid.

HEPTOIC ALDEHYDE, $C^7H^{14}O = C^6H^{13}.CHO$. *Cœnanthaldehyde*, *Cœnanthal*, *Cœnanthol*.—A polymeride of this aldehyde is formed by prolonged contact with potassium carbonate. It is a solid body which may be purified by recrystallisation, melts at 51°–52°, and when heated to 160°–170°, yields a liquid distillate which easily solidifies on cooling, but previous to that change of state, exhibits the characteristic reactions of an aldehyde with alkaline bisulphites and with silver nitrate. Similar polymeric modifications are formed in like manner with acetaldehyde and benzaldehyde (Braylants, *Ber.* viii. 414).

HEPTYL ALCOHOLS, $C^7H^{16}O$. Eleven alcohols of this group are at present known, two primary, four secondary, and five tertiary, viz.

Primary.

- (1). $CH^3.(CH^2)^5.CH^2OH$ Hexyl carbinol. (2). $(CH^3)^2CH.(CH^2)^4.CH^2OH$ Isohexyl carbinol.

Secondary.

- (3). $\begin{array}{c} CH^3 \\ CH^3(CH^2)^4 \end{array} \left\{ \begin{array}{c} CH^3 \\ CH^2OH \end{array} \right.$ Methyl-pentyl carbinol. (4). $\begin{array}{c} CH^3 \\ (CH^3)^2CH.(CH^2)^3 \end{array} \left\{ \begin{array}{c} CH^3 \\ CH^2OH \end{array} \right.$ Methyl-isopentyl carbinol.
(5). $CH^3.CH.OH.C \left\{ \begin{array}{c} C^2H^5 \\ (CH^3)^2 \end{array} \right.$ or $CH^3.CH.OH.CH \left\{ \begin{array}{c} CH^3 \\ CH(CH^3)^2 \end{array} \right.$ Methyl-katapentyl * carbinol. Methyl-pseudisopentyl carbinol.
(6). $CH(CH^3)^2.CH.OH.CH(CH^3)^2$ Di-isopropyl carbinol.

* The prefix *kata* is applied to the radicals of tertiary alcohols.

HEPTOIC ACIDS.

Normal Heptote Acid				Isocrotonic Acid		Diethyl-methylacetic Acid
	From Eucanthal (Grimshaw & Schorlemmer)	(Mehlis)	From Heptane (Grimshaw & Schorlemmer)	From Normal Heptyl Cyanide (Lied en u. Janczek)	From Ethyl-amy! (Grimshaw)	
Free Acid	Boils under 763 mm. pressure at 223°-224°. Melts and solidifies at -10°. Sp. gr. (at 0° = 0.9345 (water at. at 85° = 0.9278 4° = 1) (at 10° = 0.9208 21° = 0.9110	Boils at 219°. Solidifies at -12° to a crystalline mass which melts at -5°. Sp. gr. at 21° = 0.916	Did not solidify in a freezing mixture (pro ably from impurities). Sp. gr. (at 0° = 0.9339 at 9° = 0.9318 at 28° = 0.9233	Boils under 734 mm. at 224°. Solidifies in a freezing mixture to a crystalline mass melting at 10°. Sp. gr. (at 0° = 0.935 at 20° = 0.9198 at 40° = 0.9084	Boils at 210°-213°. Colourless oily liquid having a sour and unpleasant odour	Boils at 208°-213°
Ethylc Ether	Boils under 763 mm. at 187°-188°. Remains liquid at 16° = 0.8765	Distils at 188°-188°. Remains liquid at 14°. Sp. gr. at 21° = 0.871		Boils under 747°6 mm. at 189°. Sp. gr. 0.8879 at 0°, 0.8716 at 20°, 0.8589 at 40°		
Barium Salt	(C ¹⁷ H ³³ O ⁷)Ba. Thin laminae or broad needles. 100 c.c. of the aqueous solution saturated at 12° contain 1.774 grm. of the salt.	White iridescent laminae, melting with decomposition at 238°-239°. Dissolves in 64 pts. water at 22°; mol-erately soluble in boiling 65 per cent. alcohol	Thin laminae or broad needles. 100 c.c. of the solution saturated at 12° contain 1.774 grms of this salt	100 c.c. of the aqueous solution saturated at 8°-10°, contain 1.6473 grms of anhydrous salt	Remains as an amorphous pellicle when its solution is left to evaporate	+ 5H ² O. Separates on rapid cooling in saturated solutions; on slow cooling in dilute solutions, gives fine, all the water easily wetted by SO ² H ² . Not easily dissolved in water, but dissolves freely therein, forming supersaturated solutions
Calcium Salt	(C ¹⁷ H ³³ O ⁷) ² Ca. Thin flat needles. 100 c.c. of the solution saturated at 8°-5° contain 0.9046 grm. of the anhydrous salt		Thin flat needles. 100 c.c. of the solution saturated at 8°-5° contain 0.9046 grm. of the anhydrous salt	+ H ² O. 100 c.c. of the solution saturated at 11°-12° contain 0.9166 to 0.9268 grm. of the anhydrous salt	Separates on evaporation by heat as an amorphous film; but crystallises by spontaneous evaporation in long transparent needles or prisms	
Silver Salt	Small woolly needles	White bulky precipitate, turned brown by light. Insoluble in cold water and alcohol; slightly soluble in boiling water			Separates from hot solution as a granular or flocculent precipitate. Crystallises by spontaneous evaporation in small needles	Bulky white precipitate, slightly soluble in boiling water, and separating on cooling in tufts of small needles, turned brown by light

Tertiary.

- (7). $\left. \begin{array}{c} \text{CH}^3 \\ \text{CH}^3 \end{array} \right\} \text{COH}$
 Dimethyl-isobutyl carbinol.
- (8). $\left. \begin{array}{c} \text{CH}^3 \\ \text{CH}^3 \end{array} \right\} \text{COH}$
 Dimethyl-katabutyl carbinol.
- (9). $\left. \begin{array}{c} \text{CH}^3 \\ \text{C}^2\text{H}^5 \end{array} \right\} \text{COH}$
 Methyl-ethyl-propyl carbinol.
- (10). $\left. \begin{array}{c} \text{CH}^3 \\ \text{C}^2\text{H}^5 \end{array} \right\} \text{COH}$
 Methyl-ethyl-isopropyl carbinol.
- (11). $(\text{C}^2\text{H}^5)^3.\text{COH}$.
 Triethyl carbinol.

PRIMARY HEPTYL ALCOHOLS.

(1). **Normal Heptyl Alcohol, or Hexyl Carbinol**, is produced: α . From α -naphthaldehyde by the action of sodium-amalgam. The best way of proceeding is to dissolve the aldehyde in strong acetic acid, add liquid sodium-amalgam to the solution, saponify the resulting heptyl acetate with potash, and rectify the alcohol over sodium. Heptyl alcohol thus prepared boils at 175.5° under a pressure of 755 mm. (Schorlemmer, *Liebig's Annalen*, clxxvii. 304 *); see also *2nd Suppl.* 644.

C. J. Cross (*Chem. Soc. J.* 1877, ii. 123) also finds that normal heptyl alcohol prepared from α -naphthaldehyde boils at 175.5° (bar. 764 mm.), and has a specific gravity of 0.838 at 0° , 0.830 at 16° , 0.824 at 27° . The *chloride*, $\text{C}^7\text{H}^{15}\text{Cl}$, prepared from it by the action of hydrochloric acid, boils at 159.2° (bar. 750 mm.), and has a specific gravity = 0.881 at 16° . The *bromide*, $\text{C}^7\text{H}^{15}\text{Br}$, boils at 178.5° (bar. 750.6 mm.), and has a specific gravity of 1.133 at 16° . The *iodide*, $\text{C}^7\text{H}^{15}\text{I}$, boils at 201° (bar. 754.8 mm.), and has the specific gravity 1.346 at 16° .

The *acetate*, $\text{C}^7\text{H}^{15}.\text{C}^2\text{H}^3\text{O}_2$, prepared by heating the iodide at 180° with potassium acetate and glacial acetic acid, has a fragrant odour of pears, boils at 191.5° (bar. 758.5), and has the specific gravity 0.874 at 16° .

Heptyl α -naphthylate, $\text{C}^7\text{H}^{15}.\text{C}^7\text{H}^{13}\text{O}_2$, prepared by heating the iodide at 180° with silver α -naphthylate (normal), is a liquid having a faint but disagreeable fatty odour, and boiling at 270° – 275° (bar. 760 mm.)

Heptyl-ethyl oxide, $\text{C}^7\text{H}^{15}.\text{O}.\text{C}^2\text{H}^5$, produced by heating the iodide with an alcoholic solution of sodium ethylate, is a liquid having an odour of lemons, boiling at 166° (bar. 755 mm.), and having a specific gravity of 0.791 at 0° ; 0.790 at 16° (Cross).

(2). **Isoheptyl Alcohol, or Isohexyl Carbinol**, either

This alcohol is obtained, together with methyl-isopentyl carbinol, by passing dry chlorine into the vapour of boiling ethyl-amyl, converting the resulting mixture of primary and secondary chlorides into acetates, and saponifying the latter. The iso-primary alcohol boils at about 165° (Grimshaw, *2nd Suppl.* 642).

SECONDARY HEPTYL ALCOHOLS.

(3). **Methyl-pentyl Carbinol**, $\text{CH}^3.\text{CHOH}.\text{CH}^2.\text{CH}^3$ (T. M. Morgan, *Chem. Soc. J.* 1875, 301). This alcohol has been obtained from normal heptane (from Pennsylvanian petroleum) by the following process. The hydrocarbon (b. p. 96° – 99°), treated with chlorine in the manner above described, yielded a mixture of chlorides boiling between 144° and 156° , which, when passed in the state of vapour over quicklime heated to a temperature just short of redness, were converted into heptylenes, C^7H^{14} , boiling between 96° and 99° . On mixing these heptylenes with strong hydrochloric acid, and passing a stream of hydrogen chloride through the mixture, a heptyl chloride was formed, which boiled with decomposition between 138° and 142° , and was resolved by heating with potassium acetate and acetic acid into hydrogen chloride and a heptylene. This latter treated with hydriodic acid was converted into an iodide, from which, by decomposition with lead acetate and saponification of the resulting acetic ether, a heptyl alcohol was obtained, which boiled between 140° and

* The boiling point of the alcohol is there misprinted 155.5° .

141°, and was converted by oxidation with chromic acid mixture, first into a ketone (b. p. 137°–141°), and afterwards into a mixture of acetic and normal butyric acids: it appears therefore to be a secondary alcohol, but its constitution has not been exactly determined.

The portion of the heptylenes not attacked by cold hydrochloric acid, yielded, when heated to 120° with hydriodic acid, an iodide, partly convertible by the action of lead acetate at 120° into a heptyl acetate boiling between 170° and 174°, and yielding by saponification a heptyl alcohol boiling between 155° and 158°. This alcohol, oxidised by cold chromic acid solution, yielded a ketone boiling between 146° and 149°, and convertible by further oxidation into a mixture of acetic and normal valeric acids. Hence, according to Popoff's law (*1st Suppl.* 765), the ketone consists of methyl-pentyl ketone, and the alcohol of methyl-pentyl carbinol.

(4). **Methyl-isopentyl Carbinol**, or **Methyl-amyl Carbinol**, $\text{CH}^3\cdot\text{CHOH}\cdot(\text{CH}^2)^2\cdot\text{CH}(\text{CH}^3)^2$, is obtained, together with the isoprimary alcohol, from ethyl-amyl or dimethyl-butyl-methane, in the manner already mentioned (p. 1024). Boils at 146°–148°. Converted by oxidation into methyl-amyl ketone, $\text{CH}^3\cdot\text{CO}\cdot\text{C}^6\text{H}^{11}$ (Grimshaw).

(5). A third secondary heptyl alcohol, which may be represented by either of the formulae,

most probably by the former, is obtained in like manner from dimethyl-diethyl-methane, $\text{C}(\text{CH}^3)^2(\text{C}^2\text{H}^3)^2$. It boils at 148°–150° (Schorlemmer, *Chem. Soc. J.* 1873, 320; see also *2nd Suppl.* 643).

(6). **Di-isopropyl Carbinol**, $(\text{CH}^3)^2\text{CH}\cdot\text{CHOH}\cdot\text{CH}(\text{CH}^3)^2$, obtained by the action of nascent hydrogen on di-isopropyl ketone, is a liquid having a pleasant ethereal odour like that of peppermint, a specific gravity 0.8323 at 17°, and boiling at 130°–132°. It dissolves partially in water, easily in alcohol and ether. By gradual oxidation with chromic acid solution, it is reconverted into di-isopropyl ketone (R. Munch, *Ber.* vii. 1129).

TERTIARY HEPTYL ALCOHOLS.

(7). **Dimethyl-isobutyl Carbinol**, $\begin{array}{c} \text{H}^3\text{C} \\ \text{H}^3\text{C} \end{array} \text{C} \text{OH} \cdot \text{CH}^2 \cdot \text{CH} \begin{array}{c} \text{CH}^3 \\ \text{CH}^3 \end{array}$. Discovered by Markownikoff (*Zeitschr. f. Chem.* 1871, 268), and further examined by Pawlow (*Liebigs Annalen*, clxxiii. 192). Markownikoff prepares it from the pseudoheptylene, $(\text{CH}^3)^2=\text{C}=\text{CH}-\text{CH}=(\text{CH}^3)^2$, obtained by heating oxyisocaprolic acid with water (p. 1027). On passing gaseous hydrogen iodide through this hydrocarbon, dimethyl-isobutyl iodide, $(\text{CH}^3)^2=\text{CI}-\text{CH}^2-\text{CH}=(\text{CH}^3)^2$, is obtained as a heavy liquid, which, when treated with moist silver oxide, yields the tertiary alcohol (Markownikoff).

Pawlow obtains the same alcohol by dropping valeryl chloride (1 mol.) into cooled zinc-methyl (2 mols.), leaving the mixture to itself for 30 days, and then decomposing it with water:

The product is fractionated by distillation, and treated with acid sodium sulphite to remove admixed methyl-isobutyl ketone.

Dimethyl-isobutyl carbinol is a colourless liquid, lighter than water, nearly insoluble therein, and has a camphorous odour. When oxidised with chromic acid mixture, it is converted, according to Pawlow, into acetic and isobutyric acids; according to Markownikoff, it is resolved thereby into water and pseudoheptylene.

Dimethyl-isobutyl-carbinyl Iodide, $(\text{CH}^3)^2\cdot\text{Cl}\cdot\text{CH}^2\cdot\text{CH}(\text{CH}^3)^2$, formed from the alcohol by saturation with hydriodic acid, with addition of a little water, or from the pseudoheptylene by direct combination, is a heavy oil which is decomposed by distillation, and converted by heating with alcoholic potash into a heptylene which differs in constitution from that just mentioned, and is reconverted by silver oxide and water into dimethyl-isobutyl carbinol. The corresponding *bromide*, $\text{C}^7\text{H}^{12}\text{Br}$, formed also from pseudoheptylene by direct combination, is converted by heating with water at 100°, chiefly into pseudoheptylene, together with a small quantity of dimethyl-isobutyl carbinol.

(8). **Dimethyl-katabutyl Carbinol**, $\text{HO.C} \begin{Bmatrix} (\text{CH}^3)^2 \\ \text{C}(\text{CH}^3)_3 \end{Bmatrix}$, *Pentamethyl-ethol*, or *Pentamethylated Ethyl Alcohol*, $\text{C}(\text{CH}^3)_3\text{—C}(\text{CH}^3)_2\text{OH}$ (Butlerow, *Liebig's Annalen*, clxxvii. 176).—This alcohol is formed by the action of trimethylacetyl chloride, $\text{C}(\text{CH}^3)_3\text{COCl}$, (1 mol.) on zinc-methyl (2 mols.) A few lumps of sodium are thrown into the freshly-prepared mixture; the liquid decanted from the zinc thereby separated is heated for some hours at $60^\circ\text{--}65^\circ$ in a sealed tube; the contents, which have become crystalline, are then decomposed with water, whereupon marsh gas is given off; the mass is acidulated with hydrochloric acid; and the oil which then separates is distilled with water. By repeating these operations several times, pressing the crystals which separate, and drying them over caustic baryta, the dimethyl-katabutyl carbinol is obtained as a hydrate having the composition $2\text{C}^7\text{H}^{16}\text{O} + \text{H}^2\text{O}$. This hydrate forms long prismatic needles, slightly soluble in water, easily in alcohol and ether, has a burning taste, and a camphorous and at the same time mouldy smell. It begins to boil and give off water at 100° , and at 130° the anhydrous alcohol begins to distil. The dehydration may be also partially effected by leaving the hydrate over baryta in a closed vessel, and if this operation is performed at a temperature of 100° , the dehydration becomes complete in a few days, the anhydrous alcohol remaining as an oil.

Warm and dilute chromic acid mixture acts very slowly on the hydrate, but bromine acts readily on it, yielding a white solid, which by the further action of bromine is converted into an oily body. The solid product appears to be a mixture of $\text{C}^7\text{H}^{15}\text{Br}$ and $\text{C}^7\text{H}^{14}\text{Br}^2$.

Pentamethyl Ethol, prepared from its hydrate, as above described, forms an oil which boils at 131° . When strongly cooled, it solidifies, forming white needles which melt at $+17^\circ$; and it readily absorbs water, reproducing the hydrate, so that when moist air is passed into the upper part of a bottle containing the alcohol, glistening leaflets of the hydrate are produced, and float about in the air over the liquid.

Pentamethyl-ethyl chloride, $\text{C}^7\text{H}^{15}\text{Cl}$, or $\text{C}^2(\text{CH}^3)_3\text{Cl}$, obtained by treating the hydrate with phosphorus pentachloride, and washing the product, is a white solid, smelling like 'artificial camphor.' It separates from its alcoholic solution in white needles, which melt at 136° , and sublime rapidly at a higher temperature; but it is also volatile at the ordinary temperature, and yields up its chlorine to a warm solution of silver nitrate.

The *iodide* prepared by the action of hydriodic acid on the alcohol, smells like the chloride, is soluble in alcohol, and melts with partial decomposition at $140^\circ\text{--}142^\circ$. Alcoholic potash decomposes it, forming a heptylene which has the constitution $\text{H}^2\text{C}=\text{C} \begin{Bmatrix} \text{CH}^3 \\ \text{C}^2\text{H}^5 \\ \text{CH}(\text{CH}^3)_2 \end{Bmatrix}$ (p. 1027).

(9 and 10). **Methyl-ethyl-propyl Carbinol**, $\text{HO.C} \begin{Bmatrix} \text{CH}^3 \\ \text{C}^2\text{H}^5 \\ \text{CH}^3\text{CH}^2\text{CH}^3 \end{Bmatrix}$, and

Methyl-ethyl-isopropyl Carbinol, $\text{HO.C} \begin{Bmatrix} \text{CH}^3 \\ \text{C}^2\text{H}^5 \\ \text{CH}(\text{CH}^3)_2 \end{Bmatrix}$, are formed by the action

of a mixture of zinc-methyl and zinc-ethyl on the chlorides of butyryl and isobutyryl respectively. The former boils at $135^\circ\text{--}138^\circ$; the heptylene prepared from its iodide at $90^\circ\text{--}95^\circ$; the latter alcohol boils at $124^\circ\text{--}127^\circ$, its heptylene at $75^\circ\text{--}80^\circ$ (Pawlow, *Liebig's Annalen*, clxxxviii. 122).

(11). **Triethyl-carbinol**, $(\text{C}^2\text{H}^5)_3\text{COH}$. This alcohol, already described (2nd Suppl. 1182), is formed by the action of zinc-ethyl on propionyl chloride. It is a colourless liquid, having a specific gravity of 0.8593 at 0° , becoming viscid at 20° , and boiling at $140^\circ\text{--}142^\circ$ (Nahapetian).

HEPTYLENES, C^7H^{14} . These hydrocarbons are obtained, together with heptyl acetates, by heating the several heptyl chlorides with potassium acetate and glacial acetic acid. 1. The mixture of heptylenes thus obtained from the chlorides produced by the action of chlorine on normal heptane, boils at $98^\circ\text{--}99^\circ$ (Schorlemmer, *Chem. Soc. J.* 1873, 322); between 96° and 99° (Morgan, *ibid.* 1875, 303). Respecting the reaction of these heptylenes with hydrochloric acid, see p. 1025.

The heptylene which boils at 96° unites with water, forming a hydrate which when dropped into a vessel heated over an oil-bath is resolved into water, a resin, and a body which boils at 140° , and exhibits the properties of an unsaturated alcohol (Le Bel, *Compt. rend.* lxxxi. 967).

2. The heptylene from ethyl-amyl boils at 91° and has a sp. gr. of 0.7060 at 16°

(Grimshaw, *Chem. Soc. J.* 1873, 313); that from dimethyl-diethyl-methane boils at 90°–92° (Schorlemmer, *Chem. Soc. J.* 1873, 320).

3. A heptylene having the constitution $\text{CH}(\text{CH}_3)_2\text{CH}_2\text{C} \begin{smallmatrix} \text{CH}_3 \\ \text{CH}_2 \end{smallmatrix}$ is produced by the action of alcoholic potash at 100° on dimethyl-isobutyl-carbinyl iodide (p. 1026). It is a liquid boiling at 83°–84°, has a sp. gr. of 0.7144 at 0°, and unites directly with bromine to form a dibromide. It also unites with hydriodic acid, reproducing dimethyl-isobutyl-carbinyl iodide, $\text{C}_7\text{H}_{15}\text{I}$ (Pawlow, p. 1026).

4. A heptylene having the constitution $(\text{CH}_3)_2\text{C}=\text{CH}-\text{CH}(\text{CH}_3)_2$ is produced by heating oxyisocaproic acid (2nd Suppl. 885) with water; $\text{C}_8\text{H}_{16}\text{O}_3 = \text{C}_7\text{H}_{14} + \text{CO}_2 + \text{H}_2\text{O}$. It boils at 81°–83°; has a sp. gr. of 0.6985 at 14°; is readily acted on by bromine, with evolution of HBr, and unites with HI, producing methyl-isobutyl-carbinyl iodide (Markownikoff, *Zeitsch. f. Chem.* 1871, 268).

5. A heptylene, $\text{H}_2\text{C}=\text{C} \begin{smallmatrix} \text{CH}_3 \\ \text{C}(\text{CH}_3)_2 \end{smallmatrix}$, which may be called *methyl-katabutyl-ethylene*, is formed by the action of alcoholic potash on dimethyl-katabutyl iodide (p. 1026). It is a liquid which does not solidify in a freezing mixture, and forms a solid, translucent, very-volatile dibromide (Butlerow).

6. The heptylene obtained from methyl-ethyl-propyl carbinol boils at 90°–95°; that from methyl-ethyl-isopropyl carbinol boils at 75°–80° (Pawlow).

HEPTYLENE-THIOCARBIMIDE, $\text{C}_7\text{H}_{14}(\text{NCS})_2$. When thiocarbamide and cenanthal are dissolved together in alcohol, a few drops of hydrochloric acid then added, and the mixture warmed, *cenanthodisulphureide*, $\text{C}_7\text{H}_{14}(\text{CSN}^2\text{H}^2)_2$, is formed; and this, on addition of a few more drops of hydrochloric acid, is converted into heptylene-thiocarbimide:

Heptylene-thiocarbimide is a thick oily liquid having a very repulsive odour. Alcoholic ammonia converts it into the disulphureide (H. Schiff, *Ber.* xi. 830).

HERACLEUM. The essential oil of the cow-parsnep (*Heracleum sphondylium*) has been examined by W. Müslinger (*Liebig's Annalen*, clxxxv. 26). 126 kilos. of the fruits gathered in 1874 yielded, by distillation with steam, 1163 grams of oil (0.92 per cent.); 173.16 kilos. gathered in the autumn of 1875 yielded 1460.5 grams of oil (0.84 per cent.), the yield in each case being affected by the mode of distillation, and being most abundant when the distillation was conducted in a current of steam, and not merely from a vessel filled with water.

The examination of the oil yielded results differing in some respects from those obtained by Zincke (1st Suppl. 697; 2nd Suppl. 644), whose statements indeed are inapplicable to oil obtained from fruits either not quite ripe or only lately ripened, and appear to be true, if at all, only for fruits which have been quite ripe for a long time. The oil of *Heracleum sphondylium* agrees perfectly in composition, so far as regards its lowest boiling portions, with that of *Heracleum giganteum*; both these oils contain ethyl butyrate. The distillation-water contains chiefly—together with ammonia, but no substituted ammonias—methyl alcohol, ethyl alcohol (in smaller quantity), acetic acid and caproic acid, but no perceptible quantity of butyric acid. The oil contains also small quantities of hexyl compounds, apparently only the acetate; that of *H. giganteum* contains chiefly hexyl butyrate (2nd Suppl. 644). The oil of *H. sphondylium* does not contain octyl butyrate, but the octyl-ethers of higher fatty acids, viz. caproic, capric, and lauric; whether it contains also those of the intermediate acids, or of acids still higher in the series, is not yet determined.

The oil of 1874 yielded, after several rectifications, the following fractions:

Boiling Point . . .	110°–175°	175°–190°	190°–200°	200°–203°
Weight of Fraction . .	6.5	15.75	4.5	32 grams
Boiling Point . . .	203°–206°	206°–208°	208°–210°	210°–240°
Weight of Fraction . .	702.75	104.5	35.25	117.5 grams
Boiling Point . . .	240°–291°	Residue with crystals		
Weight of Fraction . .	42.5	28 grams		

Fraction 110°–175° consists chiefly of ethyl butyrate: it has an acid reaction, due to free acetic and butyric acids. Fraction 203°–206° consists of octyl acetate; 210°–240° of octyl acetate and caproate. Free octyl alcohol, observed by Zincke, was not found by Müslinger. Hexyl alcohol was found in the fruit gathered in 1875. The lowest fraction of the oil (80°–110°) yielded by saponification a liquid containing hexyl and octyl alcohols.

HERAPATHITE. See CINCHONA ALKALOIDS (p. 490).

HERNIARIA. The ash of *Herniaria glabra*, grown on siliceous and on dolomitic soil, has been analysed by C. G. Wittstein (*Arch. Pharm.* [3], iv. 341).

1. *From siliceous soil.* Total ash in air-dried plant, 7.132 per cent.

K ² O	Na ² O	Na(with Cl)	CaO	MgO	Al ² O ³	Fe ² O ³
24.380	4.110	1.702	14.349	6.300	1.321	1.038
Mn ² O ³	Cl	SO ³	PO ⁴	SiO ²	CO ²	
—	2.624	1.717	9.729	14.445	17.694.	

2. *From dolomitic soil.* Total ash, 6.622 per cent.

K ² O	Na ² O	Na(with Cl)	CaO	MgO	Al ² O ³	Fe ² O ³

—	1.066	1.746	8.421	6.367	21.505.	

HESPERETIC ACID, and HESPERETIN. See the next Article.

HESPERIDENE, C¹⁰H¹⁶. A terpene contained in the volatile oil of orange-peel. It boils at 178° (corr.); is oxidised by *chromic acid mixture*, chiefly to carbonic acid and water, together with acetic acid, a trace of formic acid, and a small quantity of a liquid compound, C¹⁰H¹⁶O, isomeric with camphor; no toluic or terephthalic acid is formed. With *nitric acid*, it yields oxalic acid, and an acid called hesperic acid, which, when dried over sulphuric acid, has the composition C²²H²⁰O¹⁷.2H²O; no terephthalic acid is formed in the reaction. Hesperidene is not converted into a more highly hydrogenised compound by heating with hydriodic acid and phosphorus. When *hydriodic acid gas* is passed into it, a liquid hydriodide, C¹⁰H¹⁶.HI, is formed, which does not solidify on cooling, and is decomposed by heat or by exposure to light. When the alcoholic solution of this hydriodide is heated with silver cyanide, and the product is boiled with potash, ammonia is given off, and a brown mass is formed, together with a small quantity of a non-volatile amorphous acid, soluble in ether. Hesperidene, heated with *phosphorus pentasulphide*, yields cymene (Wright, *Chem. Soc. J.* 1873, 549).

On Nitrosohesperidene, see TERPENES, NITROSO-.

HESPERIDIN, C²²H²⁶O¹². This substance, discovered by Lebreton (iii. 150), exists in many fruits of the genus *Citrus*. It is best prepared from the dry unripe bitter oranges of commerce (*Poma aurantii immaturi*). The fruit is exhausted with water, and the residue is treated with a mixture of equal parts of water and alcohol containing one per cent. of caustic potash. On adding hydrochloric acid to this solution, impure hesperidin separates out, and may be dissolved in potash-solution of 5 per cent. On adding alcohol a resinous mass is deposited, and from the clear liquid almost pure hesperidin separates on adding hydrochloric acid. To obtain it quite pure it must be boiled with water containing acetic acid.

Hesperidin crystallises from water, alcohol, or dilute acids in white microscopic needles, and acids precipitate it from an alkaline solution in globular masses. It is almost insoluble in cold water, and dissolves in 500 parts of boiling water. It dissolves more freely in alcohol and hot acetic acid, but is insoluble in ether, benzene, and volatile oils. It is not decomposed by dilute acids, and does not reduce an alkaline copper-solution. Its solution in dilute potash becomes yellow and orange-coloured on standing; and on evaporating it to dryness and treating the residue with dilute sulphuric acid, it turns red and afterwards violet. Hesperidin fused with potash yields protocatechuic acid (E. Hoffmann, *Berl. Ber.* ix. 26).

According to Paternò a. Briosi (*Gazz. chim. ital.* 1876, 169) hesperidin melts at 243°–245°, which is nearly the melting point of limonin (244°). It is decomposed by evaporation to dryness with ammonia, does not unite with picric acid, acetyl chloride, or baryta. It dissolves readily in aniline, and the solution mixed with ether deposits spherical groups of crystals the composition of which has not yet been determined.

Hesperidin is a glucoside, and is resolved by dilute acids into glucose and hesperetin, C¹⁶H¹⁴O⁶:

Hesperetin, C¹⁶H¹⁰O².O.C¹⁰H⁸O³, when purified by crystallisation from ether, forms white crystals melting at 223° and having an intensely sweet taste. It is soluble in cold water, nearly insoluble in alcohol; dissolves in alkalis, and is not

extracted from the solution by ether; gives a brown-red coloration with ferric chloride; is precipitated by lead acetate. Heated to 100° with potassium hydroxide, it is resolved almost quantitatively into hesperetic acid and phloroglucin:

Heated with water to 250° in a sealed tube, it yields a product having a strong smell of vanilla (Hoffmann).

Hesperetic acid, $\text{C}^{10}\text{H}^{10}\text{O}^4$, is likewise formed by the action of alkalis on hesperidin, and it may be purified by conversion into the soluble calcium salt, removal of colouring matters with lead acetate, reprecipitation with acetic acid, and crystallisation from alcohol. It melts at 225°, and sublimes at 223°, being partly decomposed at the same time, with formation of a body smelling like vanilla. By fusion with potash it is resolved into acetic and protocatechuic acids:

The substance called *Hesperidin* by de Vrij, and obtained from the aqueous portion of the residue left on distilling the flowers of *Citrus decumana*, is in reality the body called by Hoffmann aurantiin (p. 136). A body prepared by de Vrij from orange-peel (*Albedo cort. aurans*) is, according to Hoffmann, pure hesperidin. The following is a comparison of the composition and properties of hesperidin with those of allied glucosides.

	Composition	Melting point	Phenol reaction
Hesperidin	$\text{C}^{22}\text{H}^{26}\text{O}^{12}$	245°	brown-red
Aurantiin	$\text{C}^{23}\text{H}^{26}\text{O}^{12} + 4\text{H}^2\text{O}$	171	"
Murrayin	$\text{C}^{18}\text{H}^{22}\text{O}^{10}$	170	blue-green
Limonin	?	244	?

HESPERISIC ACID. See HESPERIDENE (p. 1028).

HESSITE, Ag^2Te . See TELLURIUM.

HETEROMORPHITE. According to Pisani (*Compt. rend.* lxxxiii. 747) this mineral occurs at Alsberg in Westphalia, mixed with brown blende, mostly massive; in cavities also, apparently in monoclinic crystals. Sp. gr. = 5.59–5.73.

S	Sb	Pb	Zn
19.90	31.20	47.86	0.60 = 99.56.

Pisani represents these numbers by the formula $\text{Pb}^7\text{Sb}^8\text{S}^{10} = 7\text{PbS}.48\text{Sb}^8\text{S}^8$. H. Rose assigned to heteromorphite the formula $\text{Pb}^8\text{Sb}^8\text{S}^8 = 2\text{PbS}.8\text{Sb}^8\text{S}^8$ (iii. 151).

HEUBACHITE. A hydrated oxide of nickel and cobalt, occurring in extremely thin soot-like deposits, or more rarely in the form of dendritic foil and fine globular aggregations, on clefts in barytes, at the St. Anton Mine in the Heubachthal, near Wittichen. Colour deep-black; the streak exhibits a semi-metallic lustre. Hardness = 2.5. Sp. gr. 3.44. It is infusible before the blow-pipe, but dissolves in hydrochloric acid with evolution of much chlorine, the solution having a deep bluish-green colour, but changing into rose-red on dilution with water. Chemical composition as follows:—

CoO	NiO	Fe^2O^3	MnO^2	H^2O
65.50	14.50	5.13	1.50	12.59 = 99.22.

Heubachite is a very recent formation, being found only on clefts in barytes, and cementing together fragments of quartz and felspar, which have arisen from the disintegration of the neighbouring vein-rocks and been carried by the action of water into the barytes clefts. This water no doubt contained the constituents of heubachite in solution in the form of carbonates. Heubachite is found occurring under exactly similar circumstances at the Eberhard mine near Alpirsbach in the Swabian Schwarzwald (Sandberger, *Jahrb. f. Min.* 1877, 299).

HEULANDITE. This mineral, from the conglomerates of a South African miclaphyre, was found by E. Cohen (*ibid.* 1875, 116) to contain:

SiO^2	AlPO^2	CaO	K^2O	Na^2O	Loss by ignition
59.53	16.82	6.95	0.32	1.42	15.30 = 100.34.

HEXACETYLMANNITE. See MANNITE.

HEXACROLEIC ACID, $C^{18}H^{24}O^6$. An acid polymeric with acrolein, produced by heating that liquid into an alcoholic solution of potash (iii. 150); found also among the products obtained by heating acrolein hydrochloride with sodium ethylate (p. 42 of this Supplement).

HEXAGONITE. A variety of tremolite (iii. 169) from Edwards, St. Lawrence County, New York, first described by Goldsmith, who placed it in the beryl group. König, however (*Jahrb. f. Min.* 1877, 202), finds that the crystals are monoclinic, and exhibit the combination $0P.\infty P$; tabular through $0P$. The prism-angle, $124^\circ 30'$, agrees closely with that of tremolite ($124^\circ 30'$). Cleavage prismatic and imperfect, parallel to $0P$. Hardness = 6.5. Sp. gr. = 2.996. Colour, white or violet. Lustrous strongly vitreous. Melts with difficulty before the blow-pipe to a white enamel. Gives the reaction of manganese with borax. Chemical composition as follows:

SiO ²	MgO	CaO	Na ² O	MnO	Al ² O ³ a. Fe ² O ³
58.20	24.14	12.20	1.90	1.37	1.40 = 99.21

HEXANE, C^6H^{14} . Normal hexane (b. p. 68° – 70°), from Pennsylvanian petroleum, is converted by the action of chlorine chiefly into two hexyl chlorides (b. p. 120° – 134°), which when saponified with alcoholic potash yield a mixture of two hexylenes (b. p. 68° – 70°) not separable by distillation. But on passing a stream of hydrochloric acid gas through a mixture of these hexylenes with strong hydrochloric acid, a hexyl chloride gradually separates, boiling, with decomposition, at 116° – 118° ; and the remaining portion of the hexylene, heated with hydrochloric acid to 130° – 140° for ten or twelve hours, yields a hexyl chloride boiling at 122° – 124° . The first-mentioned chloride (b. p. 116° – 118°) heated with acetic acid and lead acetate, is converted into an acetic ether, yielding by saponification a small quantity of the corresponding hexyl alcohol. This alcohol, however, is much more readily obtained by similar treatment of the hydriodide produced by agitating the mixture of hexylenes above mentioned with concentrated hydriodic acid. It boils at 125° – 129° , smells like peppermint-oil, and is converted by a strong solution of chromic acid into a ketone boiling at 121° – 124° , and yielding by further oxidation, acetic and probably also propionic acid.

The chloride boiling at 122° – 124° is for the most part converted by heating to 120° with lead acetate and acetic acid, into an acetic ether yielding by saponification another hexyl alcohol, which boils at 132° – 137° , and is oxidised by chromic acid, even at ordinary temperatures, to a ketone boiling at 124° – 126° , and converted by further oxidation into a mixture of acids consisting chiefly of acetic and butyric acid: hence this alcohol appears to be methyl-butyl-carbinol, $CH^3.CH(OH).C^4H^{11}$ (Morgan, *Chem. Soc. J.* 1875, 301).

These results seem to show that the action of chlorine on normal hexane gives rise only to secondary chlorides, whereas Schlorlemmer (*2nd Suppl.* 646), by chlorination of normal hexane (prepared by the action of nascent hydrogen on methyl-butyl iodide), obtained a primary as well as a secondary chloride.

When *bromine-vapour* is passed into the vapour of boiling normal hexane, in daylight, substitution-products are formed, which are partly decomposed by distillation. The portion which distils without decomposition consists of a hexyl bromide, the alcohol from which is converted by oxidation into acetic and normal butyric acids, and therefore consists of methyl-butyl-carbinol. In like manner normal heptane yields a bromide convertible into methyl-pentyl carbinol. Hence it appears that the action of bromine on normal paraffins gives rise only to secondary bromides, $CH^3.CHBr.C^4H^{11}$, or that the methyl groups which are present in these hydrocarbons, and are readily attacked by chlorine, are not touched by bromine at all.

In addition to the secondary bromides, other products are formed which, on distillation, either decompose completely, or are resolved into hydrobromic acid and non-saturated hydrocarbons, which are probably olefines (Schorlemmer, *Phil. Trans.* 1878, p. 1).

More highly brominated derivatives are obtained by heating normal hexane with bromine to higher temperatures in sealed tubes. At 130° – 140° the compound C^6Br^8 is formed, and this at a higher temperature is resolved into perbromobenzene, C^6Br^6 , and free bromine. If the heating at 130° – 140° be not too long continued, the crystalline compound, $C^6H^4Br^8$, is likewise obtained. At 120° – 125° this latter is the chief product, mixed however with $C^6H^2Br^8$ and $C^6H^0Br^8$. The brominated derivatives of hexane now known are:

(Wahl, *Ber.* x. 402, 1234).

HEXBROMACETONE, $\text{C}^3\text{Br}^6\text{O}$ (Weidel a. Grüber, *Ber.* x. 1147). This compound is formed by the action of bromine on a very dilute aqueous solution of the hydrochloride or hydrobromide of triamidophenol, $\text{C}^6\text{H}^2(\text{NH}^2)^3\text{OH}$, or on bromodichromazin, $\text{C}^{18}\text{H}^3\text{Br}^{11}\text{N}^3\text{O}^7$, the first product of the action of bromine on these salts, this body being suspended in water and bromine added to the liquid. At ordinary temperatures the reaction takes several hours to complete, but at 100° in sealed tubes it is completed in a few minutes. The hexbromacetone separates on cooling in lustrous scales, and may be purified by crystallisation from chloroform, from which it separates in large strongly-refracting monoclinic crystals. Its formation from bromodichromazin may be represented by the equation—

Hexbromacetone is absolutely insoluble in water, whether cold or boiling, but dissolves easily and without alteration in chloroform, carbon disulphide, benzene, and pure ether. It likewise dissolves in alcohol, either aqueous or absolute, but is at the same time partly decomposed, a small portion of it separating out unaltered as the alcohol evaporates, while the greater portion is converted into a red-brown oil smelling like chloroform. The ethereal and alcoholic solutions are neutral. The crystals are tasteless, but excite after some time a persistent burning sensation on the tongue. Hexbromacetone melts at 107° – 109° , in the dry state; below 100° , when immersed in water. At a higher temperature it decomposes, only a small portion subliming unchanged. When boiled with a caustic alkali it yields bromoform and an alkaline carbonate:

It is decomposed in a similar manner when heated with water to 180° . It dissolves in boiling nitric acid, and separates out unchanged on cooling; but when the two are heated together at 150° , bromopicrin is formed, with evolution of carbon dioxide:

Dry ammonia-gas passed over hexbromacetone converts it quantitatively into tri-bromacetamide and bromoform:

On adding water to a solution of hexbromacetone in methyl alcohol till the compound begins to separate, and then adding sodium-amalgam, pseudopropyl alcohol is formed:

HEXBROMODIPHENYLAMINE. See BENZENES, PHENYLAMIDO- (p. 208).

HEXBROMONAPHTHALENE, $\text{C}^{10}\text{H}^2\text{Br}^6$, is prepared by dropping bromine containing iodine, but free from chlorine, on naphthalene, which is kept cool, then heating the product with excess of bromine in a sealed tube, first to 80° – 100° (as long as hydrogen bromide escapes on opening the tube), afterwards continuing the heating for twenty or thirty hours, and raising the temperature from 50° to 60° till it finally rises to 350° – 400° . Hexbromonaphthalene is insoluble in alcohol and in ether, moderately soluble in hot benzene, toluene, chloroform, and aniline; crystallises and sublimes in slender needles; melts at 245° – 246° , resolidifies at 200° – 195° , and volatilises without decomposition (E. Gessner, *Ber.* ix. 1505).

HEXCHLORETHANE, C^2Cl^6 . This compound reacts with aluminium iodide in such a manner as to form aluminium chloride, tetrachlorethylene, and free iodine, together with an amorphous carbon compound containing iodine (Gustavson, *Ber.* ix. 169).

HEXETHYL-TRIAMIDOBENZOYL-BENZENE,

This compound is formed, together with triethyl-diamidobenzophenone, $\text{CO}[\text{C}^6\text{H}^4\text{N}(\text{C}^2\text{H}^5)^2]^2$, by heating diethyl-aniline with carbonyl chloride in a sealed tube to 120° :

The product is boiled with water to remove excess of diethylaniline, and the undissolved residue, after washing on a filter, is treated with hydrochloric acid, which

dissolves the tetrethyl-diamidobenzophenene, and leaves the hexethyl-triamidobenzoylbenzene.

The latter body crystallises from alcohol in fine crystals melting at about 170° , and belonging, according to Arzruni's measurements, to the triclinic system. They are tabular in the direction of the base c , and exhibit a right and left hemiprism m and m' , together with a tetartopyramid o , between m and c (truncation of the acute edge). Angles of the normals, $c : m' = 58^{\circ} 19'$; $c : m = 63^{\circ}$; $o : c = 61^{\circ} 55'$ (Michler, a. Gradman, *Ber.* ix. 1912).

HEXHYDROBENZENE, HEXHYDROTOLUENE, &c. See BENZENE (p. 160).

HEXINE, C^6H^{10} . *Hexylene*.—A modification of this hydrocarbon, most probably having the constitution $CH^3.C\equiv C.CH^2.CH^2.CH^3$, is obtained by heating monobromohexylene (derived from mannite hexylene) with alcoholic potash in sealed tubes, at 170° for twelve hours, about one third of the bromide then remaining undecomposed. The hydrocarbon is a colourless mobile liquid, having a pungent, disagreeable odour. It is optically inactive, and its sp. gr. is 0.7494 at 0° , and 0.7377 at 13° , referred to water at 0° . It remains liquid at -20° , and boils between 80° and 83° ; it is miscible in all proportions with alcohol, ether, chloroform, carbon bisulphide, benzene, light petroleum, and glacial acetic acid; dissolves in sulphuric acid, sp. gr. 1.83 ; does not produce a precipitate in ammoniacal solutions of silver or cuprous salts. By boiling with chromic acid mixture it is oxidised to butyric, acetic and carbonic acids. The formation of acetic and butyric acids is represented by the equation:

The carbonic acid is formed (as was proved by direct experiment) by further oxidation of a portion of the butyric acid.

Hexine dibromide, $C^6H^{10}Br^2 = CH^3.CBr\equiv CBr.CH^2.CH^2.CH^3$, produced by the direct union of bromine and hexine, is an optically inactive liquid, of a pale-yellow colour. Sp. gr. 1.6977 at 0° , 1.5543 at 100° . It does not solidify at -20° , begins to decompose at 130° . Bromine acts slowly upon it, with evolution of hydrobromic acid, and formation of a heavy yellow oil (probably a mixture of $C^6H^{10}Br^4$ and $C^{12}H^{18}Br^4$), which has a density of 2.1625 at 0° , thickens to a syrup at -15° , and begins to decompose at 160° (Hecht, *Ber.* xi. 1050).

HEXMETHYLDIAMIDOBENZOIC ACID, $C^6H^4(CH^3)^2N^2O^2(OH)^2$. See BENZOIC ACIDS (p. 274).

HEXMETHYL-ISOSTILBENE, $C^{20}H^{24} = CH^2\equiv C[C^6H^2(CH^3)^3]^2$, is formed by the action of sulphuric acid on a mixture of mesitylene and monochloraldehyde:

It is an oily liquid, boiling at a high temperature and readily attacked by bromine (E. Hepp, *Ber.* vii. 1418).

HEXMETHYL-TRIAMIDOBENZOYL BENZENE,

is prepared, like the corresponding ethyl-compound (p. 1031), by heating dimethylaniline in a sealed tube with liquid carbonyl chloride (Michler, *Ber.* ix. 716); also by passing gaseous carbonyl chloride (phosgene) into boiling dimethylaniline as long as it is absorbed (Michler a. Dupertuis, *ibid.* 1899). The compound forms monoclinic crystals having the axial ratio $a : b : c = 0.5865 : 1 : 0.7138$. Angle $ac = 125^{\circ} 18'$. Observed faces $\infty R2$, $\infty R\infty$, P , $P\infty$, 0 . Angle $P : 0P = 75^{\circ} 33'$; $P : P = 53^{\circ} 38.5'$. $\infty R2 : \infty R2 = 65^{\circ} 6.5'$ (Groth).

HEXNITRODIPHENYLAMINE, $C^{12}H^5N^7O^{12} = NH \begin{array}{l} C^6H^2(NO_2)^3 \\ C^6H^2(NO_2)^3 \end{array}$. *Dipicrylamine* (Gnehm, *Ber.* vii. 1399).—This compound is formed by heating diphenylamine, or methyl-diphenylamine, with nitric acid as long as red vapours are given off; in the latter case the methyl-group is removed by oxidation. The product is washed with water and crystallised from alcohol or glacial acetic acid, from the latter of which it separates in light yellow prisms melting at 233° – 234° . It forms salts with bases. The *barium salt*, $C^{12}H^3BaN^7O^{12}$, crystallises in rhombohedrons having a fine red colour; the *ammonium salt* forms red laminæ.

Hexnitrodiphenylamine constitutes the yellow dye known as 'aurantia' (Gnehm, *Ber.* ix. 1245, 1557).

HEXNITRO-INOSEITE. See INOSEITE.

HEXNITRO-MANNITE. See MANNITE.

HEXOIC ACIDS, $C^6H^{12}O_2 = C^5H^{11}.CO^2H$. *Caproic acids*.—Of the eight possible modifications of this acid, five are at present known, viz.:

(1). **Normal Hexoic or Caproic, Pentyl-formic, Butyl-acetic or Propyl-propionic Acid,** $CH^3.CH^2.CH^2.CH^2.CH^2.COOH$. Formed by saponification of normal pentyl cyanide, and found among the products of the butyric fermentation of sugar; produced, also, together with other acids of the fatty series, by the oxidation of albuminous substances and of fatty acids of higher atomic weight. Respecting its physical properties and those of its barium salt, calcium salt, and ethylic ether, see table (p. 378). It is oxidised by nitric acid to acetic and succinic acids (Erlenmeyer, Siegel a. Belli. *Ber.* vii. 696). Respecting its conversion into normal valeric acid, see VALERIC ACIDS.

(2). **Isohexoic or Isocaproic, Isopentyl-formic, Isobutyl-acetic, or Isopropyl-propionic Acid,** $(CH^3)^2CH.CH^2.CH^2.CO^2H$, is formed by saponification of isopentyl or amyl cyanide (from fermentation amyl alcohol); also by hydrogenation of pyroterebic acid, $C^6H^{10}O_2$, namely by heating 2.5 to 3 grams of that acid to 180° – 190° for six to eight hours with 15 grams of hydriodic acid saturated at 0° , and 0.5 gram of red phosphorus. The acid thus prepared agrees exactly in its properties with the caproic acid from amyl cyanide; boiling at 199° – 199.5° (mercury-column wholly in the vapour), and remaining liquid at -18° . Its calcium salt forms long colourless prisms having the composition $(C^6H^{11}O_2)^2Ca + 3H^2O$, and not much more soluble in hot than in cold water. 100 parts of the solution saturated at 21° contain 4.58 parts of anhydrous salt. The barium salt, $(C^6H^{11}O_2)^2Ba + H^2O$, crystallises less easily. 100 parts of its solution saturated at 17.5° contain 19.11 parts, and at 22° the same quantity of solution contains 18.4 parts of the anhydrous salt (W. C. Williams, *Ber.* vi. 1098; Fittig a. Mielck, *ibid.* vii. 649; Mielck, *Liebig's Annalen*, clxxx. 45).

(3) and (4). **Diethylacetic Acid,** $(C^2H^5)^2CH.CO^2H$, and **Methyl-isopropyl-acetic Acid,** $\begin{matrix} (CH^3)^2CH \\ | \\ CH^3 \end{matrix} CH.CO^2H$ (A. Saytzeff, *Ber.* xi. 511). *Diethylacetic acid*, obtained from the product of the action of potassium cyanide on diethyl-carbinyl iodide, is a colourless liquid boiling at 190° . It has a pleasant odour, and is only slightly soluble in water. Sp. gr. at $18^\circ = 0.9196$.

Methyl-isopropylacetic acid, obtained from the product of the action of potassium cyanide on methyl-isopropyl iodide, or amylene hydriodide, closely resembles the preceding acid. It boils at 193° , and its sp. gr. at 18° is 0.9279.

The sp. gr. of *ethylic di-ethylacetate* (b. p. 151°) is 0.8686 at 18° , and that of *ethylic methylpropylacetate* (b. p. 153°) is 0.867 at the same temperature.

The silver salts of these acids are deposited from hot saturated solution, on cooling, in needle-shaped crystals. *Silver di-ethylacetate* is less soluble in cold, but more soluble in hot water than its isomeride.

The barium salts are easily soluble in water and in alcohol. *Barium di-ethylacetate* is crystalline, but *barium methylpropylacetate* forms a thick syrup which dries to a gum-like mass. The solubility of *calcium di-ethylacetate* in water increases with the temperature. *Calcium methylpropylacetate* is less soluble in hot than in cold water. The lead salts are very soft and easily fusible.

The zinc salts dissolve in alcohol; they are more soluble in cold than in hot water. Ferric chloride forms a yellow precipitate with ammonium di-ethylacetate, insoluble in excess, whilst with the methylpropylacetate it produces a flesh-coloured precipitate soluble in excess of the reagent.

(5). **Ethyl-dimethylacetic Acid,** $(CH^3)^2(C^2H^5)C.COOH$ (Wischnegradsky, *Liebig's Annalen*, clxxiv. 56; clxxviii. 103). To prepare this acid, ethyldimethyl-carbinyl iodide is heated with potassio-mercuric cyanide, and the product repeatedly fractionated by distillation, whereby the corresponding cyanide is obtained as a liquid, which boils at 128° – 130° , and solidifies in a mixture of snow and salt; and on heating this cyanide with fuming hydrochloric acid in sealed tubes for six days to 100° , and then for two days to 120° , ethyl-dimethylacetic acid is obtained as a liquid which may be purified by drying and rectification. The same acid is produced by oxidation of methyl-katapentyl ketone, $CH^3.CO.C(CH^3)^2(C^2H^5)$, and ethyl-katapentyl ketone.

Ethyl-dimethylacetic acid boils at 184° – 186° , and solidifies in a freezing mixture to a laminated mass of slender needles melting at -14° . It is insoluble in water and has a faint fatty odour. Both in the free state and in its salts it resembles trimethyl-

acetic acid. The *neutral sodium salt* is very soluble and does not crystallise; its solution, mixed with the free acid, deposits a sparingly soluble *acid salt* in stellate groups of needles. The *barium salt*, $(C^6H^{11}O_2)^2Ba.5H_2O$, crystallises from an aqueous solution saturated at the boiling heat, as a laminar mass; from a less concentrated solution in large transparent plates. It effloresces in dry air, dissolves easily in water, but is not easily wetted thereby. It shows a tendency to the formation of super-saturated solutions, and gives off a portion of its acid when its solution is boiled. The *calcium salt* forms shining slender needles very soluble in water. The *magnesium salt* is a gummy mass. The *zinc salt*, $(C^6H^{11}O_2)^2Zn$, separates as a white bulky precipitate on mixing slightly warmed solutions of the sodium salt and zinc sulphate, and crystallises from solution in a large quantity of water by slow evaporation in transparent prisms. Its aqueous solution, saturated at ordinary temperatures (containing 2.4 per cent. of anhydrous salt at 16°), becomes turbid when heated, and gradually stiffens, in consequence of the separation of a translucent basic salt, but becomes clear and fluid again on cooling. The *silver salt*, $C^6H^{11}O_2Ag$, is a white precipitate more soluble in hot than in cold water, and separates on cooling in slender needles having a silky lustre; blackens slightly when exposed to light. The *lead salt* is a bulky precipitate which, when boiled with water and a small quantity of the free acid, yields slender needles of an *acid salt*. The *copper salt* is obtained by precipitation as a greenish-blue powder; it dissolves in alcohol, and crystallises therefrom in dark green very efflorescent prisms.

A *trichlorhexoic acid*, $C^6H^3Cl^3O_2$, the exact constitution of which is not known, is produced by the action of fuming nitric acid on hexyl chlorid (p. 1036), the two liquids being kept in contact for twenty-four hours, and the product poured into about eight times its volume of water. The trichlorhexoic acid then separates as an oil which solidifies after a time, and may be crystallised from a mixture of benzene and petroleum. The acid melts at 64° , and is almost insoluble in water, but very soluble in alcohol, ether, and benzene, less so in petroleum. It is strongly acted upon by zinc-dust in presence of water, and if hydrochloric acid be then gradually added, the surface of the zinc in the course of a few days becomes covered with long, flat needles of a *hexylenic acid*, $C^6H^{10}O_2$, metameric with hydrosorbic, pyroterebic, and ethylcrotonic acids. It melts at 39° , is almost insoluble in water, but very soluble in alcohol, ether, benzene, and petroleum (Pinmer, *Ber. x.* 1052).

HEXYL ALCOHOLS, $C^6H^{11}O = C^6H^{12}.OH$. Of these alcohols, seventeen are possible and eight are known, viz., two primary, three secondary, and three tertiary.

PRIMARY. (1). **Normal Hexyl Alcohol**, $CH^3.CH^2.CH^2.CH^2.CH^2.OH$, is obtained: 1. From the essential oil of *Heracleum giganteum*, which contains hexyl butyrate (*2nd Suppl.* 646). 2. Together with the secondary alcohol, methyl-butyl carbinol, by treating normal hexane, from American petroleum, with chlorine, converting the resulting mixture of primary and secondary hexyl chlorides into the corresponding acetates, and distilling the latter with potash. The mixed alcohols thus obtained cannot be separated by distillation, but they yield by oxidation the corresponding products, viz., normal caproic acid and methyl-butyl ketone (Schlorlemmer, *2nd Suppl.* 645). 3. By the action of sodium-amalgam on normal caproic aldehyde (Lieben a. Rossi, *Liebig's Annalen*, cxxxiii. 178; Lieben a. Janacek, clxxxvii. 126). The following are the properties of the hexyl alcohol prepared by the last process, and of some of its ethers, as determined by Lieben a. Janacek (compare *2nd Suppl.* 646).

	Alcohol	Iodide	Bromide	Chloride	Ethylate
Boiling point . .	157.2° at 740.8 mm.	181.4° at 746.8 mm.	155.5° at 743.8 mm.	133°	$134^\circ-137^\circ$
Specific Gravity	0.833 at 0°	1.4607 at 0°	1.1935 at 0°		
	0.8204 at 20°	1.4363 „ 20°	1.1725 „ 20°		
	0.8107 „ 40°	1.4178 „ 40°	1.1561 „ 40°		

(2). **Isohexyl Alcohol**, $CH(CH^3)^2.CH^2.CH^2.CH^2.OH$. This is probably the constitution of the hexyl alcohol which Faget obtained from fusel oil. B. p. about 150° . Converted by oxidation into ordinary caproic acid.

SECONDARY HEXYL ALCOHOLS.

(1). **Methyl-butyl Carbinol**, $\text{CH}^3\text{.CHOH.}(\text{CH}^2)^3\text{CH}^3$. *β -Hexyl-Alcohol*.—This is the alcohol whose iodide is produced by boiling mannite or dulseite with highly concentrated hydriodic acid (iii. 154). It is likewise obtained, as already described (p. 1034), from the mixture of chlorides produced by the action of chlorine on petroleum hexane. The alcohol boils at 137° , the iodide at 167.5° (bar. at 752 mm.); the chloride at about 120° (Wanklyn a. Erlenmeyer); 122° – 124° (Morgan).

Methyl-butyl Thiocyanate, or *β -Hexyl Thiocyanate*, $\text{S} \left\{ \begin{smallmatrix} \text{CN} \\ \beta\text{C}^6\text{H}_{13} \end{smallmatrix} \right.$, is prepared by boiling equal parts of the alcohol and potassium thiocyanate—the latter dissolved in the smallest possible quantity of ethyl alcohol—for an hour on the water-bath in a reflux-apparatus. When precipitated by water, dried, and rectified, it forms a liquid boiling at 206° – 207.5° and having an alliaceous odour.

The corresponding *Isothiocyanate*, or *β -Hexyl-thiocarbimide*, $\text{N} \left\{ \begin{smallmatrix} \text{CS} \\ \beta\text{C}^6\text{H}_{13} \end{smallmatrix} \right.$, is obtained by boiling β -hexylamine with ethyl alcohol and carbon disulphide, evaporating off the alcohol, and heating the residue with solution of mercuric chloride. It is a colourless liquid, having a specific gravity = 0.9253, and boiling at 197° – 198° . When heated with strong sulphuric acid it is reconverted into the amine, with separation of sulphur (Uppenkamp, *Ber.* viii. 55).

5. **Methyl-katabutyl Carbinol**, or **Pinacolyl Alcohol**, $\text{CH}^3\text{.CHOH.C}(\text{CH}^3)^3$, formed by the action of nascent hydrogen on the corresponding ketone (pinacolin), is a liquid having a density of 0.8347 at 0° , boiling at 120.5° , and solidifying at low temperatures to a mass of long silky needles, which melts at $+4^\circ$. By oxidation with chromic acid mixture it yields the ketone. See further 2nd *Suppl.* 982, where this alcohol is formulated as a tertiary alcohol, dimethyl-isopropyl carbinol, $(\text{CH}^3)^2\text{COH—CH}(\text{CH}^3)^2$.

Ethyl-propyl Carbinol, $\text{C}^2\text{H}^5\text{.CHOH.C}^3\text{H}^7$, is formed: α . By the action of nascent hydrogen (water and sodium-amalgam) on ethyl-propyl ketone, prepared by distilling a mixture of butyrate and propionate of calcium (O. Völker, *Ber.* viii. 1019). β . The corresponding *iodide* is obtained by the action of hydriodic acid on diethylic ethyl oxide or ethyl-propyl-carbinyl ethylate (p. 746):

The iodide is then converted into the *acetate*, and the acetate by saponification into the alcohol (Lieben, *Liebig's Annalen*, cxxxviii. 1).

Ethyl-propyl ketone is a liquid boiling between 134.5° and 135.5° (corr.), and having a density of 0.8335 at 0° . By oxidation with chromic acid it is converted into propionic acid (Völker).

TERTIARY HEXYL ALCOHOLS.

Dimethyl-propyl, and **Dimethyl-isopropyl Carbinol**, $\left\{ \begin{smallmatrix} (\text{CH}^3)^2 \\ \text{C}^3\text{H}^7 \end{smallmatrix} \right\} \text{C.OH}$, are obtained by treating butyryl and isobutyryl chloride respectively with zinc-methyl, and decomposing the resulting chloride with water:

and

Dimethyl-propyl Carbinol, obtained in this manner by Butlerow, is a liquid resembling tertiary butyl alcohol; rather viscid; lighter than water, and somewhat soluble therein; having an alcoholic and camphorous odour; boiling at 115° (Butlerow), between 122.5° and 123.5° (Jawein, *Liebig's Annalen*, cxiv. 254); not solidifying in a freezing mixture; oxidised by chromic acid mixture to acetic and propionic acid. The corresponding *chloride* is a liquid having a disagreeable odour, and boiling, with decomposition, at 100° .

Dimethyl-isopropyl Carbinol, $\left\{ \begin{smallmatrix} (\text{CH}^3)^2 \\ \text{CH}(\text{CH}^3)^2 \end{smallmatrix} \right\} \text{COH}$, after drying with baryta, distils over for the most part at 112° – 113° (Prianchnikow); at 117° (Pawlow). It is a colourless liquid, having a camphorous odour, perceptibly soluble in water, becoming viscid at -20° , and solidifying at -35° , in long, slender, white needles having a

silky lustre. Sp. gr. = 0.8364 at 0°. Its expansion-coefficient for one degree between 0° and 50° is 0.00099. By oxidation with chromic acid mixture it yields acetone and a small quantity of acetic acid (Prianehnikow, *Bull. Soc. Chim.* [2], xvi. 303).

Friedel a. Silva regard pinacolyl alcohol (2nd *Suppl.* 982) as dimethyl-isopropyl carbinol; but pinacolyl alcohol boils at 120.5°, and melts at +4°, whereas dimethyl-isopropyl carbinol boils at 112°–113°, and does not solidify till cooled to –35°. Moreover the mode of formation of pinacolyl alcohol, by the action of nascent hydrogen on pinacolin, which is a ketonic body, and its reversion into that body by oxidation, show that it has the constitution of a secondary alcohol.

Methyl-diethyl Carbinol, $(\text{CH}_3)(\text{C}^2\text{H}_5)_2\text{COH}$, is obtained by acting on acetyl chloride, CH_3COCl , with zinc-ethyl, and treating the product with water. It boils at 120°, and yields by oxidation nothing but acetic acid. The corresponding chloride boils at 110°.

On the relations between the constitution of Hexyl Alcohols and their Boiling points, see *HEAT* (p. 945).

HEXYL CHLORAL, $\text{C}^6\text{H}^1\text{Cl}^3\text{O} = \text{C}^6\text{H}^1\text{Cl}^3\text{CHO}$ (Pinner, *Ber.* f. 1052). This compound is separated by fractional distillation from the higher-boiling portions of crude butyl chloral (p. 50). It has a peculiar odour; distils undecomposed between 212° and 214°; is insoluble in water, but dissolves in alcohol, ether, and benzene. It does not unite either with water or with hydrocyanic acid. Its physiological action appears to be but feeble. Alkalis decompose it, producing a formate, a chloride, and a dichloropentylene:

Nitric acid converts it into a trichlorocaproic acid (p. 1034).

HEXYLENES, C^6H^{12} . On the hexylènes obtained by decomposition of the hexyl chlorides from normal hexane, see Morgan (p. 1030).

Mannite Hexylene.—This modification is obtained by the action of potash on the hexyl iodide prepared by boiling mannite with concentrated hydriodic acid (iii. 152). It boils at 68°–70°. When oxidised by chromic acid it yields normal butyric, acetic, and carbonic acids; and the same products are obtained by oxidation of the corresponding glycol. This result shows that mannite hexylene has the constitution of propyl-methyl-ethylene:

The carbonic acid is produced by further oxidation of a portion of the butyric acid (O. Hecht, *Ber.* xi. 1152, 1154).

The **dibromide**, $\text{C}^6\text{H}^{12}\text{Br}_2$, prepared by dropping bromine into this hexylene cooled to –17°, and purified by washing, first with dilute aqueous potash, then with water, and subsequent drying and rectification (whereby it is partly decomposed), is a faintly yellow liquid, having a density of 1.6058 at 0°, and 1.5809 at 19°, and boiling at 195°–197° under a pressure of 739.5 mm.

Monobromhexylene, $\text{C}^6\text{H}^{11}\text{Br}$, prepared by dropping bromine into the dibromide warmed in a vessel with ascending condenser, pouring the resulting distillate into water, and collecting the oil which sinks to the bottom, is, after drying and rectification, a slightly yellowish liquid having a density of 1.2205 at 0°, and 1.2025 at 15°, and boiling at 140°–141° (Hecht u. Strauss, *Liebig's Annalen*, clxxii. 62).

A hexylene boiling at 66°–68°, doubtless identical with that just described, is obtained as a secondary product in the preparation of diethyl ethyl oxide, or methyl-propyl ethylate (p. 746).

Hexylenes from Tertiary Hexyl Alcohols (Jawein, *Liebig's Annalen*, cxcv. 253–264). 1. **Tetramethyl-ethylene**, $\text{C}^2(\text{CH}^3)_4$.—This compound is formed by the action of alcoholic potash on dimethyl-isopropyl-carbinyl iodide, in the manner shown by the following equation:

It boils at 73°, and unites directly with bromine, forming a solid **dibromide**, $\text{C}^2\text{H}^{12}\text{Br}_2$, which dissolves in alcohol, ether, and benzene. The ethereal solution deposits it in long needles, which melt with partial decomposition at 140°. The **hydriodide**, $\text{C}^6\text{H}^{12}\text{HI}$, boils at 140° and solidifies at –22°. The **hydrochloride**, $\text{C}^6\text{H}^{12}\text{HCl}$, boils

at 112° and solidifies at -14° . Tetramethyl-ethylene is completely oxidised to acetone by a 10 per cent. solution of chromic acid. Sulphuric acid at 60° converts it into a dihexylene, $C^{12}H^{24}$.

Pinacone, $C^6H^{14}O^2$, is probably tetramethyl-ethylene glycol, $C^2(CH^3)^4H^2O^2$, inasmuch as pinacone-hydrate is formed by the action of baryta on the ether obtained by treating tetramethyl-ethylene bromide with silver nitrate (Pawlow, *Ber.* xi. 513).

2. Ethyl-dimethyl-ethylene, $C^2H(CH^3)^2(C^2H^3)$. Of this hexylene there are two modifications, viz.: *a.* Having its two methyl-groups attached to the same carbon-atoms. *β.* Having these groups attached to different carbon-atoms.

a. This hexylene is obtained by the action of alcoholic potash on dimethyl-propyl-carbinyliodide:

When purified by boiling with sodium and subsequent fractional distillation, it boils at $65^{\circ}5'$, and has a density of 0.702 at 0° , 0.687 at 19° . Coefficient of expansion for $1^{\circ} = 0.0017$. By oxidation with chromic acid it yields chiefly acetic acid, propionic acid, and acetone.

β. The ethyl-dimethyl-ethylene, having its two methyl-groups attached to different carbon-atoms, is obtained in like manner from ethyl-dimethyl-carbinyliodide:

This hydrocarbon, first obtained by Tschakowsky, and further examined by Jawein, boils at 69.5° – 71° (bar. 760 mm, at 0°), and has a density of 0.712 at 0° ; 0.698 at 19° . Expansion-coefficient for $1^{\circ} = 0.00116$. By oxidation with chromic acid, which takes place very slowly—a portion of the hydrocarbon remaining unaltered even after several months contact with the acid at ordinary temperatures—it is converted into acetic acid, together with a small quantity of a ketone, probably methyl-ethyl ketone.

Polymerisation of Hexylenes.—The polymerisation of the two ethyl-dimethyl-ethylenes above described is best effected by agitating 1 volume of the hexylene with somewhat more than 2 volumes of a mixture of SO^4H^2 (2 pts.) and water (1 pt.), the vessel being immersed in a mixture of ice and salt, and the agitation continued till the whole of the hexylene is dissolved. On subsequently exposing the solution to the temperature of the air, an oily layer separated on the surface, of smaller volume than the hexylene employed. This layer was separated, purified by boiling with metallic sodium, and subjected to fractional distillation. The vapour-densities of the condensation-products thus obtained showed them to be dihexylenes.

α-Ethyl-dimethyl-ethylene, $C^2H^3.CH=C(CH^3)^2$, yielded a dihexylene boiling at 193° – 197° , and having a density of 0.795 at 0° , 0.786 at 19° . Expansion-coefficient for $1^{\circ} = 0.00065$.

β-Ethyl-dimethyl-ethylene, $\text{CH}^3.CH=C(CH^3)(C^2H^3)$, yielded a dihexylene boiling at 196° – 199° , and having a density of 0.809 at 0° ; 0.798 at 19° . Expansion-coefficient for $1^{\circ} = 0.00080$.

HIPPURIC ACID, $C^9H^9NO^3 = \text{CH}^2.NH(C^7H^5O).COOH$. Some of the derivatives of this acid have been examined by W. Conrad (*J. pr. Chem.* [2], xv. 241–260). He finds that *ethyl hippurate* melts at 60.5° , and distils, with partial decomposition, at temperatures above 180° ; according to Stenhouse (iii. 162), it melts at 44° . *Methyl hippurate* melts at 80.5° , and cannot be distilled at all (melts at 60° , and decomposes at 250° , Stenhouse). *Hippuramide*, $\text{CH}^2.NH(C^7H^5O).CONH^2$, formed by the action of ammonia on either of these ethers, melts at 183° . It is a weak base, and forms a crystalline hydrochloride.

The conversion of hippuric into *benzoglycollic acid*, $\text{CH}^2.O(C^7H^5O).COOH$, is most readily effected by the action of alkaline hypochlorites. Benzoglycollic acid forms crystals melting at almost exactly the same temperature as benzoic acid (120°).

Nitrohippuric acid, $C^9H^8(NO^2)NO^3$, melts at 162° (at about 150° , Stenhouse), and is resolved by heating with fuming hydrochloric acid into glycocine and metanitrobenzoic acid (m. p. 141° – 142°).

Amidohippuric acid, $C^9H^8(NH^2)NO^3$, melts at 194° , forms crystallisable salts, and is resolved by heating with hydrochloric acid into glycocine and metamidobenzoic acid (m. p. 165°).

Diazohippuric acid, $C^9H^7N^3O^3$, formed by the action of nitrous acid on amido-hippuric acid, is converted by boiling with dilute sulphuric acid into *oxyhippuric acid*, $C^9H^8NO^4$ (Griess, 1st *Suppl.* 701); and this when boiled with strong hydrochloric acid is resolved into glycocine and meta-oxybenzoic acid melting at 197° (Conrad).

Formation of Hippuric Acid in the Animal Organism. A. Hoffmann (*Chem. Centr.* 1877, 409) finds from experiments on himself that, after the introduction of benzoic acid into the human organism, neither benzoic nor hippuric acid occurs in the perspiration. In one experiment in which benzoic acid alone was taken, that acid was found in the urine in addition to hippuric acid; whereas in another experiment, in which benzoic acid and glycocine were taken, no benzoic acid, but only hippuric acid, was detected in the urine, indicating that a combination of the benzoic acid with the glycocine had taken place. Experiments were also made by passing through fresh kidney removed from the body, defibrinated blood containing alanine, ($C^3H^7N(O)^2$)—in addition to benzoic acid—whereby an acid (perhaps alanine-hippuric acid) was obtained in large white needles very different in appearance from the crystals of hippuric acid. Two experiments in which leucine and benzoic acid were passed together through the kidney, showed that either these bodies do not combine in the kidneys, or that the compound formed is decomposed by the treatment required for its separation. Further experiments showed that no hippuric acid was formed, when blood containing benzoic acid and glycocine and having its oxygen replaced by carbon oxide, was passed through a kidney removed from the body; but that the kidney, after blood saturated with carbon oxide had been passed through it for two hours, still possessed the power of forming hippuric acid from benzoic acid and glycocine when they were dissolved in oxygenated blood. A kidney removed from the body, and poisoned by passing blood containing quinine through it, showed little or no power of inducing the formation of hippuric acid from benzoic acid and glycocine: hence it would appear that this power is essentially a function of the living kidney.

The urine of dogs fed exclusively on animal food is generally supposed to contain little or no hippuric acid; according to Salkowski, however (*Ber.* xi. 500), such urine always contains a small quantity of that acid, not exceeding 1 part of hippuric acid to 129 parts of urea.

Formation of Hippuric acid in Herbivora.—Experiments on the formation of this acid in the organisms of herbivorous animals fed on different kinds of fodder have been made by Weiske, Kellner a. Wienand (*Chem. Centr.* 1876, 522, 536). The copious excretion of hippuric acid observed in animals fed on meadow-hay is due to the herbs mixed with the grass. Addition of common salt to the hay produces in the sheep a slight increase in the excretion of hippuric acid; addition of wheat, beans, or potatoes to the hay is followed by diminished excretion of hippuric acid. Benzoic acid added to the hay is almost wholly converted into hippuric acid; when, on the other hand, salicylic acid is mixed with the fodder, only a portion of it appears as salicyluric acid, the rest being excreted unaltered. When sheep were fed with peas, wheat, or oats, or with pea-straw, bean-straw, or unpeeled potatoes, no hippuric acid was found in their urine, but feeding with wheat or oat-straw was followed by excretion of that acid. When the animals were fed with meadow hay which had been treated with dilute sulphuric acid (1.25 per cent.), no hippuric acid was formed, and feeding with hay which had been macerated in potash-ley (1.25 per cent.), led to a diminished excretion of hippuric acid. Hofmeister, on the other hand, found that the treatment of hay with boiling water did not interfere with its property of forming hippuric acid, but that this property was completely destroyed by alcohol and by boiling potash solution of the strength of 3 per cent. (2nd *Suppl.* 647). Hence it may be inferred that the substance which gives rise to the formation of hippuric acid in the bodies of herbivorous animals is insoluble in boiling water, partially soluble in solution of potash (1.25 per cent.), and completely soluble in dilute sulphuric acid (1.25 per cent.), as well as in boiling alcohol and in boiling potash-solution of 3 per cent. Benzoic acid, added to the beans or potatoes with which the animals were fed, passed off unaltered, even when glycocine was likewise added to the fodder, but hippuric acid, added to beans or potatoes, was decomposed in the body.

For the numerical results obtained in these experiments, see *Zeitschrift f. Biologie*, xii. 241–265; *Chem. Soc. J.* 1877, i. 217–220.

HOMILITE. A mineral occurring, together with erdmannite and molinophane, at Stockoe near Brevig in Norway. The crystals, according to Nordenskiöld's measurement, are monoclinic, but the angle of the inclined axes differs so little from 90° that they may be very nearly represented as orthorhombic, with the axial ratio $a : b : c = 0.6362 : 1 : 0.6473$. Observed faces $\infty P \infty$, ∞P , ∞P_2 , P , P_2 , $\bar{P} \infty$. Angle $\infty P : \infty P_2 = 160^\circ 48'$; $\infty P_2 : \infty \bar{P}_2 = 103^\circ 41'$; $\infty \bar{P}_2 : \bar{P} \infty = 115^\circ 18'$; $\bar{P} \infty : P =$

116° (nearly); ∞ P : P = 139° 39'. Colour black to brownish-black. Lustre resinous to vitreous. Slightly transparent in thin fragments. Hardness = 5.5. Sp. gr. = 3.28. Fuses easily to a black glass; is readily decomposed by hydrochloric acid. Its analysis gave:

SiO ²	B ² O ³	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	Na ² O	K ² O	Loss on ignition
31.875	18.085	1.50	2.145	16.25	27.275	0.52	1.09	0.41	0.41 = 99.56.

These numbers (after deducting Fe²O³) lead to the formula (CaO.FeO)³.2SiO².B²O³.

Homilite is very nearly related, both in form and in composition, to datolite (Pajkull, *Jahrb. f. Min.* 1877, 536).

HOMOCINCHONINE,* C¹⁰H²²N²O. This, according to Hess (*Ber.* x. 2157), is the true composition of the base called 'cinchonine' by Skraup (p. 481).

HOMOCREATINE, C⁵H¹¹N³O². This base is formed by prolonged contact of the concentrated aqueous solutions of α -methylamidopropionic acid and cyanamide, in presence of a small quantity of ammonia:

It crystallises in monoclinic prisms, sparingly soluble in cold water and alcohol, easily in hot water, and turning brown at 150°–160°. The hydrochloride crystallises in needles, and forms double salts with zinc chloride and platinic chloride, the latter crystallising in octohedrons. Homocreatine, boiled with baryta-water, is decomposed, with evolution of ammonia (Lindenberg, *J. pr. Chem.* [2], xii. 244).

HONEY. The following analyses of honey from various sources are given by J. C. Brown (*Analyst*, 1878, 257):

	England	Wales	Nor-mandy	Ger-many	Greece	Lisbon	Jamaica	Cali-fornia	Mexico
Water expelled at 100° . . .	19.10	16.40	15.50	19.11	19.80	18.80	19.46	17.90	18.47
Water expelled at a high temperature and loss . . .	7.60	6.56	4.95	11.00	7.80	6.66	7.58	8.13	10.03
Lævulose . . .	36.60	37.20	36.88	33.14	40.00	37.26	33.19	37.85	35.96
Dextrose . . .	36.55	39.70	42.50	36.58	32.20	34.94	35.21	36.01	35.47
Cane-sugar (?) } doubt-ful						1.20	2.20		
Wax, pollen, and insoluble matter	trace	trace	trace	trace	0.05	1.00	2.10	trace	trace
Mineral matter .	0.15	0.14	0.17	0.17	0.15	0.14	0.26	0.11	0.07

The sp. gr. of honey is about 1.41, but varies slightly with the proportion of water.

A solution of 16.26 grams of crude honey in 100 c.c. water produces a deviation of –3.2° to –5° at 60° F. Greek honey produces a deviation of –5.5°. The same weight of dried honey in 100 c.c. water gives a deviation of about –4.8°.

* On page 489 of this Supplement, line 7, for 'Homocinchonine' read 'Homocinchonidine.'

Erlenmeyer a. von Planta (*N. Rep. Pharm.* xxiii. 610) also found the amount of water in six samples of honey to vary between 17.5 and 19.5 per cent. Senegal honey contained 25.6 per cent. water, and the amount of phosphoric acid (reckoned on the dry substance) was found to vary between 0.0123 and 0.883. The nectar of the flowers of *Fritillaria imperialis* contains nitrogen but no albumin, also phosphoric acid and a large quantity of gummy substances.

HOPS. *Composition.*—The following results, obtained from various samples of hops by extraction with ether, have been published by E. Porter (*Analyst*, 1878, 176). F denotes fine, M medium, L low quality:

	Moisture per cent.	Oil, resin, and bitter principle per cent.		Moisture per cent.	Oil, resin, and bitter principle per cent.
1. Worcester, F	4.02	14.98	7. Bavaria, M	9.97	13.08
2. Spalt, F	6.96	14.08	8. American, M	7.87	12.63
3. East Kent, F	6.15	13.60	9. Sussex, L	8.55	9.95
4. Worcester, M	8.10	13.35	10. Sussex, L	9.87	9.23
5. Kent, M	8.20	13.27	11. Poperingho, L	10.25	9.25
6. Sussex, M	7.05	11.75	12. Worcester, L	9.20	8.80

The ethereal residues from Nos. 1, 2, and 3 had a golden tint, all the others were of a greenish hue.

The tannin in hops is said to vary between 2 and 4.5 per cent. A good percentage of tannin doubtless increases the value of hops, as the tannin precipitates the mucilaginous matter in the beer; but the value depends mainly on the oil, resin, &c.

On the Tannin and Bitter Principle of Hops, see O. Etti (*Dingl. pol. J.* cxxviii. 491; *Chem. Soc. Jour.* xxxiv. 797).

Basic Constituents of Hops (Griessmayer, *Dingl. pol. J.* cxxii. 67).—When the aqueous extract of hops is distilled with lime or calcined magnesia, and the distillate, which smells of ammonia and trimethylamine, is neutralised with hydrochloric acid, evaporated to dryness on the water-bath, and exhausted with alcohol, ammonium chloride remains undissolved, and the alcoholic solution, when evaporated, yields crystals of trimethylamine hydrochloride. On rendering the mother-liquor alkaline with potash, shaking it up with ether, and leaving the ethereal solution at the ordinary temperature in a shallow dish till the ether and the still remaining trimethylamine have evaporated, an alkaline residue is obtained which smells like conine, has a cooling not bitter taste, and exhibits the following reactions: *Platinic chloride*, after addition of alcohol and ether, produces a greenish-yellow precipitate; *strong sulphuric acid* and *potassium chromate*, a violet coloration; *fuming nitric acid*, a yellow colour, soon becoming green and dark-green, bluish on the edges, and the liquid after a short time becoming colourless; *tannic acid*, *silver nitrate*, *Fehling's solution*, and *mercuric chloride*, white precipitates; *auric chloride*, a white precipitate soluble in hydrochloric acid; *iodine solution* a brown, *bromine* a sulphur-yellow precipitate changing to orange and brown; *phosphotungstic acid*, a bulky yellow precipitate; *Nessler's reagent* produces the ammonia reaction. These reactions are attributed by Griessmayer to the presence of an alkaloid, which he designates as lupuline.

Sulphuring of Hops.—According to A. Schwarz (*Jahresh. f. Chem.* 1875, 1133), American hops are always sulphured. The effect of this operation is to alter the character of the essential oil, and render the resin less soluble in the beer-wort. Hence American beers deposit but very little resin during fermentation, and clarify but slowly.

To detect sulphurous acid in hops, Griessmayer (*Dingl. pol. J.* cxiix. 227) adds to the filtered hop-extract a small quantity of sodium-amalgam and a few drops of hydrochloric acid, whereby, if the hops have been sulphured, hydrogen sulphide will be produced, and may be detected by lead-paper. According to A. Vogel (*ibid.* cxxv. 283), this reaction, which may likewise be produced with zinc and hydrochloric acid, may lead to erroneous conclusions regarding the sulphuration of hops, inasmuch as a large number of dried vegetable matters, for example mallow-leaves, lime-leaves, and many kinds of lupin, also give off hydrogen sulphide when treated with zinc and hydrochloric acid. With sodium-amalgam, however, these vegetable substances exhibit this reaction in a lower degree only, so that for the purpose in question it is more likely to give correct indications than zinc and hydrochloric acid.

HORBACHITE. According to A. Knop (*Jahrbuch f. Min.* 1873, 520), the nickel ore occurring in irregular lumps in the serpentinised gneiss of Horbach in the Schwarzwald, and hitherto regarded as a nickeliferous magnetic pyrites, has partly

the composition $4\text{Fe}^2\text{S}^3\cdot\text{Ni}^2\text{S}^3$. That other ores of this locality have a different composition is shown by an older analysis by Rammelsberg (*Pogg. Ann.* cxxi. 360); analysis 6 below. Analyses 1–4 are by G. Wagner. The values required by Knop's formula are given under 5. Sp. gr. of horbachite = 4.43; of magnetic pyrites from Horbach = 4.7.

	1	2	3	4	5	6
S	45.87	46.07	45.68	—	45.9	40.03
Fe. . . .	41.94	41.62	42.15	42.13	42.8	55.96
Ni. . . .	11.52	12.44	—	—	11.2	3.86
Total . . .	99.33	100.13	—	—	99.9	99.85

HORN. The composition of horn has been studied by H. Weiske (*Landw. Versuchs-Stationen*, xx. 35). A piece of stag's horn placed in water at the ordinary temperature imparts to the liquid after some time a deep red colour. The horn of the roebuck, however, does not produce this coloration. On evaporating the liquid to dryness, the colour changes to brown, and the dried residue, after treatment with common salt and acetic acid, shows under the microscope numerous crystals of hæmin. The dried extract contains 79.9 per cent. organic matter and 20.1 ash.

The ash consists of—

K ² O	Na ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	CO ²	SO ²	Cl
5.80	16.24	27.77	2.18	2.25	7.78	27.40	3.37	8.33 = 101.12.

To determine the amount of extractable matter, the powdered horn was digested first in ether and afterwards in water, and the extracts filtered, evaporated to dryness, and weighed. The following results were thus obtained:—

	Stag's horn	Roebuck's horn
Extracted by ether	0.26 per cent.	0.19 per cent.
„ water	5.76 „	4.55 „

The residue left, after extracting the ether and water, consisted of—

	Stag's horn	Roebuck's horn
Organic matter	36.32 per cent.	36.78 per cent.
Ash	63.68 „	63.22 „

The ash (allowing for carbonic acid expelled by burning) showed the following composition:—

	Stag's horn	Roebuck's horn
Lime	51.52 per cent.	51.51 per cent.
Magnesia	1.32 „	1.28 „
Phosphoric acid	39.31 „	39.08 „
Carbonic acid	4.60 „	4.88 „

The spongy part of the stag's horn amounts to about 24.94 per cent. of the total. An analysis of each part gave the following results:—

	Spongy part	Hard part
Extracted by ether	0.37 per cent.	0.11 per cent.
„ water	6.88 „	3.51 „

The residue left, after extraction with ether and water, consisted of—

	Spongy part	Hard part
Organic matter	49.89 per cent.	42.31 per cent.
Ash	50.11 „	57.69 „

The ash contained—

Lime	51.53 per cent.	51.58 per cent.
Magnesia	1.32 „	1.33 „
Phosphoric acid	39.43 „	39.79 „
Carbonic acid	4.25 „	4.03 „

For this examination a piece was cut from the middle of a large horn, whereas for the former analyses a complete antler was taken in each case, which may account for the difference in the percentage of ash. The proportion of ash to organic matter varies within certain limits, but the ash itself always shows very nearly the same composition.

HORNBLENDE and AUGITE. G. vom Rath (*Pogg. Ann. Ergänzungsbd.* vi. 229: *Jahrb. f. Min.* 1876, 201) has analysed crystals of hornblende and augite formed by sublimation in blocks ejected from Vesuvius. No. 1 is yellow augite from a block thrown out in the eruption of 1872; 2 and 3 are from a block ejected in 1822; they exhibit all the characters of simultaneous formation, and are intergrown in parallel position. 4 is from a block of leucitophyr, probably of prehistoric origin.

	1. Yellow Augite.	2. Green Augite.	3. Brown Hornblende.	4. Black Hornblende.						
	SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	Na ² O	Loss by ignition	Sp. gr.	
1.	53.2	1.5	—	2.3	23.4	19.3	—	0.2 =	99.9	3.233
2.	48.4	5.6	—	9.5	22.9	13.7	—	0.3 =	100.4	3.252
3.	41.7	8.3	14.7	—	14.5	16.5	4.1	0.2* =	100	3.112
4.	41.7	9.5	17.7	—	13.4	13.4	4.0	0.3* =	100	3.235

Vom Rath has also analysed augite (1) and hornblende (2) intimately intergrown in an augitic labrador-rock on Monte Monzoni (*Zeitschr. geol. Ges.* xxvii. 361).

	SiO ²	Al ² O ³	CaO	MgO	FeO	Sp. gr.
(1).	49.60	4.16	21.86	14.42	9.82 = 99.86	3.317
(2).	49.25	5.83	13.03	13.13	16.97 = 98.21*	3.112

The following are analyses by E. E. Schmid (*Jahrb. f. Min.* 1876, 566) of hornblendes from the diorite of the Ehrenberg near Ilmenau.

	SiO ²	TiO ²	Al ² O ³	Fe ² O ³	CaO	MgO	H ² O	
	43.26	0.82	12.18	16.44	10.93	10.84	2.57 =	97.04
	46.35	0.45	19.07	13.10	10.39	4.19	2.53 =	96.08
	43.19	0.55	19.55	19.03	11.69	2.62	3.18 =	99.81
	46.07	trace	19.89	12.93	10.69	5.00	1.53 =	96.11

Specimens of the diorite rich in hornblende—so-called 'Hornblende slate'—gave by analysis:

SiO ²	TiO ²	Al ² O ³	Fe ² O ³	CaO	MgO	Na ² O	K ² O	H ² O	
47.26	0.30	14.26	16.40	9.98	7.87	3.00		0.37	= 99.44
52.37	0.59	15.55	14.60	8.21	5.12	2.45	0.13	1.07	= 100.09

Varieties of Hornblende.—Actinolite. 1. From the bed of magnetic iron ore of the Tilley-Foster mine, Putnam County, New York (Breidenbaugh, *Sill. Am. J.* [3], vi. 26). 2. Radio-fibrous actinolite, from Felling, near Giffl in Austria. Sp. gr. = 2.99 (Egger, *Min. Mitth.* 1874, 243). 3. Fibrous dichromatic actinolite from Le Selle Monzoni. Sp. gr. = 2.71 (John, *Verh. geol. Reichsanst.* 1875, 304).

	SiO ²	Al ² O ³	FeO ³	FeO	MnO	MgO	CaO	K ² O	Na ² O	H ² O	
57.44	1.13	—	4.33	0.15	22.59	13.29	trace	trace	1.52	=	100.45

53.82	1.28	1.53	11.54	trace	18.07	10.33	0.30	1.01	2.12	=	100

Anthophyllite. 1. From Star Rock, Concord, Delaware County, Pennsylvania. Sp. gr. 3.20 (A. R. Leeds, *Sill. Am. J.* [3], vi. 25). 2. From the spherical masses of mica at Hermannschlag in Moravia (Brezina, *Min. Mitth.* 1874, 247).

SiO ²	Al ² O ³	Fe ² O ³	FeO	MnO	MgO	CaO	K ² O	Na ² O	H ² O	
55.12	0.55	—	8.20	0.33	31.18	0.75	1.01	1.55	2.21	= 100.90
57.39	2.04	0.42	6.53	—	29.08	0.69	—	—	2.56	= 98.71

Grammatite or Tremolite. Grammatite from the granular limestone of Chejnow, near Tabor, has been analysed by F. Farsky (*Verh. geol. Reichsanst.* 1876, 208):

SiO ²	Al ² O ³	FeO	MgO	CaO	
59.74	1.85	0.34	25.47	12.71	= 100.11.

On the variety called *Hexagonite*, see p. 1030.

A hornblendic mineral, occurring—together with quartz, eudialyte, nephelin, and small quantities of magnetic iron ore, orthoclase and plagioclase—as a constituent of a rock in the island of Kikkertarsursurok, West Greenland, has been analysed by J. V. Janovsky (*Ber.* vi. 1230, 1453):

SiO ²	Al ² O ³	Fe ² O ³	FeO	MnO	MgO	CaO	K ² O	Na ² O	P ² O ⁵	Loss by ignition
44.24	1.80	4.27	20.46	2.21	3.11	8.84	1.31	0.83	2.33	1.35 = 99.75
44.06		not determined				8.78		not determined		
44.27	not det.		29.33	—	3.03	8.82		"	"	

* Determined by difference.

A thin section showed the presence of enclosed apatite, so that the phosphoric acid, together with 2·76 CaO, must be reckoned as apatite, and there will then remain only 6·08 CaO to be reckoned as silicate.

Hornblende rocks. *Hornblende-Andesite*.—A specimen of this rock, from Tusnad on the Budös, near Kronstadt in Transylvania, has been analysed, together with some of its constituent minerals, by K. John (*Verh. geol. Reichsanst.* 1874, 242).

1. Analysis of the rock. 2. Felspar corresponding, after deduction of 4·73 per cent. orthoclase, with the formula Ab^2An . 3. Mica containing traces of MnO and P^2O^5 . Sp. gr. = 2·967.

	SiO^2	Al^2O^3	Fe^2O^3	FeO	CaO	MgO	K^2O	Na^2O	Loss by ignition	
1.	60·64	21·08	3·98	—	5·42	0·94	1·72	4·26	2·81	= 100·85
2.	59·79	25·33	trace	—	8·34	0·75	0·79	5·09	0·84	= 100·93
3.	40·77	15·59	26·55	0·78	0·86	5·89	5·07	1·40	2·32	= 99·23

An *augite-hornblende andesite* from Toplitia near György, St. Miklos, in Transylvania, likewise analysed by John (*ibid.* 120), was found to contain:

	SiO^2	Al^2O^3	Fe^2O^3	CaO	MgO	K^2O	Na^2O	Loss by ignition	
	61·09	20·31	5·10	6·09	0·81	2·01	3·87	0·97	= 100·25.

Sp. gr. = 2·6545. The rock contains in a dense ground-mass, small felspars consisting partly of plagioclase, partly of sanidin. The microscope shows a large proportion of augite, somewhat less of hornblende and of magnetic iron ore.

C. Doelter (*Jahrb. f. Min.* 1874, 645) gives the following analysis of a compact hornblende andesite from the Pietra Mori in the mining district of Transylvania.

	SiO^2	Al^2O^3	Fe^2O^3	FeO	CaO	MgO	K^2O	Na^2O	Loss by ignition	
	58·02	22·30	4·91	1·22	7·31	2·01	1·36	2·78	1·01	= 100·92.

The rock consists of a pitch-black ground-mass in which are imbedded shining crystals of felspar and needles of hornblende.

Hornblende-Gabbro.—This rock is found on the St. Louis river, near Duluth in Minnesota. In outward appearance it closely resembles a coarse-grained hypersthene rock, and consists of predominating plagioclase (labradorite), a little orthoclase, hornblende, diallagite, pegmatite, titanite, apatite, and extremely small quantities of copper-pyrites and epidote, together with a little quartz. The hornblende is mostly of a light or dark-green colour, owing to the presence of viridite; sometimes it is of a brown colour, and penetrated by fine dark parallel systems of lines, but a remarkable feature of this brown variety is the entire absence of 'cleavage-cracks.' The apatite occurs in thick short crystals. An analysis of this rock showed it to have the following composition, viz.:—

	SiO^2	Al^2O^3	Fe^2O^3	FeO	CaO	MgO	K^2O	Na^2O	H^2O	
	49·15	21·90	6·60	4·54	8·22	3·03	1·61	3·83	1·92	= 100·80

(Streng a. Kloos, *Jahrb. f. Min.* 1877, 113).

HORN-MERCURY. See MERCURY CHLORIDES.

HORNSTONE PORPHYRY. See PORPHYRY.

HORSE-RADISH. The fresh root of this plant, analysed by A. Hilger (*Landw. Vers. Stat.* xxii. 75), was found to contain 85·45 per cent. water. Dried at 100° it yielded 11·5 per cent. of ash, containing 72·52 per cent. of matter soluble in water containing carbonic acid, and 27·48 insoluble, including 2·5 per cent. carbon and 2·7 sand.

The soluble portion contained:—

CaO	1·19
MgO	0·89
Na^2O	0·28
K^2O	51·41
HCl	2·19
SO^3	22·73
CO^2	15·31

The insoluble part contained:—

CaO	35·38
MgO	11·92
P^2O^5	41·92
Fe^2O^3	3·47
CO^2	7·23
SiO^2	5·39

HUANTAJAYITE. A mineral found by Raymondi at Huantajaya in Southern Peru. It crystallises in cubes and octohedrons having the composition $\text{AgCl} \cdot 20\text{NaCl}$ (F. Sandberger, *Jahrb. f. Min.* 1874, 174).

HUMIC ACID and HUMUS. P. Thénard (*Compt. rend.* lxxxiii. 375) prepares pure humic acid by dissolving the crude product in potash, precipitating with

a slight excess of hydrochloric or sulphuric acid, washing the precipitate well with water, and keeping the spongy mass for forty-eight hours at a temperature of -12° to -15° . As the mass thaws, the humic acid separates in the form of a dense precipitate which is to be further washed on a filter. Preparations thus obtained leave when burnt only very small quantities of potassium salt, and exhibit on analysis a constant composition agreeing with the formula $C^{22}H^{10}O^{10}$.

According to E. Simon (*L'Institut*, 1875, 133) pure humic acid absorbs nitrogen, which then enters into chemical combination with the other constituents. Melsens finds that the faculty of absorbing nitrogen is not possessed by all humous substances. Experiments by Simon, which, however, seem to require confirmation, point to the conclusion that humic acid renders ordinary calcium phosphate soluble, by replacing part of its phosphoric acid. Humic acid and ammonium humate do not diffuse through parchment-paper, whereas the compounds of humic acid with phosphoric acid diffuse through it readily.

Diazoxybenzoic acid, $C^7H^4N^2O^3$, a black substance obtained by the action of nascent hydrogen on dinitrobenzoic acid, appears to be related to the group of humous substances (p. 277).

HUMITE. *Chondrodite*.—Several varieties of this mineral are found on the vein of magnetic iron ore in the Tilley-Foster mine, Putnam County, New York. It occurs in small grains disseminated through the entire vein, and accumulates especially in the neighbourhood of clefts and in the clefts themselves; it is then imbedded in distinctly crystalline forms in white serpentine. The following are analyses: *a*, of a brown variety; *sp. gr.* = 3.2; *b*, of a red variety.

	SiO ²	MgO	FeO	F	Total (?)	O (?)	Total (?)
<i>a.</i>	35.42	54.22	5.72	9.00	104.36	3.79	100.57
<i>b.</i>	35.42	51.88	9.73	5.38	102.41	2.26	100.15

A grey-brown variety, probably a variety of the red, likewise occurs, but the quantity of it that could be isolated was not sufficient for analysis (E. S. Breidenbaugh, *Sill. Am. J.* [3], vi. 212).

According to E. S. Dana (*ibid.*, x. 89) the chondrodite crystals of the Tilley-Foster mine may be referred to the three types distinguished by Seacchi and vom Rath (i. 930; 2nd Suppl. 650). Two analyses, by G. W. Hawes, of very pure material belonging to the second type gave:

SiO ²	MgO	FeO	Al ² O ³	F	Sp. gr.
34.10	53.17	7.17	0.48	4.14 = 99.06	3.22
34.05	53.72	7.28	0.41	3.88 = 99.34	

From the optical examination of the crystals (*ibid.* xi. 139), Dana concludes that those of the second type—if not the others—belong, not to the rhombic, but to the monoclinic system. According to C. Klein, the Vesuvian crystals of chondrodite are also monoclinic. Des Cloizaux (*Phil. Mag.* [5], ii. 286), likewise on optical grounds, refers the crystals of the first type to the rhombic, those of the second and third types to the monoclinic system, and proposes to designate the first type as *humite*, the second as *chondrodite*, and the third as *clinohumite*.

On the relations of form and composition of Humite and Lievrite, see Websky (*Jahrb. f. Min.* 1876, 660; *Jahresb. f. Chem.* 1876, 1252; *Chem. Soc. J.* 1877, ii. 117).

Chondrodite from the dolomitic limestone of Svinetic, between Vodnan and Bavorov in the Bohemian forest, is described by R. Helmhaecker (*Min. Mittheil.* 1873, 274).

HYZENIC ACID, $C^{25}H^{50}O^2$ (1st Suppl. 701). This acid appears to be contained, together with oleic acid, in the mixture of fatty acids produced by saponification of the compound ethers obtained from the grease of sheep's wool (Schulze a. Alrich, *Ber.* vii. 570).

HYDANTOIC ACID, $C^8H^6N^2O^3$ (1st Suppl. 702). *Glycoluric acid*.—This acid is formed: 1. By the action of cyanic acid on glycocine:

An aqueous solution of glycocine sulphate is heated with a slight excess of potassium cyanate, and the liquid, mixed with a considerable quantity of alcohol, is filtered from potassium sulphate, and left to evaporate (Wislicenus, *Liebig's Annalen*, clxv. 103).

(¹) Including the O replaced by F. (²) Equivalent to the fluorine. (³) After deduction of the corresponding oxygen.

2. By heating glycocine with urea (Heintz, 1st *Suppl.* 702):

The formation of hydantoic acid in this manner is facilitated by boiling the two substances together with baryta-water; if an excess of urea is used, the conversion of the glycocine is almost complete (Baumann a. Hoppe-Seyler, *Ber.* vii. 34).

Methyl-hydantoic acid, $\text{C}^4\text{H}^5\text{N}^2\text{O}^3 = \text{C}^3\text{H}^3(\text{CH}^3)\text{N}^2\text{O}^3$. This acid, first obtained by O. Schultzen (*Ber.* v. 578) from the urine of a dog whose food was mixed with sarcosine (methyl-glycocine), has lately been produced synthetically from that compound by Baumann a. Hoppe-Seyler (*loc. cit.*) in the same manner as hydantoic acid from glycocine, viz.

1. By the action of cyanic acid:

An aqueous solution of sarcosine is digested with potassium cyanate and an equal quantity of ammonium sulphate for two days in an air-bath at about 40° ; the liquid is then concentrated and freed from potassium sulphate by addition of alcohol; the alcoholic solution is supersaturated with baryta-water and evaporated; the baryta, after dilution of the liquid with water, is precipitated by carbonic acid; and the filtered liquid, after concentration to a small bulk, is mixed with a large quantity of strong alcohol. The resulting precipitate of barium methyl-hydantoate, which becomes quite hard after a while, is washed with alcohol, dissolved in water, and cautiously decomposed by dilute sulphuric acid; the solution is repeatedly shaken up with ether containing alcohol; the united extracts are distilled in a water-bath; and the remaining solution is evaporated over sulphuric acid.

2. By boiling sarcosine and urea with excess of baryta-water, or digesting the same mixture for two days at 40° :

Methyl-hydantoic acid crystallises in transparent plates, not very soluble in cold water or alcohol, but easily soluble in the same liquids when warm; also in ether containing water or alcohol; it has a strong acid reaction and pleasant sour taste. The dilute solution may be heated to boiling without decomposition; but when the concentrated solution is heated on the water-bath, the methyl-hydantoic acid is resolved into water and methyl-hydantoin or glycolyl-methyl-carbamide:

The crystals of methyl-hydantoic acid may, however, be heated to 100° for a short time without decomposition, but if the heating be continued, water is gradually given off. In this respect the crystallised acid is more stable than its concentrated solution. The same conversion of methyl-hydantoic acid into methyl-hydantoin takes place when the acid is boiled with carbonate of lead or carbonate of barium to form the corresponding methyl-hydantoates, only traces of the acid passing into solution. The barium and copper salts of methyl-hydantoic acid do not crystallise (Baumann a. Hoppe-Seyler).

When moist silver oxide is added to a hot aqueous solution of methyl-hydantoic acid, and the liquid is filtered, the filtrate on cooling deposits a pulp of white shining laminae, the amount of silver in which agrees with the composition of silver-methyl-hydantoin, $\text{C}^4\text{H}^3\text{AgN}^2\text{O}^2$.

Methyl-hydantoic acid heated in a sealed tube at 130° – 140° with a hot-saturated solution of barium hydrate, yields ammonia, carbon dioxide, and a non-crystallisable syrup which has a sweetish taste, an acid reaction, and dissolves cupric hydrate abundantly. It forms a zinc salt which crystallises in large four-sided prisms, and contains a quantity of zinc indicating a mixture of methyldi- and methyltri-glycolamic acids (E. Salkowski, *Ber.* vii. 116).

The formation of methyl-hydantoic acid in the animal organism after the introduction of sarcosine does not appear to depend on the presence of previously formed urea. When sarcosine and urea were dissolved in a 2 per cent. solution of sodium bicarbonate, or in a 1 per cent. solution of the normal carbonate, and the liquid was

kept for two days at a temperature of about 40° (blood-heat), no formation of methyl-hydantoic acid took place; neither was hydantoic acid obtained by proceeding in a similar manner with urea and glycocine. Moreover, hydantoic acid was not produced by passing carbon dioxide into a cooled solution of glycocine in strong aqueous ammonia, or when dry carbon dioxide and ammonia gases (which together form ammonium carbamate) were passed into a capacious flask containing glycocine hydrochloride. These experiments show that carbamic acid, when brought in contact with glycocine or sarcosine, has no tendency to unite with it and eliminate water; and they rather tend to support the view which ascribes the formation of urea or of methyl-hydantoic acid in the animal organism, to the direct addition of a cyanic acid residue to ammonia or sarcosine respectively (Baumann).

Methyl-hydantoin, formed as above-mentioned by dehydration of methyl-hydantoic acid, may also be prepared by melting sarcosine with urea:

It melts, according to Salkowski, at 154°–155°, *i.e.* at a temperature about 10° higher than the melting point originally assigned to it by Neubauer (*1st Suppl.* 703). Baumann found that a preparation which at first melted at 145°–146°, acquired, after repeated crystallisation, the higher melting point determined by Salkowski.

Phenyl-hydantoin: $\text{C}_6\text{H}_5\text{N}^2\text{O}^2 = \text{CO} \begin{array}{c} \text{N}(\text{C}_6\text{H}_5)-\text{CH}_2 \\ | \\ \text{NH}-\text{CO} \end{array}$, is obtained by fusing a

mixture of urea and phenyl-glycocine at 155°. It forms a crystalline mass of slender needles; melts at 191°; dissolves in water and in alcohol after prolonged boiling; but is only slightly soluble in cold alcohol, and still less in cold water. It dissolves in alkalis and is reprecipitated by acids. The ammoniacal solution gives white precipitates with silver nitrate and barium chloride, and does not dissolve freshly precipitated mercuric oxide or silver oxide. The aqueous solution does not exhibit the reactions just mentioned (P. Schwebel, *Ber.* x. 2045).

Tolyl-hydantoic acid, $\begin{array}{c} \text{CH}_2\text{N}(\text{C}_6\text{H}_5)\text{CO.NH}^2 \\ | \\ \text{COOH} \end{array}$, and **Tolyl-hydantoin**,

$\begin{array}{c} \text{CH}_2\text{N}(\text{C}_6\text{H}_5) \\ | \\ \text{CO}-\text{NH} \end{array} \text{CO}$, are obtained, together with other compounds, when urea and paratolyl-glycocine are fused together in equal numbers of molecules. Hot alcohol extracts from the fused product tolyl-hydantoic acid and monotolyl-carbamide, leaving tolyl-hydantoin and a crystalline substance (m. p. 174°) undissolved. On evaporating the alcoholic extract, tolyl-hydantoic acid is obtained as a white powder, insoluble in cold water and cold alcohol, and sparingly soluble in boiling alcohol. It decomposes at 200° without melting, and is precipitated from its solution in ammonia by acids. On adding hydrochloric acid to the mother-liquor from the tolyl-hydantoic acid, the monotolyl-carbamide separates out, and is deposited from a solution in hot alcohol in silvery needles, which are insoluble in water and ammonia, and are not attacked by acids or alkalis. It decomposes at 200°. Tolyl-hydantoin crystallises in colourless needles (m. p. 210°) insoluble in cold water, but soluble in alcohol (Schwebel, *Ber.* xi. 1128).

Thiohydantoin or **Glycolyl-thiocarbamide**, $\text{C}_2\text{H}_4\text{N}^2\text{OS} = \text{CS} \begin{array}{c} \text{NH}-\text{CH}_2 \\ | \\ \text{NH}-\text{CO} \end{array}$

(p. 400). This compound, unlike thiocarbamide itself (p. 395), does not unite directly with chlorine and bromine, but is decomposed by chlorine in presence of water at low temperatures in the manner represented by the equation:

Bromine acts in a similar manner at ordinary temperatures, but the carbamide at the moment of its formation is resolved into CO^2 and NH_3 . Thiohydantoin, heated to 130°–140° with *ethyl bromide* and *alcohol*, yields, not an additive compound, but ethylic thiocarbimidacetate:

x. 1965).—This compound is formed when chloroacetanilide and thiocarbamide dissolved in alcohol are heated together on the water-bath. Thiohydantoïn then crystallises out first, and from the filtrate water throws down phenyl-thiohydantoïn. The same compound is formed when phenyl-thiocarbamide and ethyl-monochloroacetate are heated together in alcoholic solution, and the product, after being made alkaline, is treated as above.

Phenyl-thiohydantoïn forms small shining slightly yellow needles or prisms, which melt at 108° ; it is nearly insoluble in water, sparingly soluble in cold, easily in hot alcohol, also in ether and in acids. With caustic soda-solution it forms a very soluble and easily crystallisable sodium-salt.

Tolyl-thiohydantoïn, $\text{CS} \begin{array}{l} \text{NH} \text{---} \text{CH}^2 \\ \diagdown \quad \diagup \\ \text{N}(\text{C}^7\text{H}_7) \text{---} \text{CO} \end{array}$, prepared as above from chloracetoluide and thiocarbamide, crystallises in small shining needles or prisms melting at 183° (Meyer, *loc. cit.*)

A second phenyl-thiohydantoïn appears to be formed on fusing together phenyl-glycoccine and thiocarbamide.

Thiohydantoic or Thiocarbamidacetic acid, $\text{C}^6\text{H}_5\text{N}^2\text{O}^2\text{S}$, is formed by the action of thiocarbamide, aided by heat, on a solution of the monochloroacetate of sodium or ammonium. It is a white crystalline powder composed of microscopic four or six-sided tablets and prisms, soluble in hot water, also in alkalis and acids, otherwise insoluble. It decomposes when heated. The aqueous solution is quite neutral, and does not form a precipitate with silver nitrate; but, on adding a small quantity of ammonia, yellowish flocks are thrown down. The acid appears to form salts, but they are very unstable. By alkalis, even sodium carbonate, and by acids, it is easily converted into thiohydantoïn, and the same change takes place partially even on recrystallising the acid (R. Maly, *Wien Akad. Ber.* [2 Abth.], lxxv. 712).

HYDRASTIS. The root of *Hydrastis canadensis* is known to contain two alkaloids, viz. hydrastine and berberine (iii. 178; *2nd Suppl.* 655), and a third has been detected in it by A. E. Hale (*Pharm. J. Trans.* [3], iv. 105). When ammonia is added to the aqueous extract of the plant from which the hydrochloride of berberine has already been separated, as long as a precipitate is thereby produced, and the solution of this precipitate in alcohol is left to evaporate, a crystalline substance is obtained apparently coloured by a yellow powder. If, on the other hand, the aqueous filtrate be merely neutralised with ammonia, and the resulting precipitate dissolved in alcohol, the solution thus obtained deposits colourless crystals of hydrastine. On further addition of ammonia, however, a new precipitate is formed of darker colour than berberine, neutral in alcoholic solution to test-paper, and differing from berberine also in other respects, being less soluble in cold nitric acid, and forming a solution which turns red when warmed. Its solution in hydrochloric acid does not deposit crystals till it is nearly cold. The new alkaloid dissolves in hot sulphuric acid with red-brown colour; it is more soluble than berberine in water and in cold potash solution, and forms, with a solution of mercuric iodide in potassium iodide, a slight yellow precipitate.

The existence of this third alkaloid in *Hydrastis canadensis* is confirmed by J. C. Burt (*Pharm. J. Trans.* [3], vi. 467), who finds that the sulphate crystallises in radial tufts of prismatic needles, and that the hydrochloride gives precipitates of yellow to reddish- or brownish-yellow colour.

The alkaloid, distilled in alkaline solution with potassium permanganate, gives off traces of ammonia, and therefore probably contains nitrogen.

HYDRATES. Church (*Chem. News*, xxxiii. 203) proposes to classify hydrates occurring in nature according to the conditions under which their combined water is retained: viz. (1) *Cryohydrates*, which retain their water only at low temperatures. (2) *Hygrohydrates*, which retain it only in a moist atmosphere. (3) *Barohydrates*, which give it up under diminished pressure. An example of a hygro- and barohydrate is afforded by the native uranio-calcic phosphate called *autunite*, which in the natural state is a hygrohydrate containing 10 mol. H^2O , 5 of which it gives off in dry air, being thereby converted into a barohydrate, which gives off 3 mol. H^2O in a vacuum.

On *Cryohydrates*, see also pp. 1005–1009.

On the Heat of Formation of Crystalline Hydrates, see HUNT, p. 982; on their Decomposition by Heat, pp. 1012–1016.

Reactions.—(1). With Sulphur. Phenyl-hydrazine heated with sulphur is decomposed—the action beginning at 80°—with formation of nitrogen, ammonia, hydrogen sulphide, benzene, aniline, thiophenol, phenyl sulphide, and phenyl disulphide.

The action of sulphur upon the hydrazines appears, therefore, for the most part, to be limited to their nitrogenous group, and is similar to the decomposition of these bases by oxidation in their alkaline solution. The formation of aniline, which occurs to the extent of 30 per cent. of the phenyl-hydrazine employed, is explained by the equation:

that of benzene and the various sulphur-derivatives enumerated resembles the ordinary decomposition of the diazo-compounds.

2. With Halogens. Aqueous emulsions of phenyl-hydrazine, treated alternately with *iodine* and potassium hydrate, take up iodine and form diazo-benzenimide, aniline, and iodanilines, probably according to the equation:

Chlorine and bromine act much more energetically, decomposing the nitrogen-group of the hydrazine.

3. With Nitrous acid and Nitrites. When gaseous nitrogen trioxide is passed into an aqueous or ethereal solution of phenyl-hydrazine, diazobenzenimide, $\text{C}^6\text{H}^5.\text{N}^2$, is formed, together with dark-coloured resinous products:

When, on the other hand, sodium nitrite is added in excess to a cooled solution of phenyl-hydrazine hydrochloride in 10 pts. of water, the liquid becomes turbid, gives off the intoxicating odour of diazobenzenimide, and after a while deposits yellow crystalline flocks of phenyl-nitrosohydrazine:

This reaction is very characteristic of the primary hydrazines.

4. With Diazobenzene. The action of diazobenzene-salts on the aromatic hydrazines does not give rise to compounds analogous to the diazo-amido-compounds, which are formed by the action of diazobenzene-salts on amines (*e.g.* diazo-amido-benzene and diazo-dimethylamide from aniline and dimethylamine respectively), but proceeds in a different manner, which is as characteristic of the primary hydrazines as the action of nitrous acid.

When pure nitrate or sulphate of diazobenzene is added to a cold aqueous solution of phenyl-hydrazine hydrochloride, the liquid soon becomes turbid, from separation of diazobenzenimide, while a salt of aniline remains dissolved:

This reaction is analogous to that which Griess observed with diazobenzene nitrate and hydrodiazobenzoic or hydrazine-benzoic acid, or with diazobenzoic nitrate and phenyl-hydrazine, whereby diazobenzoic imide, $\text{C}^6\text{H}^4(\text{CO}^2\text{H})\text{---}\overset{\text{N}}{\underset{\text{N}}{\text{N}}}\text{=N}$, and aniline nitrate, or diazobenzenimide and amidobenzoic nitrate, are produced (p. 276). The formation of the diazo-benzoic imide is attributed by Fischer to a regeneration of aniline and nitrous acid, consequent on the assumption of 2 mol. H^2O by the diazobenzene, and to the action of the nitrous acid thus formed on hydrazine-benzoic acid, thus:

To explain the simultaneous formation of amidobenzoic acid and diazobenzenimide, it is necessary to suppose that the hydrazine-group is split up, and that nitrogen is transferred to the diazobenzene. This result may likewise be brought about by assumption of water, the hydrazine being resolved into the corresponding amine and hydroxylamine:

The last reaction has not, indeed, been effected in the simple form here represented; but there are sufficient grounds for supposing it to take place, especially in the secondary hydrazines. The hydroxylamine thus formed will unite with the diazobenzene, forming water and diazobenzonimide:

That such is actually the case may be shown by pouring a mixture of the cold aqueous solutions of diazobenzene sulphate and hydroxylamine hydrochloride into a cold dilute solution of sodium carbonate, whereupon diazobenzonimide separates out nearly in the quantity required by theory. Further evidence in support of the explanation just given is that the secondary base, methylphenyl-hydrazine, is decomposed in a similar manner by diazobenzene, yielding diazobenzonimide and methylaniline.

5. *Reconversion of Hydrazines into Diazo-compounds.*—This transformation may be effected through the medium either of the sulphonates or of the ordinary salts (chlorides, sulphates, &c.) of the hydrazines, most readily, however, with the former. The hydrazine sulphonate is prepared by heating 2 mol. of the base with 1 mol. potassium pyrosulphate, whereby a pasty mixture of potassium sulphate, phenyl-hydrazine sulphate, and phenyl-hydrazine sulphonate is formed, which soon solidifies:

To isolate the last salt, the melt is dissolved in hot water, and the greater part of the sulphuric acid removed by barium carbonate, the phenyl-hydrazine which was combined with that acid then separating for the most part as an oil; and on adding strong potash-ley to the hot filtered liquid, the hydrazine-sulphonate is deposited in a mass of crystals which may be obtained pure by one recrystallisation from hot water. The hydrazine-sulphonate may then be converted into the yellow diazosulphonate, $\text{C}^6\text{H}_5\text{N}_2\text{SO}^2\text{K}$, by oxidation with mercuric oxide or potassium dichromate.

The conversion of the sulphate, chloride, &c., of the hydrazine to a diazo-compound by oxidation is less easy and requires special precautions to prevent the occurrence of secondary reactions. The best way of proceeding is to add the aqueous solution of the hydrazine salt gradually, and with continual agitation, to water holding in suspension an excess of mercuric oxide. The reaction then takes place to a great extent in the manner represented by the equation:

The formation of phenyl-hydrazine from diazobenzene, and its reconversion into the latter by the reactions above described, are more readily explained by Kekulé's formula of the diazobenzene-compounds, viz. $\text{R}-\text{N}=\text{N}-\text{R}'$, containing only trivalent

nitrogen, than by Stroecker's formula $\begin{array}{c} \text{R}-\text{N}-\text{R} \\ ||| \\ \text{N} \end{array}$, in which one of the N-atoms is quin-

ivalent (p. 636). For all these reactions, indeed, Stroecker's formula would require intra-molecular transpositions, and the conversion of quinivalent into trivalent nitrogen by addition, and of trivalent into quinivalent nitrogen by abstraction of hydrogen, which does not appear very probable.

4. *Oxidation of Phenyl-hydrazine in Alkaline Solution.*—The oxidation of phenyl-hydrazine, in presence of mineral acids, gives rise, as already observed, to diazobenzene or its transformation-product, diazobenzonimide, and is not attended with evolution of gas; in alkaline solutions, on the other hand, Fehling's solution for example, nitrogen is evolved, and the products formed are aniline and benzene. The formation of aniline is explained by the equation:

that of benzene is probably due to the decomposition of a diazo-compound, with entire evolution of its nitrogen in the form of gas, and the entrance of its hydrogen into the benzene residue.

When cyanogen gas is passed into an emulsion of 1 pt. phenyl-hydrazine and 10 pts. water, yellowish-red crystals are obtained which, after washing with water, may be purified by recrystallisation from alcohol, with addition of animal charcoal. They are still however yellow after this treatment, and it is only by repeated solution in ether and precipitation with ligroin, which is attended with great loss of substance, that they can be obtained nearly white. They consist of phenyl-dicyanhydrazine, which,

from the analogy of its mode of formation to that of dicyananiline, may perhaps be represented by the constitutional formula above given.

Phenyl-dicyanhydrazine dissolves easily in alcohol, and in ether, sparingly in water and in ligroin. From hot water it crystallises in jagged feathery groups which unite into laminae; from benzene, chloroform, or an ethereal solution mixed with ligroin, it separates in crystals which, according to Arzruni, are monoclinic, with strongly curved faces. It turns brown at 160°. and melts with decomposition at a slightly higher temperature. It dissolves in dilute hydrochloric acid, and is separated from the solution by neutralisation with soda. Its cold aqueous solution gives with Fehling's solution a dingy green precipitate and a blue-green coloration. It reduces ammoniacal silver solutions. Its alkaline solution, when exposed to the air, absorbs oxygen and turns brown. The cyanide is not much affected by acids, but when heated to 150° for several hours with water, it is converted into white needle-shaped crystals. Its solution in sulphuric acid gives a white flocculent precipitate with potassium nitrite.

Phenyl-azonium Compounds. Azonium compounds are bodies related to the hydrazines in the same manner as the ammonium compounds to the amines, and produced in like manner by the combination of hydrazines with the bromides, chlorides, hydroxides, &c., of alcohol-radicles.

Phenyl-diethyl-azonium Bromide, $C^6H^5.N^2H^2(C^2H^5).C^2H^5Br$.—When phenyl-hydrazine and ethyl bromide are mixed together in molecular proportions, reaction begins at ordinary temperatures, and must be moderated at first by immersing the vessel in cold water, but to complete it the mixture must be gently heated in a reflux apparatus. With 1 mol. of the base to $1\frac{1}{2}$ mol. ethyl bromide (a slight excess of the latter being advantageous), the liquid solidifies completely to a magma of white slender needles, which may be freed from the slight excess of ethyl bromide by warming on the water-bath. This product dissolves completely in water, and the solution, after being freed from volatile bases by extraction with ether, yields phenyl-diethylazonium bromide as a precipitate composed of white slender needles; and by passing these between filter paper and recrystallising from boiling alcohol, the compound is obtained in short transparent prisms, or by slow evaporation of the alcoholic solution in shining splendidly developed rhombic prisms, exhibiting the combination ∞P , $\bar{P}\infty$, $0P$ (fig. 5), mostly elongated in the direction of the macrodiagonal. The faces ∞P and $\bar{P}\infty$ are often equally developed, while $0P$ is narrow, and striated parallel to its combination edge with $\bar{P}\infty$. Axes $a : b : c = 0.8219 : 1 : 0.8265$. The plane of the optic axes is parallel to the brachypinacoid, and the first median line coincides with the axis c . Dispersion of the optic axes $\rho < v$. Double refraction positive, strong.

FIG. 5.

$$c = 0P, a = \bar{P}\infty, m = \infty P.$$

Phenyl-diethylazonium bromide dissolves very easily in water, very sparingly in strong alkalis, and is insoluble in ether. At 180° it begins to turn brown, and at 193° it decomposes rapidly, giving off gas and yielding a yellow oily distillate, while a half-charred mass remains in the retort.

In its chemical relations, this bromide exhibits the characters of an ammonium compound; it is not altered by alkalis, but is easily debrominated by the oxide and salts of silver, yielding with the former a hydroxide easily soluble in water and having an alkaline reaction. By agitating its aqueous solution with recently precipitated silver chloride, it is quickly converted into the chloride, which is likewise easily soluble in water, and unites with platinum chloride, forming brown-yellow crystals of the platinum chloride, $[C^6H^5N^2H^2(C^2H^5)^2Cl]^2PtCl_4$.

The constitution of these azonium-compounds seems at first sight to throw some doubt on the universality of Hofmann's conclusion that the formation of compounds of the ammonium-type from those of the ammonia-type takes place only after the typical hydrogen of the latter has been completely replaced by alcohol-radicles. The discrepancy may, however, be removed by supposing that in the action of ethyl bromide on the hydrazine base, the hydrogen of the NH -group is first replaced by ethyl, and the ethyl bromide added on to the ethylimidogen-group thus formed, the nitrogen then becoming quinquivalent:

The correctness of this view is indeed demonstrated by the fact that phenyl-diethyl-azonium bromide is likewise produced by heating phenyl-ethyl-hydrazine, $C^6H^5.N(C^2H^5).NH^2$, with ethyl bromide. It must therefore be inferred that the formation of a compound of the ammonium-type, while it indicates the presence of a tertiary amine group, does not afford any criterion as to the number of hydrogen-atoms which may be present therein in combination with nitrogen, but that such a compound may contain imide- or amide-groups yet intact.

Derivatives of Phenyl-hydrazine containing Acid Radicles.

1. **Phenyl-nitrosohydrazine**, $C^6H^5-N(NO)-NH^2$. The formation of this compound by the action of sodium nitrite on phenyl-hydrazine hydrochloride has been already noticed (p. 1049). The yellow-brown flocks first deposited may be purified by washing with water, pressure between filter-paper, solution in warm ether, and precipitation with ligroin, which throws down the compound in yellow laminae.

Phenyl-nitrosohydrazine, like other nitroso-bases, exhibits Liebermann's colour-reactions with phenol and sulphuric acid (*2nd Suppl.* 901); the blue colour with potash does not however appear immediately, but only after agitation with air, because the colouring matter, at the moment of its formation, is reduced by the hydrazine-group—just as Liebermann observed that it was reduced by zinc-dust—and the colour does not appear till oxidation has taken place by the action of the air. Similar reactions are exhibited by most nitroso-derivatives of the hydrazine-bases.

Phenyl-nitroso-hydrazine may be exposed to the air without alteration for several days, especially in the state of fine powder and in thin layers; but when kept in closed vessels, it decomposes very quickly, at summer temperature even in a few hours, and is converted into a dark brown strong-smelling liquid. Its vapour is very poisonous, acting like that of amyl nitrite, but much more strongly, the inhalation even of a small quantity producing determination of blood to the head and violent headache.

Phenyl-nitroso-hydrazine treated with zinc and sulphuric acid, or with zinc-dust and acetic acid, yields considerable quantities of aniline. This reduction, differing as it does from that observed by Baeyer a. Caro (p. 205) in the case of dimethyl-nitrosaniline, in which the NO-group is contained within the benzene-nucleus, shows that in phenyl-nitroso-hydrazine, the NO is situated in the hydrazine group N^2H^2 , and as moreover Heintz has shown (*Liebig's Annalen*, cxxxviii. 316) that in the ordinary amine-bases, the formation of a nitrosamine takes place only when imide-groups are present, it may be inferred as highly probable that the same is the case with hydrazines, and that consequently in the compound under consideration the NO is situated in the NH-group, so that its constitutional formula is $C^6H^5.N(NO).NH^2$. This conclusion is strongly corroborated by the fact that the secondary aromatic hydrazines, to be described further on, in which the hydrogen of the NH-group is replaced by an alcohol-radicle, are decomposed by nitrous acid in a totally different way.

Phenyl-nitroso-hydrazine, gently heated with a dilute alkali, is completely resolved into water and diazobenzenimide, $C^6H^5.N^2$:

2. **Phenyl-hydrazides**. Two of the hydrogen-atoms in phenyl-hydrazine are easily replaced by acid organic radicles; for the third the substitution has not yet been effected. The resulting compounds exhibit, in general, the characters of ordinary amides. The first acid radicle which enters appears always to take the place of a hydrogen-atom in the NH^2 -group of the hydrazine, as is proved by the direct conversion of some of the resulting compounds into azo- and diazo-compounds; the position of the second is as yet undecided.

Monobenzoyl-phenyl-hydrazide, $C^6H^5.NH.NH(COC^6H^5)$, is formed by gradually adding benzoyl chloride (1 mol.) to a solution of phenyl-hydrazine (2 mol.) in 5 pts. of ether. The crystals which separate are freed from phenyl-hydrazine hydrochloride by treatment with hot water, and then recrystallised from alcohol. The compound dissolves sparingly in hot water and in ether, freely in hot alcohol acetone, and chloroform, and crystallises from all these solutions in slender white prisms. It melts at 168° , and decomposes at higher temperatures; dissolves without alteration in potash-ley, but is decomposed by hydrochloric acid at 100° into phenyl-hydrazine and benzoic acid. On adding mercuric oxide to its solution in chloroform, the oxide is reduced and the liquid acquires a dark red colour, from formation of

benzoyl-diazobenzene, $C^6H^5-N \equiv N-COC^6H^5$. This latter compound is a dark red oil which dissolves easily in alcohol, ether, and chloroform; detonates slightly when heated; is completely decomposed by boiling with water or with acids; is not further oxidised by Fehling's solution; and is reconverted by zinc and acetic acid into benzyl-phenyl-hydrazide.

Dibenzoyl-phenyl-hydrazide, $C^6H^5.N^2H.CO.C^6H^5$, may be obtained by the action of benzoyl chloride on monobenzoyl-phenyl-hydrazide, but is more easily prepared by that of benzoyl chloride on potassium phenyl-hydrazine-sulphonate:

It is very slightly soluble in water, moderately in hot alcohol; by dilute alkalis at the boiling heat, it is taken up slowly but in considerable quantity, and separated unaltered by acids. In alcoholic solution it immediately reduces ammoniacal silver nitrate. Heated in a sealed tube with fuming hydrochloric acid, it is completely resolved into phenyl-hydrazine and benzoic acid. It melts at $177^\circ-178^\circ$, and decomposes at a higher temperature, yielding a distillate containing benzoic acid, benzoic aldehyde, and benzanilide, and a resinous residue which ultimately carbonises.

Acetyl-phenyl-hydrazide, $C^6H^5.N^2H^2.CO.CH^3$, is produced, with great rise of temperature, on mixing acetic anhydride (1 mol.) with phenyl-hydrazine (2 mol.), the liquid turning brown and solidifying slowly to a slightly coloured crystalline mass. This is dissolved in hot water, and the solution is filtered from a small quantity of resinous products and left to cool, whereupon it deposits the acetyl-phenyl-hydrazide in nearly colourless laminae, which may be purified by crystallisation from dilute alcohol. The compound may also be prepared by boiling phenyl-hydrazine for several hours with three times its weight of glacial acetic acid, the excess of the latter being removed by distillation at 160° , and the residue purified as above.

Acetyl-phenyl-hydrazide is slightly soluble in cold water and ether, easily in hot water, alcohol, chloroform, and benzene, and crystallises from most of these solutions in six-sided prisms often shortened to thin plates, and having a bright silky lustre. It melts at 128.5° , and distils at a higher temperature, for the most part without decomposition; is resolved by boiling with strong acids into acetic acid and phenyl-hydrazine. Its aqueous solution instantly reduces Fehling's solution when gently heated therewith. Dissolved in dilute sulphuric acid and treated with sodium nitrite, it yields an unstable nitroso-derivative. By prolonged boiling with acetic anhydride, it is converted into a syrupy mass, probably containing a diacetyl-derivative. Acetyl-phenyl-hydrazide, oxidised in chloroform-solution by mercuric oxide, is decomposed like the benzoyl-compound, yielding a dark red oil, probably consisting of acetyl-diazobenzene, $C^6H^5.N^2.CO.CH^3$.

Oxalyl-diphenyl-hydrazide, $(C^6H^5.N^2H^2)^2C^2O^2$.—This compound, analogous in composition to oxamide, is produced in a similar manner by heating a mixture of 1 mol. ethyl oxalate and 2 mol. phenyl-hydrazine to 110° , alcohol being given off with ebullition, and the solution solidifying to a faintly yellow laminar crystalline mass. It begins to soften at 260° , and melts completely at $277^\circ-278^\circ$; at a higher temperature it distils for the most part unaltered, and the distillate on cooling immediately solidifies in the crystalline form. It is but slightly soluble in most solvents; is dissolved by strong sulphuric acid in the cold with red-violet colour, and without further alteration, and is completely decomposed on boiling.

Derivatives of Phenyl-hydrazine containing Aldehyde-radicles.

Phenyl-hydrazine and the aldehydes unite, with elimination of water, to form in nearly all cases well crystallised, indifferent bodies, containing the residues of 1 mol. of each reagent: in this respect they differ from the otherwise similar derivatives of the ordinary amine bases. Some of the compounds thus formed are very stable, while others are completely decomposed by boiling with water, or by prolonged exposure to the air. By heating with fuming hydrochloric acid, they are all completely resolved into phenyl-hydrazine and the corresponding aldehyde.

Benzylidene-phenyl-hydrazide, $C^{13}H^{12}N^2 = C^6H^5-NH-N=CH-C^6H^5$. On mixing phenyl-hydrazine with bitter almond oil, a violent reaction takes place, the mixture becoming turbid from separation of water, and solidifying on cooling to a slightly coloured crystalline mass. In preparing large quantities it is advisable to moderate the violence of the reaction by adding about 2 vols. of alcohol, and to mix the base and the aldehyde in equal numbers of molecules. The crystalline mass

which separates is filtered off and purified by recrystallisation from absolute alcohol. The reaction takes place according to the equation:

Benzylidene-phenyl-hydrazide is quite colourless when pure, but quickly becomes rose-red when exposed to the air. It melts at 152.5° ; distils without decomposition;

Fig. 6.

$m = \infty P$; $n = \infty P2$;
 $c = 0P$; $a = -E\infty$.

dissolves easily in hot alcohol, acetone, and benzene, sparingly in ether. By slow evaporation of a dilute alcoholic solution, it may be obtained in well-defined elongated prismatic crystals (fig. 6) of rose-red colour. They belong to the monoclinic system. Axes $a : b : c = 0.853 : 1 : 0.670$. Angle $ac = 87^\circ 40' 30''$. Observed combination $8P \cdot \infty P2 \cdot 0P \cdot -P\infty$. Angle $\infty P : 0P = 88^\circ 14'$; $\infty P : \infty P2 = 47^\circ 30'$. Plane of the optic axes coincident with the plane of symmetry.

Benzylidene-phenyl-hydrazide does not reduce Fehling's solution, even with the aid of heat. By prolonged boiling with fuming hydrochloric acid, or better, with sulphuric acid of 30 per cent., it is slowly resolved into phenyl-hydrazine and benzaldehyde.

Ethylidene-phenyl-hydrazide, $\text{C}^6\text{H}^5\text{.N}^2\text{H.CH.CH}^3$, is obtained by adding to an ethereal solution of phenyl-hydrazine rather more than an equivalent quantity of recently distilled acetaldehyde, till the mixture no longer reduces Fehling's solution. When the oily residue left on evaporation of the ether is stirred up with cold water, it gradually solidifies to a crystalline mass, which may be freed from colouring matters and obtained pure by repeated crystallisation from ligroin. This compound dissolves easily in ether and in alcohol, deliquesces slowly in the air to a red-brown liquid, and is resolved by boiling with water or dilute acids into aldehyde and phenyl-hydrazine.

A product essentially different from the above is obtained when the mixture of phenyl-hydrazine and aldehyde is directly heated with strong hydrochloric acid. The solution then becomes dark green, and, on addition of water or potash-ley, deposits a granulo-crystalline mass of complex composition. It exhibits weak basic properties, and dissolves in strong acids, but is separated therefrom even by water. It appears to be a hydrazine-derivative produced by further aldehyde-condensation, probably analogous to the bases which H. Schiff obtained in a similar manner from aniline.

Phenyl-furfurazide, $\text{C}^6\text{H}^5\text{.N}^2\text{H.C}^4\text{H}^3\text{O}$.—When phenylhydrazine and furfural are mixed in molecular proportions, the liquid becomes very hot, and slowly solidifies on cooling to a yellow crystalline mass, which may be purified by repeated solution in ether, drying with calcium chloride, and precipitation with ligroin. It then crystallises in faintly yellow laminæ; melts at 96° ; decomposes at a higher temperature; dissolves easily in alcohol and ether, very sparingly in ligroin; and is resolved by boiling with hydrochloric acid into phenyl-hydrazine and furfural. Its formation is represented by the equation:

Phenyl-carbazides.

Carbazides are compounds derived from carbamides or ureas by substitution of one or two hydrazine groups, N^2H^3 , for NH^2 -groups. Those in which both the NH^2 -groups are thus replaced are called simply carbazides; those in which only one NH^2 -group is replaced are called semi-carbazides, thus:

Phenyl-carbamide	$\text{NH}^2\text{.CO.NH(C}^6\text{H}^5\text{)}$
Phenyl-semicarbazide	$\text{NH}^2\text{.CO.N}^2\text{H}^3\text{(C}^6\text{H}^5\text{)}$
Phenyl-carbazide	$\text{N}^2\text{H}^3\text{.CO.N}^2\text{H}^3\text{(C}^6\text{H}^5\text{)}$
Diphenyl-carbazide	$\text{(C}^6\text{H}^5\text{)N}^2\text{H}^3\text{.CO.N}^2\text{H}^3\text{(C}^6\text{H}^5\text{)}$

There are also carbazic acids related in like manner to the carbamic acids, e.g. *phenyl-carbazic acid*, $\text{C}^6\text{H}^5\text{.N}^2\text{H}^3\text{.CO.OH}$; and thiocarbazides, thiocarbazic acids, &c. analogous in constitution to the preceding, but containing sulphur in place of oxygen.

Carbazides are formed from hydrazines by reactions precisely analogous to those by which carbamides or ureas are formed from amines; but they differ considerably from carbamides in many of their reactions, the presence of the hydrazino-group exerting a modifying influence, which is especially conspicuous in the action of nitrous acid, and in the decomposition of the thiocarbazates by alkalis.

Phenyl-ethyl-semicarbazide, $\text{N}^2\text{H}^2(\text{C}^6\text{H}^5)\cdot\text{CO}\cdot\text{NH}(\text{C}^2\text{H}^5)$, is formed by direct union of phenyl-hydrazine and ethyl-carbimide:

It dissolves in hot alcohol, and separates therefrom in well-formed monoclinic tabular crystals, exhibiting the combination $\infty \text{P} \cdot 0\text{P} \cdot + \text{P} \cdot \text{R} \infty$ (fig. 7). Axes $a : b : c = 0.8268 : 1 : 1.1457$. Angle $ac = 61^\circ 0'$. Plane of the optic axes parallel to the plane of symmetry. First median line in the acute angle ac . It melts at 151° . Heated to 100° with strong hydrochloric acid, it is resolved into ethylamine, phenyl-hydrazine and carbon dioxide:

Nitrous acid converts it into a nitroso-derivative, $\text{C}^6\text{H}^5\cdot\text{N}^2\text{H}(\text{NO})\cdot\text{CO}\cdot\text{NH}(\text{C}^2\text{H}^5)$, which crystallises in slender yellow needles, melts at 86.5° , and is decomposed by boiling with alkalis into ethylamine, diazobenzenimide and carbon dioxide, according to the equation:

Phenyl-semicarbazide, $\text{N}^2\text{H}^2(\text{C}^6\text{H}^5)\cdot\text{CO}\cdot\text{NH}^2$, obtained by the action of potassium cyanate on a normal salt of phenyl-hydrazine, crystallises in colourless plates melting at 170° . It is analogous to the preceding compound in all its reactions.

Phenyl-hydrazine Phenyl-carbazate,

Phenyl-hydrazine absorbs dry carbon dioxide very readily, and solidifies to a white crystalline mass having this composition. The same compound is more easily prepared by saturating a cooled emulsion of 1 pt. phenyl-hydrazine and 10 pts. water with carbon dioxide, and may be obtained by rapid filtration, pressure between filter-paper, and washing with ether, as a white crystalline mass, soft to the touch, and having a rather strong odour recalling that of phenyl-hydrazine. It dissolves sparingly in water and in ether, easily in alcohol, from which, however, it cannot again be separated. Acids and hot water decompose it readily. On exposure to the air, it gives off carbon dioxide, and deliquesces to an oily red-brown mass. It volatilises easily in a stream of carbon dioxide, and immediately reduces Fehling's solution.

Phenyl-hydrazine Phenyl-thiocarbazate,

is formed in like manner by direct addition of CS^2 to phenyl-hydrazine, the combination taking place at ordinary temperatures and being attended with considerable evolution of heat, on which account it is necessary to mix the base with 4 vol. ether before adding the carbon disulphide, otherwise decomposition will ensue. The liquid boils up violently, and the salt immediately separates in the solid form; it may be obtained pure by filtering and washing with ether. It is sparingly soluble in ether, carbon sulphide, chloroform, and ligroin, easily in warm acetone, and crystallises from ether by spontaneous evaporation in six-sided tablets or prisms. The freshly prepared substance, when quickly heated in a capillary tube, melts between 96° and 97° , with slight evolution of gas, to a slightly yellow liquid; by slower heating, on the other hand, it is completely decomposed, without fusion, at a much lower temperature.

The position of the sulphur-group in the constitutional formula above assigned to this salt is analogous to that which it occupies in the thiocarbamates, and is further justified by the resolution of the compound, under the influence of acids, into phenyl-hydrazine and phenyl-thiocarbazic acid:

Phenyl-thiocarbazic acid, $\text{C}^6\text{H}^5\cdot\text{N}^2\text{H}^2\text{S}^2$, is precipitated, on adding dilute sulphuric acid to a solution of the phenyl-hydrazine salt in dilute aqueous potash, in thin shining laminae, which have at first a greenish colour, arising from admixture with a dark colouring matter, but may be purified and rendered quite white by filtration, pressure, stirring up with the smallest possible quantity of absolute alcohol, and repeated filtration.

This compound possesses marked acid properties, dissolving easily and without

FIG. 7.

$$c = 0\text{P}; m = \infty \text{P}; p = + q = \text{R} \infty.$$

decomposition in alkalis, but no definite salts have yet been obtained from it. It dissolves readily in ether, acetone, glacial acetic acid and alcohol, but decomposes in these solutions with extraordinary facility into the phenyl-hydrazine salt and free carbon disulphide. The same decomposition takes place, though much more slowly, in the dry state at ordinary temperatures, quickly at a moderate heat, but the phenyl-hydrazine salt is then further resolved into H^2S and diphenyl-thiocarbazine:

Diphenyl-thiocarbazine, $(\text{C}^6\text{H}^5.\text{N}^2\text{H}^2)\text{CS}$. To prepare this compound, the crude salt obtained by combination of phenyl-hydrazine and carbon disulphide (p. 1055) is freed from ether by pressure and drying in contact with the air, then finely pulverised and heated to 110° – 140° in an oil-bath, in layers of moderate thickness, whereupon it fuses, swells up, and gives off large quantities of hydrogen sulphide. The gaseous products of the decomposition are removed by a stream of carbon dioxide, the action of the heat being assisted by occasional stirring of the pasty mass, and the operation is interrupted as soon as the odour of hydrogen sulphide is replaced by that of ammonia. The greenish melt thus obtained solidifies on cooling to a crystalline mass; and on pulverising this mass, exhausting it with absolute alcohol, which dissolves the greater part of the secondary products, and recrystallising the residue from hot alcohol—prolonged boiling being avoided as much as possible—the thiocarbazine is obtained in hard colourless triangular prisms.

Diphenyl-thiocarbazine dissolves sparingly in alcohol, acetone, chloroform, benzene, and glacial acetic acid, sparingly at ordinary, more readily at higher temperatures; aniline also dissolves it with the aid of heat, forming a solution of deep green colour in thin layers, dark red in thicker layers. The solution in glacial acetic acid also becomes green to dark red on boiling, and the same coloration is produced, though slowly, in the solutions of the thiocarbazine in hot alcohol, benzene, and chloroform—further, though in a lesser degree, by the action of heat on the dry substance. The red colouring matter is, however, most easily produced by the agency of dilute aqueous or alcoholic potash, which dissolves the thiocarbazine readily at a gentle heat, forming a dark red solution which, on acidulation, deposits the colouring matter in blue-black flocks. On separating these by filtration, dissolving them in warm chloroform, and precipitating with alcohol, the colouring matter is obtained in blue-black slender microscopic needles.

The analysis of this red colouring matter leads to the formula $\text{C}^{12}\text{H}^{12}\text{N}^4\text{S}$, according to which it contains 2 atoms of hydrogen less than diphenyl-thiocarbazine; but as the analytical differences between the two bodies are but small, and the mode of formation of the red substance, in which the conditions of oxidation can scarcely be said to be present, gives no account of the removal of these two hydrogen-atoms, it is more probable that the red substance is an isomeride of diphenyl-thiocarbazine, produced therefrom by atomic transposition. It is to some extent analogous to Baeyer's phenol-colouring matters, and to the nitrogenous colouring matters which Liebermann obtained by the action of nitrous acid on phenol and its homologues (*2nd Suppl.* 901).

The solution of the red colouring matter in chloroform is splendidly dichroic, the dark red of the thicker strata passing, on dilution, into a bright green of great intensity. The same solution when treated with bromine, yields substitution-products, characterised by the brilliant metallic reflection of the solid substance.

The alkaline solution of the red substance is quickly reduced by zinc-dust; yielding a colourless liquid, which becomes violet-red on exposure to the air; and on acidifying this red solution, a new colouring matter is precipitated in the form of red crystalline flocks.

Diphenyl-thiosemicarbazine, $\text{C}^6\text{H}^5.\text{N}^2\text{H}^2.\text{CS.NH.C}^6\text{H}^5$, is prepared by mixing the alcoholic solutions of phenyl-hydrazine and phenyl-thiocarbimide:

It immediately separates in the crystalline form, and may be obtained by one crystallisation from alcohol in colourless prisms. It is insoluble in water, slightly soluble in ether, carbon disulphide and ligroin, more readily in acetone, hot alcohol, and glacial acetic acid, and separates from most of these solvents in stellate groups of slender prisms. It melts at 177° , and, like most salts and derivatives of phenyl-hydrazine, becomes strongly electric by friction. It dissolves in dilute aqueous alkalis easily but without coloration, and is precipitated from the solution by acids in its original state. The stability of this body in alkaline solution shows that it differs in constitution from diphenyl-thiocarbazine and that both the hydrazine-

groups of the latter concur in the formation of the colouring matter produced from it by the action of alkalis. By prolonged boiling with strong hydrochloric acid, diphenyl-thiosemicarbazide is resolved, like thiocarbaniide, into its generators, phenyl-hydrazine and thiocarbimide. Its hot alcoholic solution immediately reduces mercuric oxide, acquiring a dark red colour, and depositing on cooling, crystalline flocks of the same colour, the composition of which has not been ascertained.

Paratolyl-hydrazine, $C^7H^{10}N^2 = C^7H^9.N^2H = C^6H^4(CH^3).NH.NH^2$, [$CH^3 : N^2H^2 = 1 : 4$], is prepared from paratoluidine in the same manner as phenyl-hydrazine from aniline (p. 1048), and crystallises from the ethereal solution of the crude product, on cooling to a low temperature, in thin white laminae. It melts at 61° , and boils, with slight decomposition, at 240° – 244° ; dissolves readily in alcohol, ether, and benzene, sparingly in water. *Dibenzoyl-tolyl-hydrazine* melts at 188° (Fischer, *Ber.* viii. 589; ix. 890).

B. SECONDARY AROMATIC HYDRAZINES.

The primary hydrazines being formed by substitution of an alcohol-radicle for one atom of hydrogen in the group NH^2-NH^2 , it is easy to see that the introduction of a second alcohol-radicle may give rise to two isomeric secondary derivatives, accordingly as the two alcohol-radicles are attached to the same or to different atoms of nitrogen. To the latter class belong the well-known hydrazo-compounds, $R-NH-NH-R'$, *e.g.* hydrazobenzene (1st Suppl. 209, 271); to the former the unsymmetrical bases $\begin{smallmatrix} R \\ R' \end{smallmatrix} > N-NH^2$, which we have now to consider.

The two isomeric derivatives of each pair are in all probability formed simultaneously by the action of alcoholic bromides on the primary hydrazines, but it has not yet been found possible to separate them. The unsymmetrical secondary bases are much more readily obtained, and indeed as sole products, by reduction of the nitrosamines of secondary amines, *e.g.* ethyl-phenyl-nitrosamine or nitrosoethyl-aniline, $C^6H^5N(C^2H^5)NO$, prepared by the action of nitrous acid on ethyl-aniline dissolved in dilute hydrochloric acid, or of potassium nitrite on ethyl-aniline hydrochloride (p. 206).

Methyl-phenyl-hydrazine, $(C^6H^5)(C^2H^5)N-NH^2$. To prepare this base, 30 grams of methyl-phenyl-nitrosamine dissolved in 120 grams of 50 per cent. acetic acid and the requisite quantity of alcohol, are added gradually and with agitation to 200 grams of cooled 90 per cent. alcohol in which 150 grams of zinc-dust are suspended, the temperature not being allowed to rise above 30° . The products of several such operations are united, filtered, and supersaturated with strong soda-ley; and the resulting solution is either distilled with steam, or directly exhausted with ether. The ether-alcoholic extract is acidulated with sulphuric acid and evaporated—the acidulation being necessary to prevent the volatilisation of the base with the alcohol-vapour;—the aqueous residue is supersaturated with soda-ley; the oil which then separates is dried with potassium carbonate and distilled; and the fraction which passes over between 190° and 240° is left to stand in shallow vessels over sulphuric acid to free it from ammonia. The residue thus obtained is a mixture of methyl-phenyl-hydrazine and methyl-aniline, which may be separated by converting them into sulphates and crystallising these salts from alcohol, in which the hydrazine salt dissolves less easily than that of methyl-aniline. For this purpose the crude base is mixed with the calculated quantity of sulphuric acid; the mixture is cooled to 0° and diluted with an equal volume of absolute alcohol; the crystalline mass which separates is filtered on a vacuum-filter, and the residue, after washing with alcohol, is freed as far as possible from mother-liquor by pressure between filter-paper, whereupon the greater part of the methyl-aniline salt passes into solution, still however mixed with a not inconsiderable quantity of methyl-phenyl-hydrazine. The mixture of bases obtained by supersaturating the mother-liquor with soda-ley, may be utilised for the preparation of substitution-derivatives of methyl-phenyl-hydrazine, which are more easily separated from the methyl-aniline. The separated sulphate of methyl-phenyl-hydrazine may be completely purified by once recrystallising it from absolute alcohol, and drying the white crystalline mass at 100° . The aqueous solution of this purified salt supersaturated with a strong alkali, yields the base in the form of an oil, which may be dried with potassium carbonate and rectified.

Methyl-phenyl-hydrazine is an oily liquid, colourless when freshly prepared, but soon becoming dark-brown by oxidation when exposed to the air. It remains liquid at -17° and boils at 222° – 224° (bar. 715 mm.) which is 10° lower than the boiling

point of phenyl-hydrazine. In this respect it differs from the ordinary amine-bases—in which the introduction of each successive alcohol-radicle is attended with a rise in the boiling point—but resembles the substituted carbamides. It dissolves sparingly in cold, more readily in hot water, and mixes in all proportions with alcohol, ether, chloroform, benzene, and carbon disulphide. Towards oxidising agents it exhibits greater stability than phenyl-hydrazine. Its *sulphate*, $(C^6H^5)(CH^3)N^2H^2SO_4$, forms thin white shining laminae. The other salts are very soluble in water, and in alcohol, and difficult to obtain in the crystallised state. Methyl-phenyl-hydrazine, like phenyl-hydrazine, unites with 1 mol. bromide or iodide of ethyl to form well-crystallised azonium-compounds.

By the action of nitrous acid on the salts of methyl-phenyl-hydrazine, the base is resolved into methyl-phenyl-nitrosamine and nitrogen monoxide:

Methyl-phenyl-hydrazine in excess, and diazobenzene nitrate mixed up to an emulsion with water, act on one another rapidly at ordinary temperatures, producing methyl-aniline, diazobenzenimide and nitric acid:

and further the oxidising action of the nitric acid gives rise to the formation of

Dimethyl-diphenyl-tetrazone, $\begin{matrix} C^6H^5 \\ CH^3 \end{matrix} \left\{ N-N=N-N \right\} \begin{matrix} C^6H^5 \\ CH^3 \end{matrix}$. This compound is likewise obtained, and more readily, by gradually adding small quantities of mercuric oxide to a solution of methyl-phenyl-hydrazine (best of the crude product) in eight times its quantity of chloroform. The solution, which must be well cooled, becomes dark brown, and the reaction is complete when the liquid, after being left at rest, no longer gives off gas. The filtered solution is evaporated to a small bulk, mixed with alcohol, and the crystalline mass which separates is pressed and re-crystallised from alcohol, to which a little zinc-dust and a very small quantity of glacial acetic acid have been added to promote decolorisation. By repeated crystallisation from alcohol, the tetrazone is obtained in thin colourless laminae which melt with decomposition at 133° . It dissolves easily in carbon sulphide, sparingly in cold alcohol and ether; is not altered by hot water, or by oxidising or reducing agents. Acids added to its alcoholic solution resolve the compound into nitrogen and methyl-aniline, the liquid becoming deep blue. In chloroform solution it unites with *iodine*, forming the compound $C^{14}H^{16}N^4 + 4I$, which consists of black microscopic needles, is very slightly soluble in chloroform, and very unstable, detonating when dry even at the ordinary temperature of a room; and decomposed by molecular silver into silver iodide and the tetrazone. The iodine-compound is also readily decomposed by dilute alkalis.

Derivatives of Methyl-phenyl-hydrazine.

This base acts with *benzoyl chloride* and *benzaldehyde* in the same way as phenyl-hydrazine (p. 1052), forming crystallisable compounds; it is strongly attacked by acetic anhydride and ethyl isocyanate. It does not unite with *carbon disulphide* at ordinary temperatures; but on applying heat, hydrogen sulphide is evolved and the mixture solidifies to a crystalline mass.

Methyl-phenyl-semicarbazide, $\begin{matrix} C^6H^5 \\ CH^3 \end{matrix} > N-NH-CO-NH^2$, is formed on mixing a concentrated solution of the crude base containing a slight excess of hydrochloric acid with an equivalent quantity of pure potassium cyanate, and separates as a dark brown oil which gradually crystallises on cooling. It may be purified by pressure between bibulous paper and solution in the smallest possible quantity of hot benzene, from which it partly crystallises on cooling, and the rest may be precipitated by ether. By repeating these operations, the compound is obtained as a dazzling white mass of slender crystals. It melts at 133° , dissolves readily in hot water, alcohol, and hot benzene, less readily in ether, ligroin, and cold water. With strong hydrochloric acid, it forms an unstable hydrochloride; heated to 100° with hydrochloric acid, it is resolved into ammonia, carbon dioxide, and methyl-phenyl-hydrazine. Fehling's solution does not act upon it; silver nitrate only at the boiling heat. With *nitrous acid* it yields a nitroso-derivative, $(C^6H^5)(CH^3)N.N(NO)CO.NH^2$, which crystallises in thin laminae having a golden lustre; melts at 77° ; is slightly soluble in water, and forms Liebermann's colouring matters with phenol and sulphuric acid (2nd Suppl. 901).

Methyl-diphenyl-thiosemicarbazide, $(C^6H^5)(CH^3)N.NH.CS.NH(C^6H^5)$, prepared from methyl-phenyl-hydrazine and phenyl-thiocarbimide, melts at 154° and dissolves readily in hot alcohol, chloroform, and benzene. The boiling chloroform solution is desulphurised by yellow mercuric oxide.

Diphenyl-hydrazine, $C^{12}H^{12}N^2 = (C^6H^5)^2N-NH^2$. This base, metameric with hydrazobenzene (1st *Suppl.* 209, 271), is formed by the action of zinc and glacial acetic acid on an alcoholic solution of diphenylnitrosamine (p. 209), the acetic acid being added by small portions and the vessel kept cool. When the action is complete, the liquid is filtered, concentrated to one-fourth of its bulk, then diluted with an equal volume of water, and mixed gradually with a large excess of fuming hydrochloric acid, the mixture being all the while kept cool and stirred. On cooling, the hydrochloride, which is but very slightly soluble in strong hydrochloric acid, separates out in blue needles contaminated with diphenylamine, which is produced simultaneously with the hydrazine base, but may be easily removed by recrystallising the crude product from hot very dilute hydrochloric acid, the greater part of the diphenylamine remaining as an oil. The hydrazine base may then be reprecipitated from the filtrate by strong hydrochloric acid, and by repeating these operations several times, the hydrochloride is obtained quite free from diphenylamine. It is still, however, slightly blue, but by recrystallisation from hot alcohol it may be obtained in slender colourless needles.

Diphenyl-hydrazine, separated from the pure hydrochloride by caustic soda, is a faintly yellow oil which becomes viscid at -17° , but does not solidify. When heated it partly volatilises undecomposed, and is partly resolved into ammonia, diphenylamine, and non-volatile resinous products. It dissolves very easily in ether, alcohol, benzene, and chloroform, very sparingly in water. It is a mono-acid base, but its salts are much less stable than those of phenyl-hydrazine and methylphenyl-hydrazine, being partially decomposed even by water. The *hydrochloride* forms white needles very slightly soluble in cold water and in strong hydrochloric acid. The aqueous solution, saturated in the cold, becomes turbid on warming, from separation of the base, but clear again as it cools; the solution in dilute hydrochloric acid is quite stable. The *sulphate*, $[(C^6H^5)^2N^2H^2]^2SO_4$, is moderately soluble in hot dilute sulphuric acid, and separates on cooling in needles mostly having a blue tint; like the hydrochloride, it is partially decomposed by pure water. The *nitrate* crystallises in slender needles sparingly soluble in cold, somewhat more freely in hot water.

Diphenyl-hydrazine is distinguished from the isomeric body hydrazobenzene, $C^6H^5.NH-NH.C^6H^5$, by its behaviour to nitrous acid and to oxidising agents, and by its capability of forming substitution-products by the entry of alcohol- or acid-radicles into the nitrogen group N^2H^2 ,—a substitution which, though theoretically possible in the case of hydrazobenzene, has not been actually effected.

Action of Nitrous Acid.—Hydrazobenzene, as shown by Baeyer (*Ber.* ii. 683), when treated with nitrous acid, in an alcoholic solution cooled by ice, is converted into a nitroso-compound, probably $C^6H^5-N(NO)-(NO)N-C^6H^5$, which is decomposed, partially at ordinary temperatures, and completely with slight detonation when gently heated, into nitrogen dioxide and azobenzene.

Diphenyl-hydrazine, on the other hand, is decomposed by nitrous acid, similarly to methylphenyl-hydrazine, into diphenylnitrosamine and nitrogen monoxide:

Oxidation.—Hydrazobenzene, under the influence of oxidising agents, is easily and completely converted into azobenzene. The mode of oxidation of diphenyl-hydrazine varies—as in the case of the hydrazines previously described—according to the reagents used, the temperature, and the concentration of the solutions. By *Fehling's solution*, the base, on account of its sparing solubility in water, is but very slowly attacked, even with the aid of heat. By *mercuric oxide*, *silver oxide*, and *ferric chloride*, oxidation is rapidly effected even in the cold, and at higher temperatures the greater part of the base is resolved into nitrogen and diphenylamine, perhaps according to the equation

At the same time there is formed a greater or smaller quantity of a blue-violet nitrogenous colouring matter easily soluble in alcohol, the composition of which has not yet been determined. If, on the other hand, the oxidation takes place in the cold, and in very dilute solution, there is formed, together with products just mentioned, a variable quantity of a compound, $C^{12}H^{12}N^4$, which, from its resemblance to dimethyl-phenyl-tetrazone (p. 1058), may be called tetraphenyl-tetrazone, and represented by the constitutional formula, $(C^6H^5)^2N=N=N-N(C^6H^5)^2$.

This compound is most readily prepared by agitating diphenyl-hydrazine with a very dilute solution of ferric chloride, as neutral as possible and well cooled, whereupon the liquid assumes a blue-violet colour, and gradually solidifies to a crystalline mass, the reaction being complete when the product has become perfectly solid. This crude product is washed on a filter, first with water, then repeatedly with alcohol, which removes diphenylamine and colouring matter, leaving the tetrazone as a slightly coloured crystalline mass, which may be further purified by rubbing it to powder, boiling it with small quantities of alcohol, and recrystallising it several times from pure warm carbon disulphide.

Tetraphenyl-tetrazone melts at 123° to a yellow liquid, with evolution of gas, and formation of diphenylamine and non-volatile products. It dissolves sparingly in ether, alcohol, chloroform, and ligroin, with moderate facility in warm carbon disulphide. When drenched with concentrated acids, it turns blue and slowly dissolves, decomposing at the same time; on heating the liquid the blue colour changes to dingy green.

Benzoyldiphenyl-hydrazine, $C^{10}H^{10}N^2O = (C^6H^5)^2N^2.H.CO.C^6H^5$. This compound is obtained by gradually adding 1 mol. benzoyl chloride to a solution of 2 mol. diphenyl-hydrazine in a ten-fold quantity of ether, washing the crystalline mass which separates with slightly acidulated water to remove diphenyl-hydrazine hydrochloride, and crystallising the residue from hot acetone. The benzoyl-derivative then separates in white slender needles having a vitreous lustre. It dissolves easily in hot acetone and chloroform, less easily in alcohol and ether. It melts at 192° , and decomposes at a higher temperature. By concentrated acids it is slowly resolved into benzoic acid and diphenyl-hydrazine.

Benzylidene-diphenyl-hydrazine, $C^{10}H^{10}N^2 = (C^6H^5)^2N^2.CH.C^6H^5$, is formed on mixing diphenyl-hydrazine and benzaldehyde in molecular proportions. This solution immediately becomes turbid, from separation of water, and on cooling solidifies to a crystalline mass of the benzylidene-compound, which may be purified by recrystallisation from hot alcohol.

Benzylidene-diphenyl-hydrazine forms small crystals mostly having a faint yellow colour, and no very characteristic form. It is easily soluble in ether, chloroform, and benzene, slightly soluble in cold water. Its melting point is 122° , which is remarkable as being lower by 30° than that of benzylidene-monophenyl-hydrazine (p. 1053).

Ethyl-derivatives of Phenyl-hydrazine. It has already been observed (p. 1051) that, by the action of ethyl-bromide on phenyl-hydrazine, there is formed, in addition to phenyl-diethylazonium bromide, $C^6H^5.N^2H^2(C^2H^5)(C^2H^5Br)$, a mixture of volatile bases. These cannot be separated from one another by fractional distillation, but their separation may be effected by taking advantage of the different behaviour of the several substituted hydrazines towards oxidising agents, especially mercuric oxide, the primary bases being thereby completely decomposed, with evolution of nitrogen, the unsymmetrical secondary bases converted into indifferent tetrazone-compounds (pp. 1058, 1059), and the symmetrical secondary bases (hydrazo-compounds) into azo-compounds, while the tertiary bases remain unaltered.

The crystallised mixture of hydrobromides obtained by warming phenyl-hydrazine and ethyl bromide in molecular proportions, is dissolved in water and mixed with alkali; the oily bases thereby separated are dissolved out with ether; and the residue left on evaporating the ether is mixed with strong hydrochloric acid to remove unaltered phenyl-hydrazine. The filtrate contains the whole of the volatile ethyl-bases, which, after addition of alkali, may again be extracted with ether, and at once treated in this solution with an excess of yellow mercuric oxide. The dark brown solution resulting from the oxidation is shaken up with dilute hydrochloric acid to remove basic products consisting of a tertiary hydrazine base not yet examined, together with small quantities of aniline and ethylaniline; and on evaporating off the ether from the remaining liquid, there remains a dark-coloured oily residue which, after a while, solidifies partially to a crystalline mass; and this, when separated from the mother-liquor, and repeatedly crystallised from hot alcohol, is obtained quite white, and has the composition of diethyl-diphenyl-tetrazone, $(C^6H^5)^2(C^2H^5)^2N^4$.

The non-crystallising oily product distilled with steam yields a light yellow oil smelling strongly like phenyl cyanide, and consisting chiefly of azophenyl-ethyl, $C^6H^5.N=N.C^2H^5$, the nitro-derivative of which was obtained by Meyer and Ambühl by the action of diazobenzene sulphate on sodium nitroethane (p. 137).

Azophenyl-ethyl volatilises without decomposition, is not acted on by dilute acids, is dissolved without alteration by strong hydrochloric acid at ordinary temperatures, but completely decomposed when heated therewith. It unites with iodine dissolved in carbon sulphide, forming a dark-coloured, heavy uncrystallisable oil. It is not altered by Fehling's solution, even at the boiling heat, but when treated in alcoholic solution with zinc-dust and acetic acid, or zinc and hydrochloric acid, it is completely converted

into ethyl-phenyl-hydrazine, $\text{C}^6\text{H}_5\text{.NH—NH.C}^6\text{H}_5$. This base distills without decomposition; reduces Fehling's solution at a gentle heat; forms easily soluble salts; and is reconverted by mercuric oxide into the azo-compound (W. Ehrhardt a. E. Fischer, *Deut. Chem. Ges. Ber.* xi. 613).

C. HYDRAZINES OF THE FATTY SERIES.

Ethyl-hydrazine, $\text{C}^2\text{H}_5\text{.NH.NH}^2$ (E. Fischer, *Deut. Chem. Ges. Ber.* ix. 111). This compound is obtained from diethyl-nitrosocarbamide, $(\text{C}^2\text{H}_5)^2\text{NH—CO—N(C}^2\text{H}_5)—\text{NO}$ (see CARBAMIDES, p. 390), by reducing that compound in alcoholic solution with zinc-dust and acetic acid to diethyl-hydrazine-carbamide, $(\text{C}^2\text{H}_5)^2\text{NH—CO—N(C}^2\text{H}_5)—\text{NH}^2$, and heating the latter with strong hydrochloric acid, whereby it is resolved into carbon dioxide, ethylamine, and ethyl-hydrazine:

The *dihydrochloride* of ethyl-hydrazine crystallises in needles which give off part of their hydrochloric acid when warmed, leaving a syrupy salt, probably the monohydrochloride, closely resembling that of diethyl-hydrazine. The free base volatilises without decomposition, dissolves easily in water and in alcohol, smells strongly ammoniacal, and exhibits reactions exactly analogous to those of phenyl-hydrazine.

The hydrazines of the fatty group containing two alcohol-radicles are produced by reduction of the corresponding nitrosamines with zinc-dust and acetic acid (E. Fischer, *Deut. Chem. Ges. Ber.* viii. 1587; xi. 2206).

Diethyl-hydrazine, $\text{C}^2\text{H}_5^2\text{N}^2 = (\text{C}^2\text{H}_5)^2\text{N.NH}^2$, is formed, together with ammonia and diethylamine, by reduction of diethyl-nitrosamine (*2nd Suppl.* 861).

The action begins at ordinary temperatures, and may easily be regulated by gradual addition of the zinc and acetic acid; towards the end however it must be assisted by gently heating the liquid till the pungent odour of the nitrosamine is no longer perceptible. The liquid is then filtered, supersaturated with potash, and distilled; the distillate containing the three bases is neutralised with hydrochloric acid and evaporated to a syrup, whereby the ammonia is almost completely removed in the form of a crystalline mass of sal-ammoniac, easily separated from the deliquescent hydrochlorides of the other two bases; and the filtrate treated with solid potassium hydrate and calcined pearlsh yields a light nearly colourless oil consisting of diethylamine and diethyl-hydrazine.

These two bases are separated by means of ethyl iodide, with which the hydrazine unites directly to form triethylazonium iodide, $(\text{C}^2\text{H}_5)^2\text{N}^2\text{H}^2.\text{C}^2\text{H}_5\text{I}$, whilst the diethylamine, if the process is carefully conducted, is converted, first into triethylamine, and only at a later stage into tetrethyl-ammonium iodide. The formation of this last compound must however be prevented as far as possible, since its subsequent separation from the tetrethyl-azonium compound does not appear to be possible. The best way of proceeding is to treat 10 grams of the mixed bases with the calculated quantity of ethyl iodide; heat the mixture gently in a reflux apparatus; cool the vessel externally as soon as the liquid becomes strongly heated by the reaction; and then add water. The undecomposed ethyl iodide thereby separated is dissolved out by ether; the remaining aqueous solution, after addition of potash is freed from volatile bases by distillation; and on mixing the residual liquid with strong potash-ley, the triethylazonium iodide is precipitated as a colourless oil which soon solidifies, and may be purified by crystallisation from hot alcohol.

This compound, $(\text{C}^2\text{H}_5)^2\text{NI—NH}^2$, crystallises in slender white needles, easily soluble in water and in hot alcohol, nearly insoluble in concentrated alkalis, and forms a sparingly soluble double salt with *platinic chloride*. By silver oxide and water it is easily converted into the corresponding hydroxide, which is soluble in water, has a strong alkaline reaction, and is decomposed by heat like the corresponding ammonium hydroxides, into water, ethylene, and diethyl-hydrazine:

To prepare diethyl-hydrazine in quantity by this process, the aqueous solution of the hydroxide is distilled in an oil-bath, the temperature being ultimately raised to $140^\circ\text{—}150^\circ$, whereby a distillate is obtained consisting of an aqueous solution of the

hydrazine, which is to be mixed with hydrochloric acid, concentrated, and decomposed with potash; and the only base thereby separated repeatedly dried over solid potash and distilled.

Diethyl-hydrazine is a colourless mobile liquid having an ammoniacal odour, easily soluble in water, alcohol and ether, sparingly soluble in concentrated alkalis. Its boiling point appears to lie between 74° and 78° ; but this determination must not be regarded as exact, since the base examined contained a small quantity of triethylamine, resulting from the decomposition of the tetrethyl-ammonium iodide formed as above mentioned, simultaneously with the azonium compound.

The salts formed by diethyl-hydrazine with mineral acids are very soluble in water and in alcohol; the *hydrochloride* deliquesces in moist air. The *picrate* is less soluble, and crystallises from a warm solution in slender yellow needles; its aqueous solution decomposes at the boiling heat, with evolution of nitrogen.

Oxidation.—Diethyl-hydrazine, like the aromatic hydrazines, is decomposed by Fehling's solution, only with the aid of heat, being then resolved for the most part into diethylamine and nitrogen:

By more energetic oxidising agents, on the other hand, mercuric oxide for example, it is converted into tetrethyl-tetrazone, $(C^2H^5)^2N^4 = (C^2H^5)^2N=N=N-N(C^2H^5)^2$, analogous in constitution to the compound $C^2H^5.O=N=N-O.C^2H^5$, which Zorn obtained by the action of ethyl-iodide on nitrosyl-silver (see Nitroso-compounds).

To prepare tetrethyl-tetrazone, a cold aqueous solution of diethyl-hydrazine (the crude product answers best) is gradually mixed with yellow mercuric oxide, till the latter is no longer reduced. The liquid then becomes turbid from separation of an oil, which on agitation is for the most part taken up by the porous mass of mercury-compounds. The aqueous solution is filtered off, and the residue repeatedly washed on the filter with small quantities of alcohol, whereby the tetrazone is dissolved, and separates again in the watery filtrate: it is then separated and dried over calcium chloride.

Tetrethyl-tetrazone thus purified is an oily liquid having a faint yellow colour and peculiar alliaceous odour. It remains liquid at -17° , and is not volatile even in a vacuum. Heated to 135° – 140° in a capillary tube, it decomposes slowly, with evolution of gas; when a larger quantity is quickly and strongly heated, it detonates slightly, and is resolved into nitrogen, diethylamine, and a pungent substance not yet examined. It has decided basic properties; being easily dissolved by dilute acids in the cold, and separated therefrom by alkalis in its original state. Its *platinochloride*, $2(C^2H^5)^2N^4.PtCl^6$, separates from a moderately dilute alcoholic solution in long gold-yellow needles. It dissolves in cold water without alteration, but on boiling the solution, it is decomposed, giving off half its nitrogen as gas, and yielding at the same time diethylamine and aldehyde. The same decomposition takes place when the tetrazone itself is heated with mineral acids, the resulting solution containing diethylamine, together with variable quantities of aldehyde and a pungent substance not yet examined. The formation of diethylamine and nitrogen is represented by the equation:

Tetrethyl-tetrazone precipitates many of the salts of the heavy metals, and unites with *mercuric chloride*, forming a white, crystalline, slightly soluble mass having the composition $(C^2H^5)^2N^4.HgCl^2$. It is easily oxidised by *silver salts*; on shaking up a cold emulsion of the tetrazone with silver nitrate, an evolution of gas takes place almost immediately, accompanied by the formation of a silver speculum. Silver oxide attacks it only when aided by heat. With *iodine* it forms an explosive compound, which separates, on agitating a solution of iodine in potassium iodide with small quantities of the base, as a dark-coloured oil which detonates even at a gentle heat.

Action of Nitrous Acid.—Diethyl-hydrazine is completely decomposed by nitrous acid at ordinary temperatures, the product consisting for the most part of nitrogen monoxide and diethylamine, together with a small quantity of tetrethyl-tetrazone. The principal reaction is represented by the equation:

Diethyl-carbazide, $(C^2H^5)^2N.NH.CO.NH^2$, is formed by the action of potassium cyanate on the neutral salts of diethyl-hydrazine. It is easily soluble in water, but may be extracted by ether from a solution strongly supersaturated with potash, and crystallises in large thin plates. With platinic chloride it forms a double salt $[(C^2H^5)^2N^2H.CO.NH^2]^2PtCl^6$, which crystallises from alcohol in slender yellow needles.

Diethyl-carbazide is resolved by prolonged boiling with alkalis into carbon dioxide, ammonia, and tetrethyl-hydrazine. Nitrous acid converts it into an oily unstable nitroso-derivative.

Dimethyl-hydrazine, $(\text{CH}_3)_2\text{N}.\text{NH}_2$, formed by reducing dimethyl-nitrosamine with zinc-dust and acetic acid, is a light volatile liquid, having an ammoniacal odour, dissolving easily in water, alcohol, and ether, and reacting with Fehling's solution in the same manner as the aromatic hydrazines, but less readily; it is also more stable in presence of alkalis. Its haloïd salts volatilise without decomposition. The *hydrochloride* crystallises from alcohol and is very hygroscopic. Its *platino-chloride* has the composition $[(\text{CH}_3)_2\text{N}-\text{NH}_2.\text{HCl}]_2\text{PtCl}_4$ (Fischer, *Ber.* ix. 111).

HYDRAZOBENZENE (DICHLORO-). See BENZENE-DERIVATIVES (p. 216).

HYDRAZOBENZENE-SULPHONIC ACID. See SULPHONIC ACIDS.

HYDRAZOBENZOIC ACID. See BENZOIC ACID (AZOXY-) (p. 275).

HYDRAZOINDOLE. See INDOLE.

HYDRAZOTOLUENE. See TOLUENE.

HYDRIODIC ACID. See IODINE.

HYDROBENZAMIDE, $\text{C}^{21}\text{H}^{18}\text{N}^2 = (\text{C}^6\text{H}^5.\text{CH})^2\text{N}^2$ (iii. 183). Borodin (*Ber.* vi. 713) regards the transformation of this compound into the isomeric body, amarine, as analogous to the conversion of tertiary amines into secondary and primary amines (2nd Suppl. 57).

Lophine, $\text{C}^{21}\text{H}^{16}\text{N}^2$ (iii. 733) prepared by the dry distillation of hydrobenzamide, is very slowly attacked by alcoholic potash, with formation of ammonia and potassium benzoate. In presence of air, this act of decomposition is accompanied by an evolution of light, which is clearly visible at $+10^\circ$, and increases with the temperature until it attains its maximum intensity at 65° . The luminosity ceases if the air is expelled from the vessel containing the lophine, either by boiling the solution, or by a current of hydrogen. A solution of lophine in glacial acetic acid does not become luminous on oxidation with potassium permanganate.

Hydrobenzamide gives with alcoholic potash a feeble evanescent light. Amarine similarly treated gives a slightly weaker light than lophine, forming at the same time ammonia and a crystalline base which melts at 204° (Radziszewski, *Ber.* x. 70).

HYDROBENZOÏN, $\text{C}^{14}\text{H}^{12}(\text{OH})^2$. See DIPHENYLENE ALCOHOLS (p. 679).

HYDROBILIRUBIN. The substance so named which Maly obtained by reduction of tribromobilirubin (p. 325), is regarded by Hoppe-Seyler as identical with the colouring matter produced by the action of reducing agents on hæmatin (p. 921).

HYDROBILIVERDIN. See BILE-PIGMENTS (p. 325).

HYDROBROMOCUMENYLACRYLIC ACID, $\text{C}^{12}\text{H}^{11}\text{BrO}^2$. See CINNAMIC ACID, HOMOLOGUES OF (p. 502).

HYDROCARBONS. A new and general method of producing hydrocarbons has been discovered by Friedel a. Crafts (*Compt. rend.* lxxxiv. 1392, 1450; lxxxv. 74; *J. pr. Chem.* [2], xvi. 233). It consists in treating organic chlorides (bromides or iodides) either alone or mixed with hydrocarbons, with chloride of aluminium, zinc, or iron. When small quantities of anhydrous aluminium chloride are added to *amyl chloride*, hydrochloric acid gas is rapidly evolved, together with hydrocarbons not absorbed by bromine, and the liquid separates into two layers, one of which contains an extremely varied series of hydrocarbons, ranging from highly volatile bodies to products having a boiling point above that of mercury. The lower members belong to the paraffin series $\text{C}^n\text{H}^{2n+2}$, while the higher members are richer in carbon. When the above reaction is made to take place in presence of a hydrocarbon, the product is a combination of the radicle of the organic chloride with the hydrocarbon, less the hydrogen replaced. Thus, on mixing amyl chloride with a considerable excess of benzene, adding aluminium chloride by small quantities at a time, and submitting the products to fractional distillation, a liquid is obtained boiling at 185° – 190° , and having the composition and properties of amyl-benzene, $\text{C}^6\text{H}^5.\text{C}^5\text{H}^{11}$. By using ethyl iodide instead of amyl chloride, ethyl-benzene is formed, together with many compounds of high boiling point. Similarly, by operating under suitable conditions with benzene and methyl chloride, toluene and other higher derivatives of benzene are obtained, viz. xylene, mesitylene, and durene. Benzyl chloride and benzene yield diphenylmethane; triphenylmethane is obtained from benzene and chloroform; tetraphenylmethane from benzene and carbon tetrachloride. Similar reactions, though less definite, are obtained with organic bromides and iodides; thus ethyl iodide and benzene yield ethyl-benzene.

Hydrocarbons obtained by the Action of Water and Acids on the Carbides of Iron and Manganese.—Clocz (*Compt. rend.* lxxviii. 1565) has examined the hydrocarbons obtained by the action at a gentle heat of hydrochloric acid diluted with 2 vols. water on spiegeleisen containing 0.04 per cent. combined carbon, 0.06 MnO₂, a small quantity of silicon, and traces of phosphorus and sulphur. The evolved gas was passed through two wash-bottles filled with water, then through an upright vessel containing lumps of pumice soaked in solution of cupric sulphate, and finally through a Woulfe's bottle containing bromine under water. An oil then collected in the wash-bottles, boiling between 118° and 124°, and having the composition of octylene C⁸H¹⁶. The bromine-liquid yielded by distillation, no ethylene bromide, but a liquid having approximately the composition of propylene bromide, C³H⁴Br₂. The residue of the distillation heated with alcoholic potash, yielded bromiheptylene, C⁷H¹⁴Br (b. p. 130°) and bromooctylene, C⁸H¹⁶Br (b. p. 150°). Soft pig iron did not yield any oily hydrocarbon.

Further experiments by Clocz (*ibid.* lxxxvi. 1248) show that neither cold nor boiling water acts on spiegeleisen, but that when superheated steam is passed over the alloy heated to dull redness, hydrogen, carbon dioxide and traces of marsh-gas are produced.

By the action of dilute sulphuric acid on a ferromanganese containing iron 56.5 per cent., manganese 38.2 per cent., and combined carbon 5.0 per cent., large quantities of paraffins and olefines were evolved; pure water, however, acts only at temperatures above 300°. An alloy, which gave by analysis, Mn 85.4, Fe 5.7, Si 1.2, combined carbon 3.7, graphitic carbon 4.0, was readily attacked by water, yielding hydrogen, together with gaseous and liquid hydrocarbons. A similar alloy, containing 81.5 per cent. manganese, when acted on by water at 100°, yielded liquid hydrocarbons and a gas which contained hydrogen mixed with olefines, the products being similar to those formed by the action of dilute acids on cast iron.

From these experiments it follows that when warm water is decomposed by a carbide of manganese and iron, part of the hydrogen set free is evolved as such, while the remainder combines with the carbon to form hydrocarbons, the metals being oxidised to monoxides.

See also F. H. Williams (*Ber.* vi. 834).

Hydrocarbons from Fatty Acids.—Hydrocarbons of the paraffin series are obtained from the products of destructive distillation of the fatty acids, by agitating the crude distillates with strong sulphuric acid, treating the oil which rises to the surface with strong sulphuric acid, then drying and rectifying it. In this way, paraffins are obtained containing from 5 to 11 atoms of carbon (Calours a. Demarcay, *Compt. rend.* lxxx. 1568).

Decomposition of Hydrocarbons by Heat. Barbier has studied the action of heat on hydrocarbons by heating them to low redness (not above 500°) in exhausted combustion-tubes protected by iron-plate. The decomposition thus effected he finds to be more definite than that which takes place when the hydrocarbons are passed through red-hot tubes. *Diphenyl* thus treated is completely resolved into stilbene and toluene: $2C^{14}H^{14} = C^{14}H^{12} + 2C^7H^8$. *Stilbene* yields phenanthrene and toluene: $3C^{14}H^{12} = 2C^{14}H^{10} + 2C^7H^8$. The decomposition of *toluene* is less definite, yielding a large quantity of bulky charcoal, impregnated with a hydrocarbon which melts below 100° and smelts strongly of diphenyl, together with a small quantity of benzene. *Solid ditolyl*, C¹⁴H¹⁴ (from bromotoluene and sodium), heated to 500° remains unaltered for many hours, but is ultimately decomposed, with deposition of charcoal; no anthracene or phenanthrene is produced. *Liquid ditolyl* (b. p. 280°–285°) heated to redness for five minutes is completely resolved into anthracene, toluene and hydrogen, $2C^{14}H^{14} = C^{14}H^{10} + 2C^7H^8 + H^2$; a small quantity of phenanthrene is produced at the same time, probably from an isomeric ditolyl. A mixture of *ethylene* and *diphenyl-vapour* passed through a red-hot porcelain tube yields, together with benzene, cinnamene and naphthalene, a mixture of phenanthrene and anthracene, in which the former predominates. The reaction therefore takes place partly according to the equation, $C^2H^4 + C^{12}H^8 = C^{14}H^{10} + 2H^2$. *Benzyl-toluene* is resolved by heat into anthracene and toluene: $2C^{14}H^{14} = C^{14}H^{10} + 2C^7H^8 + H^2$. A small quantity of phenanthrene appears also to be formed. In products which Bertholot obtained in his investigation on the action of ethylene and of cinnamene on benzene (*1st Suppl.* 261), Barbier has found both anthracene and phenanthrene. *Phenylazylene* heated to redness for three minutes yields anthracene, xylene (convertible by chromic acid into terephthalic acid) benzene and hydrogen:

Diphenylmethane heated for five minutes yields anthracene, benzene, and a small

quantity of toluene, but no fluorene: $2\text{C}^{13}\text{H}^{12} = \text{C}^{14}\text{H}^{10} + 2\text{C}^6\text{H}^6 + \text{H}^2$, and $\text{C}^{13}\text{H}^{12} + \text{H}^2 = \text{C}^6\text{H}^6 + \text{C}^6\text{H}^6$. A small quantity of phenanthrene appears also to be formed. *Phenyl-toluene* (obtained by the action of sodium on a mixture of bromobenzene and liquid bromotoluene) yields when heated, benzene and toluene, but no solid hydrocarbons.

Action of Aqueous Vapour on Hydrocarbons at a Red Heat. (Coquillion, *Compt. rend.* lxxvi. 1197-1200). Dry methane and ethylene are decomposed into carbon and hydrogen by passing over a red-hot spiral of palladium wire, twice the volume of the original gas being formed. In presence of moisture, the carbon of the hydrocarbon unites with the oxygen of the aqueous vapour, forming carbon monoxide, and hydrogen is liberated; the gaseous products in this case occupy four times the volume of the original gas, e.g. $\text{CH}^4 + \text{H}^2\text{O} = \text{CO} + 3\text{H}^2$.

When a hydrocarbon mixed with a limited supply of oxygen is passed over red-hot palladium, hydrogen, carbon monoxide and dioxide, and water are formed. The amount of carbon monoxide increases and the dioxide diminishes as the supply of oxygen is decreased.

By increasing the quantity of hydrocarbon the reaction may be made to take place in two stages—

These results explain the action of aqueous vapour on hydrocarbons in the blast furnace.

Oxidation. When hydrocarbons mixed with air are passed over red-hot platinum wire, they are oxidised to aldehydes and acids. A mixture of *methane* and air passed over a platinum spiral ignited by the voltaic current, yielded formic acid, but not formic aldehyde. *Ethylene* was oxidised to acetic acid; *toluene* to benzaldehyde. Palladium acts in this manner still more energetically than platinum, becoming wrinkled and brittle and diminishing in weight (Coquillion, *Compt. rend.* lxxvii. 444).

An aqueous solution of *isopentane* (amyl hydride) containing 1 c.c. of the hydrocarbon to 2 litres of water, mixed with half its volume of a chromic acid mixture composed of 500 pts. water, 5 pts. crystallised chromic anhydride, and 1 pt. potassium dichromate, and left to itself for six weeks at a temperature of 15° to 20° , was found to be completely converted into valeric acid. *Amylene*, on the other hand, treated in like manner, yielded, in addition to carbon dioxide, a mixture of valeric, butyric, propionic, acetic and formic acids (Berthelot, *Compt. rend.* lxxix. 1093). This result differs from those obtained by Chapman and Thorp (*1st Suppl.* 118), who, by oxidising amylene at 80° – 90° with a mixture of 4–8 pts. potassium dichromate, 100 pts. water, and the requisite quantity of sulphuric acid, obtained only acetic and a small quantity of formic acid; and by Truchot (*loc. cit.*) who obtained formic, acetic, propionic, and probably also butyric, but no valeric acid. Berthelot considers that the results obtained by these chemists are not to be explained by the formation of valeric acid in the first instance, and its subsequent oxidation to acids lower in the series, but rather on the supposition that the molecule of amylene presents several points of attack to the oxidising agent, so that sometimes a greater and sometimes a smaller number of oxidation-products may be formed simultaneously.

Oxidation of the Haloid Derivatives of Olefines.—Dibromethylene is converted by agitation with dry oxygen into bromacetyl bromide:

the reaction being attended with a rise of temperature from 15° to 55° . Tribromethylene under the same circumstances also unites with 1 atom of oxygen, forming dibromacetyl bromide:

(Demole, *Ber.* xi. 315).

The compound $\text{CH}^2=\text{CHBr}$, $\text{CCl}^2=\text{CCl}^2$ and $\text{CBr}^2=\text{CBr}^2$, treated with free oxygen in presence of platinum black, are not oxidised at all. Dichlorethylene, $\text{C}^2\text{H}^2\text{Cl}^2$, which Regnault has shown to undergo polymerisation when exposed to the air (*Ann. Chim. Phys.* [2], lxxix. 157), is found to undergo a similar change, with evolution of acid vapours, when shaken up with free oxygen.

The compound $\text{CHCl}=\text{CHBr}$, which Müller obtained (*Liebig's Annalen, Suppl.* iii. 287) by the action of potassium cyanide on $\text{C}^2\text{H}^2\text{ClBr}^2$, solidifies easily, forming a polymeric modification. This compound, when shaken up with oxygen, yields a large quantity of a fuming liquid boiling at 128° – 132° , and a small quantity of an oily liquid boiling at 140° , besides some unaltered $\text{CHCl}=\text{CHBr}$. The liquid boiling at 128° – 132° is a mixture of bromacetyl chloride and chloracetyl bromide, as shown

by its boiling point, and by its yielding with water, brom- and chloracetic acids, and with alcohol, ethyl brom- and chloracetates, together with hydrochloric and hydrobromic acids. The oily liquid boiling at 140° is a polymeric modification of C^3H^2ClBr , which solidifies on exposure to the air, and carbonises when heated above 100° . Bromamylene, which contains the group $CHBr$, remains unaltered when treated with free oxygen. From these results the following conclusions may be drawn: 1. If a bromo-, chloro-, or chlorobromo-derivative of ethylene undergoes polymerisation on exposure to the air, it is also capable of absorbing oxygen, and forming an acid compound. 2. If polymerisation does not take place, oxidation cannot. 3. The final products, C^3Cl^4 and C^2Br^1 , since they contain no hydrogen, can neither be oxidised, nor can they form polymerides. 4. The bromo-derivatives of hydrocarbons homologous with ethylene, do not appear to form polymerides, or to be oxidised by free oxygen (Demolo a. Dürr, *Ber.* xi. 1302); see also Demolo (*ibid.* 1307; *Chem. Soc. J.* xxxiv. 849).

On the Imperfect Combustion and the Inflammability of Hydrocarbons, see CHEMICAL ACTION (p. 435).

On the Analysis of Volatile Petroleum Hydrocarbons by Combustion in a stream of Oxygen, see Günsberg (*Dingl. pol. J.* ccxxviii. 454; *Chem. Soc. Jour.* xxxiv. 916).

Action of Iodine Trichloride. The action of this substance on hydrocarbons, whether of the fatty or of the aromatic group, results, for the most part, in a splitting up of the molecules, and the formation of chlorinated derivatives containing smaller numbers of carbon-atoms.

Propane (or propyl chloride, b. p. 46.5°) heated with iodine trichloride to 100° – 200° in a sealed tube (which must be frequently opened to allow the escape of hydrochloric acid and then filled with chlorine-gas) is converted into perchloroethane, C^2Cl^6 , and perchloromethane, CCl^4 . Direct experiment showed that the formation of the two bodies is preceded by the formation of perchloropropane, which, under the action of chlorine, breaks up thus:

Perchloropropane is also formed by heating trichlorhydrin to 200° with iodine trichloride, as long as hydrogen chloride continues to be evolved.

Perchloropropane, heated *per se* to 300° in sealed tubes, is resolved into a mobile liquid which distils without residue between 75° and 122° , and may be separated by fractional distillation into nearly pure perchloromethane and perchloroethene: $C^3Cl^8 = CCl^4 + C^2Cl^4$. The latter when treated with iodine trichloride yields perchlorethane.

Isobutane, when heated to 210° with iodine trichloride in sealed tubes, is converted into an oily body, which is resolved by fractional distillation into perchloromethane and perchloropropane, with a little perchlorethane.

Cumene, treated with chlorine in presence of iodine, and afterwards heated to 200° with iodine trichloride in sealed tubes, is converted into perchloromethane and perchlorobenzene:

Cymene, treated in the same manner as cumene, yields perchlorobenzene, perchloromethane, and perchlorethane, the last product and half of the second being evidently formed by the breaking up of the propyl-group in cymene.

Perchlorobenzene is not affected by prolonged heating to 300° with iodine trichloride; neither are diphenylethane, anthracene, and phenanthrene broken up by like treatment (Kraft a. Merz, *Ber.* viii. 1045, 1296).

Aromatic hydrocarbons and their derivatives, subjected to *exhaustive chlorination* with chlorine containing iodine, are for the most part converted into perchlorobenzene, C^6Cl^6 , together with hydrochloric acid and various secondary products. G. Ruoff (*Ber.* 1048, 1483) subjects the compound, either in the free state or in solution, to a stream of chlorine, at first at the ordinary temperature, and with addition of a little iodine, then to the temperature of an oil bath sometimes as high as 200° , and finally heats it with excess of iodine trichloride in a sealed tube, the temperature being gradually raised from 100° to 350° , and the tube, after several hours' heating, opened from time to time in order to reconvert the liberated iodine into trichloride, and the heating then continued at 350° , till no more gas escapes on opening the tube. The final product is freed from iodine chloride by treatment with soda-ley and careful washing, and then further purified.

Diphenyl-methane thus treated is converted into perchlorobenzene and perchloromethane; *diphenyl-trichlorethane* into perchlorobenzene and perchlorethane. *Anthracene* and *phenanthrene* yield C^6Cl^6 and perchloromethane; *turpentine-oil* dissolved in 5 vol.

chloroform yields C^6Cl^6 , perchloromethane, and perchlorethane. *Diphenyl* is converted into perchlorodiphenyl, $C^{12}Cl^{10}$, which undergoes no further alteration. *Azobenzene*, *aniline* and *diphenylamine* yield C^6Cl^6 , probably with free nitrogen. *Triphenylamine* yields C^6Cl^4 and perchlorotriphenylamine, $(C^6Cl^3)^3N$, probably according to the equations, $(C^6H^3)^3N + 15Cl^2 = (C^6Cl^3)^3N + 15HCl$, and $2(C^6Cl^3)^3N + 3Cl^2 = 6C^6Cl^4 + N^2$. *Phenol*, *cresol*, *thymol*, and *resorcin* yield C^6Cl^4 , together with CO^2 , and respectively, CCl^2 and C^2Cl^6 ; CCl^4 , CCl^4 and C^2Cl^6 ; CCl^4 . *Anisöl* yields C^6Cl^4 , CO^2 and CCl^4 ; *phenetöl* yields C^6Cl^4 , CO^2 , and C^2Cl^6 . *Tetrachloroquinone* (chloranil) yields CO^2 , CCl^4 , and C^6Cl^4 . *Camphor* is converted into CCl^4 , C^2Cl^4 , and C^6Cl^4 , probably together with CO^2 . *Pyrogallol*, $C^6H^3O^3$, is the only compound which, when subjected to exhaustive chlorination, does not yield perchlorobenzene, but only perchlorethane and a small quantity of perchloromethane.

As carriers of chlorine, antimony pentachloride and molybdenum pentachloride are in many instances more effective than iodine trichloride. Respecting the latter, see Aronheim (*Ber.* viii. 1400).

On the Action of Metallic Chlorides on Aromatic Hydrocarbons at high temperatures, see also DIPHENYL (p. 658), NAPHTHALENE and TOLUENE.

Bromination. The bromination of aromatic hydrocarbons is effected by means of bromine containing iodine, in a manner similar to that described by Ruoff for effecting the chlorination. *Benzene* thus treated is converted into perbromobenzene; *toluene* into the same compound together with perbromomethane; *naphthalene* into $C^{10}H^2Br^6$ (*E. Gessner, Ber.* ix. 1555).

Conversion of the Hydrocarbons of the series C^6H^{2n} into the corresponding Alcohols. A general method of effecting this conversion by means of water or dilute acids is given by Butlerow (*Liebig's Annalen*, clxxx. 245). *Heptylene* from pentamethylethol (p. 1026), heated in a sealed tube with water, a small quantity of nitric acid, and ethyl alcohol, is reconverted into pentamethylethol. Liquid *isobutylene*, $(CH^3)^2C=CH^2$ (p. 362), similarly treated, yields trimethyl carbinol. This last transformation may also be effected by heating the isobutylene with water and a few drops of sulphuric acid to 100° . By proceeding in this way, the greater part of the hydrocarbon is converted into trimethyl carbinol, whereas isobutylene heated to 100° with a mixture of equal parts of strong sulphuric acid and water is converted into di-isobutylene. *Pseudobutylene*, $CH^3.CH=CH.CH^3$, reacts with sulphuric acid in the same manner as isobutylene.

Formation of Hydrocarbons of the Acetylene series from Aldehydes and Ketones. G. Bruylants (*Ber.* viii. 406) describes a general method of obtaining the hydrocarbons homologous with acetylene from the corresponding aldehydes and ketones, by converting these bodies into chlorides (containing the groups $CHCl^2$ and CCl^2 respectively)—by the action of phosphorus pentachloride—and dechlorinating these chlorides by means of potassium hydroxide. The aldehydes may also be treated with PBr^3 , and the products, which contain the group $CHBr^2$, debrominated with potash.

Ethylacetylene, $CH^3.CH^2.C\equiv CH$, obtained by treating methyl-ethyl ketone with PCl^5 and the product with alcoholic potash, is regarded by Bruylants as identical with crotonylene (b. p. 20° – 24°), although the brominated derivatives of the two exhibit different properties (compare *2nd Suppl.* 401). Ethylacetylene dibromide, $C^4H^2Br^2$, is liquid; the tetrabromide, $C^4H^2Br^4$, is a solid crystalline body soluble in alcohol, ether, and carbon disulphide, subliming without previous fusion at 105° , and volatilising with vapour of water.

Orthopropylacetylene, $CH^3.CH^2.CH^2.C\equiv CH$, from methylpropyl ketone, is a mobile, colourless, alliaceous liquid, boiling at 48° – 49° . The silver compound, C^5H^3Ag , is a white, the copper compound, $C^5H^3Cu.H^2O$, a yellow powder; both decompose readily in contact with the air. As intermediate products in the action of PCl^5 on methylpropyl ketone are obtained a pentylene chloride, $C^5H^{10}Cl^2$ (b. p. 145° – 147°), and a monochloropentylene (b. p. 95° – 97°) (see PENTYLENES).

Isopropylacetylene, $(CH^3)^2CH.C\equiv CH$, prepared in this manner from valeraldehyde, is a very mobile liquid having an alliaceous odour, a sp. gr. = 0.652 at 11° , and boiling at 37° . It forms a dibromide boiling, with decomposition, at 175° , and a tetrabromide. On the intermediate products obtained in the preparation of this compound, see PENTYLENES.

Heptine, $CH^{10}.CH^2.CH^2.CH^2.CH^2.C\equiv CH$ (so-called *enanthyldene*, p. 1021), is obtained by the action of PCl^5 or PBr^3 on *enanthaldehyde*.

HYDROCAROTIN, $C^{18}H^{30}O$. This substance, which Husemann obtained, together with carotin, from the root of the carrot (*iii.* 190), exists also, according to Brimmer (*N. Rep. Pharm.* xxiv. 641) in angelica root, being identical with the so-called angelicin (*i.* 293).

HYDROCARPOL, $C^{14}H^{20}O$. A phenolic compound obtained, together with others, by the dry distillation of podocarpic acid (*q.v.*) or its calcium salt.

HYDROCASTORITE. A new mineral, occurring as a mealy deposit on kernels of castor, and exhibiting under the microscope the appearance of an aggregate of slender needles. Hardness = 2. Sp. gr. = 2.16. Colour white. Doubly refractive in polarised light. Chemical composition:

SiO^2	Al^2O^3	CaO	H^2O
59.59	21.35	4.38	14.66 = 99.98.

It is undoubtedly a product of the decomposition of castor, and is found, in company with black and red tourmaline, beryl, castor, and pollux, in veins of granite at San Piero, Elba (G. Grattarola, *Jahrb. f. Min.* 1877, 411).

HYDROCHRYSAMMIDE, $C^{14}H^4(NH^2)^2O^4$. See CHRYSAMMIC ACID (p. 462).

HYDROCHLOROXYCITRACONIC ACID, $C^6H^7ClO^3$. See CITRACONIC ACID (oxy-) (p. 516).

HYDROCINCHONINES. See CINCHONA-BASES (p. 480).

HYDROCINNAMIC ACID, $C^9H^{10}O^2 = C^6H^5.CH^2.CH^2.COOH^f$. The benzylic ether of this acid, $C^9H^9O^2.CH^2(C^6H^5)$, is obtained by adding sodium (12 pts.) in thin slices to benzyl acetate (300 pts.), and heating the liquid till all the sodium has disappeared:

At 120° the action is rapid and attended with evolution of hydrogen. When it is completed, the mass is to be thrown into water, whereupon the benzylic ether separates as a light oil, which may be dissolved in ether and purified by rectification. It boils without decomposition at a temperature above 300°, and yields hydrocinnamic acid by saponification (Conrad a. Hodgkinson, *Ber.* x. 254).

HYDROCITRIC ACID (so-called). See CITRIC ACID (p. 509).

HYDROCERULIGNONE, $C^{16}H^{18}O^4$. On the substitution-derivatives of this compound, see 2nd *Suppl.* 377, and this Supplement, p. 549.

HYDROCOTARNINE. See NARCOTINE.

HYDROCYANIC ACID. See CYANIDE of HYDROGEN (p. 610).

On the estimation of Hydrogen Cyanide in pharmaceutical prussic acid by means of silver nitrate and ammonium thiocyanate, see *Chem. Soc. Jour.* xxxiv. 749.

HYDROCYANOROSOLIC ACID. See ROSANILINE.

HYDRODIAZOBENZOIC or **HYDRAZIBENZOIC ACID**, $C^7H^8N^2O^2 = NH^2.NH.C^6H^4.CO^2H$. See BENZOIC ACIDS, DIAZO- (p. 275).

HYDRODIAZOPHENYLENE, $C^{12}H^{10}N^2$, is a green base produced by the action of stannous chloride on hydro-azophenylene hydrochloride, $C^{12}H^9N^2.HCl$, or by that of hydrogen sulphide on azophenylene mercuronitrate, $C^{12}H^8N^2Hg(NO^3)^2$ (p. 139). Its hydrochloride crystallises in green laminae (Claus a. Hensinger, *Ber.* viii. 600).

HYDRODIBROM- and **HYDRODICHLOR-OXYLEPIDENE**. See LEPIDENE.

HYDRODIMETHYLCAFFEIC ACID, syn. with Methylferulic acid. See VANILLIN-DERIVATIVES.

HYDRO-ETHYL-CEDRRET, $C^{20}H^{26}O^6$. See PYROGALLIC ETHERS.

HYDROFERULIC ACID,

is formed by the action of reducing agents on ferulic acid (p. 785). It crystallises from aqueous solution in microscopic plates, melts at 89°–90°, and dissolves very easily in alcohol, ether, and hot water. It forms acid salts in which only the hydrogen of the group CO^2H is replaced by a metal, and basic salts in which the hydroxylic hydrogen is likewise replaced. The hydroferulates of the alkalis and alkaline earths are easily soluble in water. In a solution of hydroferulic acid neutralised with ammonia, silver nitrate produces a white precipitate which quickly blackens when heated; lead acetate, a white precipitate; copper sulphate throws down from very strong solutions a bluish-white salt which dissolves in excess of ammonia with blue colour. This last reaction distinguishes hydroferulic from ferulic acid, which gives with copper sulphate a dingy green precipitate, dissolving in ammonia with green colour (Tiemann a. Nagai, *Ber.* xi. 650).

HYDROFURONIC ACID, $C^7H^{10}O^5$. See FURONIC ACID (p. 834).

HYDROGEN. *Formation, Preparation, Purification.*—Selmi (*Ber.* vii. 80) observes that hydrogen is evolved during the growth of fungi, and that arsenic, antimony and sulphur may be thereby converted into their respective hydrogen-compounds; he likewise attributes to this cause the formation of hydrogen arsenide from carpets, &c., containing arsenical dyes. The hydrogen thus evolved also converts potassium nitrate, first into nitrite, then into ammonia. Nitrogen in contact with fungi, decaying wood, &c., appears also to be converted into ammonia.

According to E. Schobig (*J. pr. Chem.* [2], xiv. 289) hydrogen may be freed from its compounds with phosphorus, arsenic, and antimony by passing it through a saturated neutral or acid solution of permanganate; hydrogen sulphide, on the other hand, is not oxidised by permanganate, and must therefore be removed by subsequently passing the gas through potash- or soda-ley. Pure hydrogen is also gradually but completely oxidised by permanganate, the neutral solution acting more readily than an acid or alkaline solution.

For the preparation of hydrogen gas free from hydrogen sulphide by means of zinc and sulphuric acid, J. Löwe (*Dingl. Pol. J.* ccxi. 193) recommends the addition of cupric sulphate to the dilute acid, whereby the sulphur is removed within the generating vessel, in the form of copper sulphide. A portion of the copper is at the same time precipitated by the zinc in the metallic state, and partly redissolves, colouring the liquid blue. The addition of cupric sulphate likewise accelerates the evolution of the gas [by forming a copper-zinc couple].

According to Violette (*Compt. rend.* lxxvii. 940) hydrogen gas prepared with zinc and dilute sulphuric acid, is not contaminated with hydrocarbons.

A. R. Leeds (*Amer. Chemist*, vii. 183, 186) observes that pure hydrogen burns with a scarcely visible bluish flame; but that hydrogen evolved by means of zinc and potash-solution, or dilute sulphuric acid, burns with a blue flame, due probably to the presence of zinc hydride, which is removed by washing the gas with water or dilute acids.

H. Giffard (*Monit. Scient.* [3], iii. 156) prepares hydrogen on the large scale by first reducing iron from its ores by ignition in a stream of carbon oxide, and then replacing the latter by a current of aqueous vapour. The evolution of hydrogen is accompanied by reproduction of iron oxide, which may again be reduced and used as before for the generation of hydrogen.

On the prevention of Explosions in Hydrogen-generators, see EXPLOSION (p. 768).

Physical Properties.—The absolute weight of an atom of hydrogen has been calculated by J. Annenheim (*Ber.* ix. 1151) from considerations founded on the limit of visibility of certain colouring matters in dilute solutions. If 0.0007 grm. of fuchsine ($C^{20}H^{19}N^3HCl$) be dissolved in alcohol and the solution diluted to 1 litre, each cubic centimeter of the liquid will contain 0.0000007 gram of colouring matter. Now one drop = $\frac{1}{25}$ c.c. of such a solution placed on a white surface exhibits a distinct red coloration, whence it follows that 0.00000002 gram of fuchsine is still recognisable by the naked eye. Assuming now that such a drop must contain at least one molecule of the colouring matter, it follows that the atomic weight of an atom of hydrogen must be estimated at the extremely small magnitude of 0.000000000059 gram, namely $0.00000002 \div 337.5$ (the molecular weight of fuchsine). Nearly the same result is obtained by experiments with cyanine ($C^{22}H^{22}N^2I = 526$). When 1 milligram of this substance is dissolved in a litre of liquid, each drop still visibly coloured contains 0.000000285 gram, whence the absolute weight of the hydrogen-atom is found to be 0.00000000054 gram. Hence it follows that the absolute weight of an atom of hydrogen cannot be greater than 0.0000000005 gram.

On the Molecular Relations and Diffusion of Hydrogen; also its Friction-coefficient, Compressibility, and Deviations from the Boyle-Mariotte Law; and its Liquefaction and Solidification, see GASES (pp. 847–857).

On the Relation between the two Specific Heats of Hydrogen, see HEAT (p. 933).—*On its Heat of Combustion* (pp. 952, 962).

On the Refraction and Dispersion of Light by Hydrogen, and on its Spectrum, see LIGHT.

On Electric Polarisation by Hydrogen, see ELECTRICITY (p. 713).

On Electrolysis, with evolution of Hydrogen at both Poles (p. 711).

Combination of Hydrogen with Chlorine. When hydrogen (dried by P_2O_3) is passed over porous charcoal saturated with chlorine, a considerable quantity of hydrochloric acid is formed, even in the dark. When 50 grams of charcoal were used in the experiment, the temperature fell to -20° . Water poured upon charcoal saturated with chlorine, is decomposed, with formation of hydrochloric acid and carbon dioxide (Melsens, *Compt. rend.* lxxvi. 92).

Reduction of Silver Nitrate by Hydrogen.—Russell found that perfectly pure hydrogen reduces silver from the nitrate, most readily in concentrated solutions, and that if the solution be left for some time in contact with an atmosphere of hydrogen, crystals of silver nitrite are also formed (*2nd Suppl.* 660). According to Pellet, on the other hand (*Compt. rend.* lxxviii. 1132), a neutral solution of silver nitrate is not reduced by pure hydrogen. A solution of fused silver nitrate, however, which is somewhat alkaline from the presence of free silver oxide, is attacked at ordinary temperatures by pure hydrogen, which reduces the free silver oxide, but on acidulating the solution with nitric acid, no precipitation takes place either at ordinary or at higher temperatures. On the other hand Russell's results have been confirmed by Boketoff (*Compt. rend.* lxxix. 1413), who finds that the quantity of silver precipitated by hydrogen from a neutral solution of the nitrate is exactly proportional to that of the hydrogen absorbed; also by A. R. Leeds (*Ber.* ix. 1456), according to whose observations the quantity of silver thrown down is nearly proportional to the time of action.

Absorption of Hydrogen by Metals. 1. By Palladium. To demonstrate the absorption of hydrogen by palladium, J. L. Smith (*Amer. Chemist*, v. 213) introduces a very thin strip of palladium foil, 1.5 cm. broad and 8 cm. long into different parts of a hydrogen flame. In the upper part, where the combustion is complete, the foil retains its form unaltered; but on bringing it into the middle, where the unburnt hydrogen impinges upon its lower surface, the foil absorbs hydrogen on that surface only, and therefore curls itself up considerably. When again placed in the upper part of the flame, it resumes its original form.

Some of the physical constants of hydrogen absorbed by palladium have been determined by J. Dewar (*N. Arch. ph. nat.* l. 207). The specific gravity was found, from the mean of eight determinations, to be 0.620. The specific heat was greater when the metal was lightly charged with hydrogen than when it was strongly charged: with palladium foil it varied between 3.93 and 5.88; with palladium in bars, between 3.79 and 5.05. The expansion-coefficient of palladium charged to the maximum with hydrogen—for which Dewar gives the formula Pd^2H_2 —was, about 0.000058 between 0° and 50°, and 0.000066 between 0° and 80°.

Development of Heat in the Absorption of Hydrogen by Platinum and Palladium.—The mode of condensation of hydrogen by platinum black differs from the mode of condensation by palladium. When the gas is brought in contact with platinum black in successive portions till complete saturation is attained, the quantity of heat evolved for equal weights of the absorbed gas is not constant, as is the case with palladium. The absorption by palladium of 1 gram of active hydrogen obtained by electrolysis of dilute sulphuric acid gave:

in the first experiment	8938 gram-degrees.
„ seventeenth experiment	9167 „

The condensation of 1 gram of ordinary gaseous hydrogen by platinum gave

in the first experiment	23075 gram-degrees.
„ fourth „	13528 „

In the latter case, then, the development of heat becomes gradually smaller (Favre, *Compt. rend.* lxxvii. 649). From further experiments (*ibid.* lxxviii. 1257–1265), Favre concludes that the absorption of hydrogen by platinum is attended with the development of 2000 heat-units for 1 gram of hydrogen, and takes place without chemical alteration, but that palladium in absorbing hydrogen undergoes an allotropic modification and forms an explosive compound.

J. Moutier (*Compt. rend.* lxxix. 1242) has calculated the quantity of heat (referred to 1 kg. hydrogen) developed in the combination of hydrogen with metals, by means of the thermodynamical formula:

$$L = 0.99432 \frac{T^2}{p} \cdot \frac{dp}{dT}$$

in which p is the dissociation-tension of the compound at the absolute temperature T , based upon the values of the dissociation-tensions determined by Troost a. Hautefeuille (*Compt. rend.* lxxviii. 968; *Ann. Chim. Phys.* [5], ii. 273). The heat of combination of hydrogen with palladium increases with the temperature between 20° and 170°; for 20°, the calculated value of L is 4147; Favre's measurements gave 4154. The calculated value of the heat of combination of hydrogen with potassium at 330° is 9300, and that of sodium 13000 gram-degrees.

From measurements of the tension of the hydrogen evolved at high temperatures from palladium-hydrogen, Troost a. Hautefeuille conclude that Pd^2H_2 is a definite chemical compound, but that any additional quantity of hydrogen is taken up by

simple absorption. The temperature most favourable to the formation of the compound Pd^2H is 100° ; above 130° it is no longer produced.

On the Absorption of Hydrogen by *Iron*, see *IRON* in this volume; on its Absorption by *Potassium* and *Sodium*, see *2nd Suppl.* 659.

Hydrogen, occluded by metals and by charcoal, exerts a reducing and hydrogenising action, similar to that which it exhibits in the so-called *nascent state*. Nascent hydrogen, in fact, is hydrogen set free in contact with, or in very close proximity to a metal, which very probably condenses or occludes a portion of the gas, and it may therefore be supposed that the activity of the hydrogen under these circumstances is but the consequence of its intimate association with the metal, that is to say, of its being in the occluded condition. The great reducing and hydrogenising power of the copper-zinc couple doubtless depends also on the absorption of hydrogen by the finely divided metal.

The following table exhibits the resemblances and differences of the action of hydrogen occluded by palladium, platinum, copper, and wood-charcoal, and by the copper-zinc couple.

Substances employed	Substances produced by :				
	Copper-zinc couple	Palladium-hydrogen	Platinum-hydrogen	Copper-hydrogen	Carbon-hydrogen
Potassium Chlorate, KClO_3 , aq. solution	Chloride	Chloride	Chloride	Chloride	Chloride
Potassium Nitrate, KNO_3 , aq. solution	Nitrite and Ammonia	Nitrite and Ammonia	Nitrite and Ammonia	Nitrite and Ammonia	Nil
Potassium Ferri-cyanide, K^3FeCy^6 , aq. solution	Ferro-cyanide	Ferro-cyanide	Ferro-cyanide	—	Ferro-cyanide
Nitrobenzene, $\text{C}^6\text{H}^5\text{NO}_2$, aqueous alcoholic solution	Aniline	Aniline	Azobenzene	—	—
Indigo, with weak solution of potash	White Indigo	White Indigo	—	—	—
Sulphurous acid, H^2SO^3 , aq. solution	Sulphur	H^2S	Sulphur (probably)	—	—
Arsenious Oxide, As^2O^3 , aq. solution	AsH^3	Metallic Arsenic	Metallic Arsenic	—	—

The increased energy of the hydrogen in these combinations may be attributed :

- (1). To its association with a more negative element; this explanation will apply to the carbon-combination as well as the others, since charcoal conducts electricity freely.
- (2). To a peculiar atomic aggregation of the hydrogen, the variations shown in the experiments being, perhaps, attributable to different states of atomic aggregation.
- (3). To the condensed condition of the hydrogen, the observed differences between the actions of the different combinations being attributable to variations in this respect, or to the more or less firm hold which the metal has upon the gas (Gladstone a. Tribe, *Chem. Soc. Jour.* xxxiii. 306–313).

Occluded hydrogen also resembles nascent hydrogen (evolved by electrolysis) in its action on nitric and sulphuric acids (Gladstone a. Tribe, *Chem. Soc. Jour.* xxxv. 172–179).

HYDROGEN DIOXIDE, H^2O^2 . On the occurrence of this compound in the air, see *ATMOSPHERE* (p. 133). J. Clermont (*Compt. rend.* lxxx. 1591) has detected it in the juices of several plants—tobacco, vine, and various species of lettuce.

On the formation of Hydrogen Dioxide, together with Nitrate and Nitrite of Ammonia, by oxidation of ammonia, see *NITROGEN OXIDES*.

According to H. Struve (*Wien. Akad. Ber.* [2 Abth.], lxxviii. 432), when a shallow basin containing a dilute solution of pyrogallol is placed in another shallow basin, and covered over with a bell-jar, and the whole is exposed to sunshine or diffused daylight, hydrogen dioxide and ammonium nitrite are formed, and may be detected in the condensed water which runs down the side of the bell-jar. If potash be added to the liquid, no hydrogen dioxide is formed, but only ammonium nitrite.

Preparation.—For preparing hydrogen dioxide in considerable quantity, the following method is given by J. Thomson (*Ber.* vii. 73). Finely divided barium peroxide, or the commercial (so-called) hydrate, is dissolved nearly to neutralisation in dilute hydrochloric acid, and to the filtered and cooled solution, baryta-water is added in quantity sufficient to throw down the foreign oxides and silica present, and to produce a slight precipitate of hydrated barium peroxide. The solution is then filtered and mixed with concentrated baryta-water, whereby crystalline hydrated barium peroxide is thrown down, which, in the moist state, may be kept for a long time in closed vessels without decomposing. To prepare hydrogen dioxide, this moist hydrate is added with stirring to dilute sulphuric acid (not stronger than 1 pt. by weight of SO_4H^2 to 5 pts. of water), till the acid is very nearly saturated; the precipitate is then left to settle, the liquid filtered, and the remainder of the acid removed by cautious addition of dilute baryta-water. The moist peroxide of barium is very easily decomposed by sulphuric acid, but the action of the acid on the dried peroxide, or even on the effloresced hydrate, is very slow and imperfect.

According to Kingzett (*Chem. Soc. Jour.* [2], xiii. 210) the compound $\text{C}^{10}\text{H}^{14}\text{O}^4$, formed by oxidation of turpentine oil, splits up, in contact with water, into hydrogen dioxide and camphoric acid: $\text{C}^{10}\text{H}^{14}\text{O}^4 + 2\text{H}_2\text{O} = \text{H}_2\text{O}^2 + \text{C}^{10}\text{H}^{16}\text{O}^4$.

Reactions.—Ammonia is readily oxidised by hydrogen dioxide, yielding nitrous acid (Weith a. Weber, *Ber.* vii. 1745). Hydrogen dioxide in dilute aqueous solution converts drying oils into non-drying oils, without itself undergoing any alteration (Cohné, *Chem. News.* xxxiii. 133).

Detection.—A solution of titanate acid in sulphuric acid is a very delicate test for hydrogen dioxide, liquids containing the latter being coloured orange or yellow by the reagent, according to the quantity present (Schönn, *Dingl. pol. J.* cxx. 317). *Argentammonium nitrate*, provided it is destitute of every trace of free ammonia, is also a delicate test for hydrogen dioxide (Böttger, *loc. cit.*)

HYDROISOPYROMELLITIC ACID. See MELLITIC ACID (2nd Suppl. 633).

HYDROMETHANTHRENEQUINONE. See METHANTHRENE.

HYDROMETHYL-PARAOXYPHENYLACRYLIC ACID (p. 505).

HYDROMUCONIC ACID, $\text{C}^6\text{H}^8\text{O}^4$. See MUCIC ACID (2nd Suppl. 827).

HYDRONAPHTHOQUINONE. See NAPHTHOLS.

HYDRO-OXYBENZOIC ACID, $\text{C}^7\text{H}^6\text{O}^3$. This acid, isomeric with uvic acid, is obtained by oxidation of oxyuvic acid, $\text{C}^7\text{H}^8\text{O}^5$. With chromic acid the yield is small; with permanganate it is somewhat larger (10 per cent. of the acid used). The oxyuvic acid dissolved in sodium carbonate is added to a slight excess of the permanganate dissolved in 40 to 60 pts. water, and the resulting hydro-oxybenzoic acid is purified by recrystallisation from water. It forms thin colourless needles melting at 274.5° (corr.) and decomposing for the most part at a higher temperature. Its solution gives a yellow precipitate with ferric chloride. The *calcium salt*, $(\text{C}^7\text{H}^5\text{O}^3)_2\text{Ca} + 2\text{H}_2\text{O}$, crystallises in small slightly coloured needles, which give off their water at 160° . The *silver salt*, $\text{C}^7\text{H}^5\text{O}^3\text{Ag}$, is obtained by precipitation from the calcium salt, but is not quite insoluble in water. Hydro-oxybenzoic acid fused with potash is converted into benzoic acid: $\text{C}^7\text{H}^6\text{O}^3 = \text{C}^7\text{H}^6\text{O}^2 + \text{H}_2\text{O}$. Oxyuvic acid is also converted into hydro-oxybenzoic acid by oxidation with weak nitric acid; but stronger nitric acid converts it into trinitrocresol (Emmerling a. Oppenheim, *Ber.* ix. 326 and 1094).

HYDRO-OXYCAMPHORONIC ACID, $\text{C}^9\text{H}^{14}\text{O}^6$. This acid is formed, together with camphoric acid, $\text{C}^{10}\text{H}^{16}\text{O}^4$, and camphoronic acid, $\text{C}^9\text{H}^{12}\text{O}^5$ (pp. 375, 376), by oxidising camphor with nitric acid, and is found, together with camphoronic acid, in the mother-liquors from which the camphoric acid has crystallised out. For the method of separating it from camphoronic acid, see p. 376. It is very soluble in hot, less soluble in cold water, and separates from the hot solution on cooling in beautiful triclinic crystals melting at 164.5° . Its aqueous solutions have a strongly acid reaction, and give no precipitate with ammonia and barium chloride, a character by which it is distinguished from camphoric acid.

Three of the hydrogen-atoms in hydro-oxycamphoric acid can be replaced by metals, and it also forms mono- and dimetallic salts. The *acid ammonium salt*, $\text{C}^9\text{H}^{13}(\text{NH}^4)\text{O}^6$, crystallises in colourless needles, forming globular aggregations, and melts at 178° , solidifying after some time to a porcelain-like mass. The neutral ammonium and potassium salts crystallise well, and deliquesce on exposure to the air.

The *monocalcic salt*, $\text{C}^9\text{H}^{12}\text{CaO}^6 + 2\text{H}_2\text{O}$, is easily soluble in water, and crystallises

in silky needles concentrically grouped. The corresponding *barium salt* has been obtained only as a gummy mass.

The *tricalcic salt*, $(C^9H^{11}O^6)_2Ca^3$, has been obtained as a colourless gummy mass. The corresponding *barium salt*, $(C^9H^{11}O^6)_2Ba^3$, separates in crystalline scales, easily soluble in water.

The *tricupric salt*, $(C^9H^{11}O^6)_2Cu^2$, is obtained as a bluish-green precipitate by boiling the aqueous solution of the acid with copper acetate. When dried it forms a bluish-green powder insoluble in water.

The *triargentic salt*, $C^9H^{11}Ag^3O^6$, is a white precipitate almost insoluble in cold, but soluble in hot water.

Hydro-oxycamphoronic acid heated with bromine in sealed tubes at 120° – 125° , gives hydrobromic acid and an acid melting at 226° , having the composition $C^9H^{12}O^6$, and therefore isomeric with oxycamphoronic acid.

HYDROTITANITE. This name is given by G. König (*Jahrb. f. Min.* 1876, 774) to a soft greyish mass, formed by the transformation of the perowskite of Magnet Cove, Arkansas. It contains:

TiO ²	FeO ²	MgO	CaO	H ² O	Sp. gr.
82.82	7.76	2.72	0.80	5.50 = 99.60	3.681.

HYDROTOLUQUINONE. See TOLUQUINOL.

HYDROVANILLOÏN. See VANILLOÏN.

HYDROVINIC ACID. See PYROTARTARIC and UVITIC ACIDS.

HYDROXAMIC ETHERS. See HYDROXYLAMINE (p. 1079).

HYDROXYCAPRYLIC ACID, $C^8H^{16}O^3 = C^6H^{13}.CHOH.COOH$ (Erlenmeyer a. Sigel, *Ber.* vii. 697, 1108; *Liebig's Annalen*, clxxvii. 102). An acid of this composition, analogous to the amidocaprylic acid already described (p. 379), is obtained as a bye-product in the preparation of the latter from œnanthol-ammonia, hydrocyanic acid, and hydrochloric acid, and in larger quantity by the use of œnanthol itself instead of the ammonia-compound. The best mode of proceeding is to mix in a well-cooled vessel equal volumes of œnanthol and absolute hydrocyanic acid (the aqueous acid, may also be used, but the mixture must then be left to itself for some time at 30°). The product, which should form a clear solution with fuming hydrochloric acid, is boiled with hydrochloric acid in a reflux apparatus (for $\frac{1}{4}$ -hour if 1.5 pts. of hydrochloric acid of sp. gr. 1.19 be used), then mixed with water. The oily layer which floats on the solution of sal-ammoniac is then dissolved in ether, and on evaporating the ether, the hydroxycaprylic acid is obtained in large plates of undeterminate form, unctuous to the touch and soft enough to be cut with a knife. It has a sour taste, cooling at first, afterwards sharp and somewhat burning. It melts at 69.5° . Heated to 120° in a sealed tube with hydrochloric acid, it is easily resolved into œnanthol and formic acid.

Ethyl Hydroxycaprylate, $C^8H^{15}(C^2H^5)O^3$, prepared by saturating the alcoholic solution of the acid with gaseous hydrogen chloride, is a liquid boiling at 229° – 230° (bar. 715 mm.)

Hydroxycaprylonitril, $C^8H^{13}NO$ or $C^6H^{13}.CHOH.CN$, remains, though not quite pure, when the product obtained by heating œnanthol with hydrocyanic acid is evaporated on the water-bath. It is a clear colourless oil of sp. gr. 0.9048 at 17° , remains liquid at -16° and cannot be distilled either alone or with vapour of water,

beginning to split up, even at 115°, into prussic acid and cyanthol. It dissolves easily in alcohol and ether, sparingly in water. The aqueous solution gives no precipitate with silver nitrate at ordinary temperatures, but a precipitate of silver cyanide on boiling. It is decomposed by potash-solution with separation of hydrocyanic acid.

Hydroxycaprylamide, $C^8H^{17}NO^2 = C^8H^{13}.CHOH.CONH^2$, is slowly formed from the nitril by solution of sodium carbonate or by cold hydrochloric acid of sp. gr. 1.1, immediately by fuming hydrochloric acid (sp. gr. 1.19), the temperature in the latter case not being allowed to rise above 40°. The clear mixture soon solidifies to a pulp of crystals, which increase on addition of water, and may be washed with water and purified by recrystallisation from hot water. The amide thus prepared forms white laminae having a satiny lustre, melting at 150°, rather sparingly soluble in cold, somewhat more easily in hot water. It also dissolves in alcohol and in ether; and is precipitated from the alcoholic solution by water in the crystalline state.

HYDROXYLAMINE, NH^2O . *Formation*.—This compound, originally obtained by the reducing action of tin and hydrochloric acid on nitrous acid and ethyl nitrite (1st Suppl. 722), is likewise produced by means of the same reagent from the nitro-paraffins and nitrolic acids.

1. *Dinitropropane* is resolved thereby into hydroxylamine and acetone:

Dilute hydrochloric acid is added to the pulverised nitro-compound in a vessel fitted with a reversed condenser, and metallic tin is added, the vessel being kept cool and the mass continually shaken. On evaporating the product, hydroxylamine hydrochloride crystallises out (V. Meyer a. Locher, *Ber.* viii. 216).

2. *Dinitrobutane*, similarly treated, yields hydroxylamine, and a ketonic body, probably methyl-ethyl ketone (Meyer, *ibid.* ix. 701).

3. *Ethyl-nitrolic acid* (2nd Suppl. 894), treated with tin and hydrochloric acid, is resolved into hydroxylamine and acetic acid:

When ethyl-nitrolic acid is suddenly brought in contact with tin and strong hydrochloric acid, a violent reaction ensues, and the greater part of the nitrolic acid is decomposed, with evolution of red nitrous vapours; but by proceeding as follows, the reaction may be made to go on regularly and without violence. The solution of the nitrolic acid in the smallest possible quantity of lukewarm water is quickly cooled, and to the fine crystalline pulp thus obtained, finely granulated tin is added, and then dilute hydrochloric acid, by drops and with constant stirring, till further addition no longer produces rise of temperature, and a sample of the liquid treated with ether no longer gives up ethyl-nitrolic acid. The acetic acid produced by the reaction is easily separated by diluting the product with water and distilling, and the hydroxylamine may be obtained from the residue (Meyer a. Locher, *loc. cit.*)

4. *Nitroform* (as ammonia-salt), treated in like manner, yielded hydroxylamine hydrochloride, hydrocyanic acid, sal-ammoniac, a small quantity of nitrogen monoxide, and a volatile substance—probably formic acid—which reduced silver-solution (Meyer a. Locher).

5. *Nitromethane*, heated with sulphuric acid, is resolved into hydroxylamine and carbon monoxide:

Equal volumes of nitromethane and fuming sulphuric acid are heated together on the sand-bath in a retort with reversed condenser till a brisk evolution of gas sets in, after which the reaction goes on spontaneously to the end, with considerable rise of temperature, so that it is necessary to mix only small quantities of the materials together at a time. The viscid products of the reaction are then heated on the water-bath till the pungent odour of sulphuric acid is no longer perceptible, then gradually added, with brisk stirring, to a mixture of alcohol and ether; and the crystalline mass which settles down is washed on a filter with the same mixture and dried under the exsiccator. If not yet quite white, it must be dissolved in water, and the solution filtered, concentrated, and mixed with alcohol, whereupon it yields snow-white shining crystals of hydroxylamine sulphate. This salt melts at 140°, and the crystals, according to measurements by Dathe, are not monoclinic as formerly stated (1st Suppl. 723), but triclinic, exhibiting the forms ∞P , $\infty P\infty$, P , $2P3$, $P\infty$, $P\infty$ (Preibisch, *J. pr. Chem.* [2], viii. 316). It unites with aluminic, chromic, and ferric

sulphates to form the following double salts, which correspond exactly in composition and crystalline form with the alums:—

A double sulphate of hydroxylamine and magnesium has also been obtained, crystallising in long needles having the composition $\text{MgSO}^4(\text{NH}^2\text{OH})^2\text{H}^2\text{SO}^4 6\text{aq}$ (Meyeringh, *Ber. x.* 1946).

Reactions.—Hydroxylamine reduces many metallic salts in neutral or alkaline solution, with formation of nitrogen monoxide or free nitrogen (1st *Suppl.* 723). By *Fehling's solution* in excess, it is completely oxidised to nitrogen monoxide and water: $2\text{NH}^2\text{O} + \text{O}^2 = \text{N}^2\text{O} + 3\text{H}^2\text{O}$ (*J. Donath, Ber. x.* 766). According to Lossen (*ibid.* viii. 357) it sometimes acts in the same manner also in acid solutions; *platinic chloride*, for example, is reduced when heated for some time with hydroxylamine hydrochloride. In some cases, on the other hand, it appears to act as an oxidising agent; thus *aldehyde* in contact with hydroxylamine is converted into acetic acid; and *thiocarbamilide* gently heated with it is decomposed, with precipitation of the whole of the sulphur and formation of a compound which crystallises in needles (*R. Schiff, Gazz. chim. ital. vi.* 244).

With *dibromonitroethane*, hydroxylamine forms ethyl-nitrolic acid:

(*Meyer a. Locher, Ber. vii.* 1614). See NITROLIC ACIDS.

Constitution and Derivatives of Hydroxylamine.

This compound is usually represented by the formula $\text{NH}^2\cdot\text{OH}$, or as ammonia having one of its hydrogen-atoms replaced by hydroxyl. This view is supported by the formation of hydroxylamine by reduction of nitric acid $\text{NO}^2\cdot\text{OH}$, which is precisely analogous to that of organic nitro-compounds to amines; also by the behaviour of the compound to acids, which exactly resembles that of ammonia, the nitrogen, which is trivalent in the base, becoming quinivalent in the salts; thus

If hydroxylamine were represented by the formula $\text{H}^2\text{N}=\text{O}$, in which the nitrogen already possesses its highest combining capacity, further combination could scarcely take place.

Additional proof that hydroxylamine should be represented by a formula in which the function of at least one of the three hydrogen-atoms is different from that of the other two, is afforded by the fact, already noticed (2nd *Suppl.* 662), that benzanis-hydroxylamine formed by the action of amyl chloride on benzhydroxamic acid, and anisbenzhydroxylamine formed by the action of benzoyl chloride on anishydroxamic acid, are not identical but isomeric. Regarding hydroxylamine as $\text{HNH}\cdot\text{OH}$, the reactions just mentioned may be represented by the following equations:

This view of the constitution of the hydroxamic acids is likewise supported by the following reactions:

1. Benzanishydroxylamine is resolved by the action of barium hydroxide into benzhydroxamic and anisic acids:

and anisbenzhydroxylamine in like manner into anishydroxamic and benzoic acids.

2. Potassium-benzanishydroxylamine is decomposed by boiling water into diphenyl-carbamide, carbon dioxide, and potassium anisate:

Potassium-anisbenzhydroxylamine, in like manner, yields potassium benzoate and dimethoxyl-phenylcarbamide:

3. Benzanishydroxylamine is resolved by distillation into anisanilide $\text{NH}(\text{C}^6\text{H}^5)(\text{C}^6\text{H}^5\text{O}^2)$ and anisic acid; anisbenzhydroxylamine yields the amide $\text{NH}(\text{C}^6\text{H}^5.\text{OCH}^3)(\text{C}^6\text{H}^5\text{O}^2)$ isomeric with anisanilide, and benzoic acid (Lossen, *Liebig's Annalen*, clxxv. 271). From further researches (*Liebig's Annalen*, clxxvi. 1-24), Lossen concludes that all the three atoms of hydrogen in hydroxylamine differ in function one from the other; inasmuch as there can exist three different tertiary derivatives, in which two of the hydrogen-atoms are replaced by benzoyl, and one by anisyl, and three others in which two hydrogen-atoms are replaced by anisyl, and one by benzoyl. Thus, distinguishing the three hydrogen-atoms by the figures 1, 2, 3, it is found that the three bodies,

Benzanisbenzhydroxylamine	$\text{N}(\overset{1}{\text{C}^6\text{H}^5\text{O}})(\overset{2}{\text{C}^6\text{H}^5\text{O}^2})(\overset{3}{\text{C}^6\text{H}^5\text{O}})\text{O}$
Dibenzanishydroxylamine	$\text{N}(\overset{1}{\text{C}^6\text{H}^5\text{O}})(\overset{2}{\text{C}^6\text{H}^5\text{O}^2})(\overset{3}{\text{C}^6\text{H}^5\text{O}^2})\text{O}$
Anisdibenzhydroxylamine	$\text{N}(\overset{1}{\text{C}^6\text{H}^5\text{O}^2})(\overset{2}{\text{C}^6\text{H}^5\text{O}})(\overset{3}{\text{C}^6\text{H}^5\text{O}})\text{O}$
are all different, as are also the three,	
Anisbenzanishydroxylamine	$\text{N}(\overset{1}{\text{C}^6\text{H}^5\text{O}^2})(\overset{2}{\text{C}^6\text{H}^5\text{O}})(\overset{3}{\text{C}^6\text{H}^5\text{O}^2})\text{O}$
Dianisbenzhydroxylamine	$\text{N}(\overset{1}{\text{C}^6\text{H}^5\text{O}^2})(\overset{2}{\text{C}^6\text{H}^5\text{O}^2})(\overset{3}{\text{C}^6\text{H}^5\text{O}})\text{O}$
Benzdianishydroxylamine	$\text{N}(\overset{1}{\text{C}^6\text{H}^5\text{O}})(\overset{2}{\text{C}^6\text{H}^5\text{O}^2})(\overset{3}{\text{C}^6\text{H}^5\text{O}^2})\text{O}.$

Moreover, each of these isomerides is capable of crystallising in different forms differing in appearance and melting point (though not in chemical reactions), so that more than one physical modification of each isomeride exists; these modifications are distinguished as α , β , γ *benzanisbenzhydroxylamine*, &c.

To prepare these bodies, benzoyl or anisyl chloride is made to react on the calculated quantity of the dry silver salt of the appropriate dihydroxamic acid, the materials being dissolved or suspended in benzene, and allowed to remain in contact at the ordinary temperatures until the decomposition of the silver salt is complete. The insoluble mass thus left consists of the required tri-derivative (practically insoluble in benzene) mixed with silver chloride and more or less of the dihydroxamic acid, according to the greater or lesser purity of the organic chloride used. On boiling with alcohol and cooling the filtered solution, the tri-derivative separates as an oily or semi-solid mass, soon becoming crystalline, and only sparingly soluble in cold alcohol.

(1). **Benzanisbenzhydroxylamine**, $\text{N}(\overset{1}{\text{C}^6\text{H}^5\text{O}})(\overset{2}{\text{C}^6\text{H}^5\text{O}^2})(\overset{3}{\text{C}^6\text{H}^5\text{O}})\text{O}^*$, is obtained by the action of benzoyl chloride on the silver salt of benzanishydroxamic acid, in three modifications, the reaction taking place according to the equation:

The α -modification crystallises in the triclinic system, and melts at 113° - 114° ; this is the modification formed in largest quantity: the β -variety crystallises in rhombic forms, melting at 124° - 125° , and is chiefly found in the alcoholic mother-liquors of the first crystallisation of the crude product of the reaction. The γ -modification crystallises in the monoclinic system, together with the α -crystals, and is separable only by hand-picking: it appeared to melt at 110° ; but after fusion and solidification (which required a week) it melted at 120° , indicating that by fusion it had become converted into the β -modification. In one preparation, out of 46 grams of the three modifications jointly, 35 of the α , about 6 of the β , and about 5 of the γ variety were obtained.

When either of these modifications is heated with dilute hydrochloric acid, decomposition is brought about in accordance with the following reaction, benzanishydroxamic acid being formed—

If, however, the acid be too strong or the action be too prolonged, more or less of the

* The names of these tertiary derivatives, and the numbers placed over their formulæ, are intended to indicate nothing more than the order in which the several radicles are introduced into the hydroxylamine molecule.

product becomes split up, in accordance with the following equation, into benzoic acid, anisic acid, and hydroxylamine:

The α -modification is partially split up, and chiefly in accordance with equation (1), by heating to 100° for half an hour with 8–10 parts of hydrochloric acid of sp. gr. 1.05; the β -modification suffers no change under these circumstances; nor is more than a small quantity decomposed if the acid have a sp. gr. of 1.14; by using fuming acid, however, it is decomposed, mostly in accordance with equation (2); benzhydroxamic acid, formed in accordance with equation (1) was however separated from the products of the reaction. Modification- γ behaves as though it were a mixture of α and β , although its crystalline form negatives the supposition that such is its character; when heated with acid of sp. gr. 1.05 to 100° , it formed benzoic and benzhydroxamic acids, like the α -modification, whilst a considerable residue remained unaltered, which on examination was found to be identical with the β -variety. Nearly 40 per cent. of the β -variety was thus obtained from the γ (selected well-defined crystals being used), far too large a quantity to be due to accidental admixture from imperfect separation of the two kinds of crystals.

Similarly, alcoholic potash decomposes each of the modifications α and β in accordance with the reaction—

forming ethyl benzoate and potassium benzanishydroxamate. When aqueous caustic potash is used, the α -modification is decomposed to a considerable extent in a similar way, forming potassium benzoate and benzanishydroxamate; but a different reaction also takes place to a small extent, forming potassium anisate and dibenzhydroxamate; whilst a small quantity of substance becomes yet further decomposed, forming a mono-hydroxamic acid.

On heating the α -modification, it decomposes, with slight carbonisation, in accordance with the reaction—

producing phenyl isocyanate and benzanisic anhydride, just as tribenzhydroxylamine forms phenyl isocyanate and benzoic anhydride; a small portion also decomposes in accordance with the reaction—

forming the isocyanate of oxymethyl-phenyl, and benzoic anhydride. Quantitative estimations of the amount of benzoic acid finally produced by first heating a weighed quantity of α -benzanisbenzhydroxylamine in a sealed tube, and then heating the products of the decomposition with strong hydrochloric acid, yielded 35.6 per cent., the first equation requiring 32.5, and the second twice as much: whence the second reaction occurs only to a very small extent.

(2). **Dibenzanishydroxylamine**, $\text{N}(\text{C}^7\text{H}^5\text{O})(\text{C}^7\text{H}^5\text{O})(\text{C}^8\text{H}^7\text{O}^2)\text{O}$, is known in two modifications only, which are obtained in the manner above described by the action of anisyl chloride on silver dibenzhydroxamate. *Modification a* melts at 110 – 110.5° ; crystals monoclinic; with hydrochloric acid of sp. gr. 1.05 it easily splits up, forming anisic and dibenzhydroxamic acids. *Modification b* melts at 109° – 110° ; crystallises in rosettes, occurring with the last crops of crystals of a : crystalline system not determined; not attacked appreciably by hydrochloric acid of sp. gr. 1.05, but split up on prolonged heating with acid of sp. gr. 1.14, dibenzhydroxamic acid being the only dihydroxamic acid produced; most of the substance, however, was wholly split up, forming benzoic and anisic acids and hydroxylamine.

The action of potassium hydroxide on these two modifications is different from what might be expected, as, instead of the last anisyl-group being eliminated, the products formed in each instance are the potassium salts of benzoic and benzanishydroxamic acids, thus:

The silver salt of the benzanishydroxamic acid thus produced is converted by benzoyl chloride into benzanisbenzhydroxylamine.

α -Dibenzanishydroxylamine is decomposed by heat exactly in the same manner as the corresponding modification of benzanisbenzhydroxylamine, the chief products

being phenyl isocyanate and benzanisic anhydride, whilst small quantities of phenylmethenyl isocyanate and benzoic anhydride are likewise produced.

(3). **Anisidibenzhydroxylamine**, $N(C^6H^5O)(C^7H^5O)(C^7H^5O)O$, is formed by the action of phenyl chloride on silver anisbenzhydroxamate. The α -modification forms monoclinic crystals melting at 137° – 137.5° . It is slowly decomposed by hydrochloric acid of sp. gr. 1.05, more readily by acid of sp. gr. 1.14, forming anisbenzhydroxamic acid; potash forms the same acid. When heated alone, it yields phenylmethoxyl isocyanate and benzoic anhydride in considerable quantity, and only small quantities of phenyl isocyanate and benzanisic anhydride, behaving in this way just conversely to the two isomerides above described.

The β -modification melts at 109.5° – 110.5° , and crystallises in small rosettes of undetermined system. It is not decomposed by hydrochloric acid of sp. gr. 1.05, and only partially attacked by acid of sp. gr. 1.14. With potash it forms anisbenzhydroxamic acid.

By reactions exactly analogous to those above described, three metameric dianisbenzhydroxylamines are produced, two of which form α and β modifications.

(4). **Anisbenzanishydroxylamine**, formed from anisyl chloride and silver anisbenzhydroxamate, melts at 152° – 153° , and separates from ethereal solution in monoclinic crystals, with tabular development in the direction of the orthodiagonal. Axes, $a : b : c = 0.8662 : 1 : 0.3803$; angle $ac = 75^\circ 21.5'$. Hydrochloric acid of sp. gr. 1.05 easily decomposes it, forming anisic and anisbenzhydroxamic acids; with potash it yields benzoic and dianishydroxamic acids. The β -modification melts at 148° – 149° , and forms monoclinic crystals with tabular development parallel to the plane of symmetry. Axes, $a : b : c = 1.0015 : 1 : 0.7887$; angle $ac = 89.51$. This modification is formed in very small quantity only as compared with the α -modification (1 : 34).

(5). **Dianisbenzhydroxylamine**, from silver dianishydroxamate and benzoyl chloride, is known in one modification only. It forms monoclinic crystals melting at 147.5° ; is slowly attacked by hydrochloric acid of sp. gr. 1.05, more rapidly by stronger acid, forming benzoic acid and dianishydroxamic acid, with no benzoylated hydroxamic acid of any kind. Caustic potash forms chiefly benzoic and dianishydroxamic acids, together with some anisic and anisbenzhydroxamic acids.

(6). **Benzdianishydroxylamine** is obtained in two modifications from silver benzanishydroxamate and anisyl chloride. The α -modification melts at 137° – 138° , and crystallises in triclinic prisms with oblique end-faces. Axes $a : b : c = 0.8025 : 1 : 0.955$; angle $bc = 99^\circ 45'$; $ac = 115^\circ 58'$; $ab = 74^\circ 43'$. Observed forms: $0P$, ∞P , ∞P , P_∞ , $\frac{1}{2}P$. Cleavage perfect parallel to ∞P . The β -modification melts at 137.5° – 138° , and likewise forms triclinic crystals, differing however from the α -modification in the magnitudes of their angles. Axes $a : b : c = 0.4284 : 1 : 1.3997$; angle $bc = 103^\circ 7'$; $ac = 96.16$; $ab = 89.25$. Observed forms $0P$, P , P , P , P , ∞P . Cleavage perfect parallel to $0P$. Both modifications are easily decomposed by hydrochloric acid of sp. gr. 1.05 into anisic and benzanishydroxamic acids; the α -modification also by caustic potash.

On comparing together the modes of decomposition of the above described tertiary hydroxylamines by hydrochloric acid, it is found that the radicle which is last introduced, and completes the formation of the tertiary hydroxylamine-derivative, is also the one first eliminated, the other two remaining later. The same rule applies to the action of potash, in many cases but not in all, benzanisbenzhydroxylamine and benzdianishydroxylamine forming partial exceptions, and dibenzanis- and anisbenzanishydroxylamine total exceptions to the rule. On the other hand, it is found that the radicle which is first introduced and forms a primary hydroxylamine derivative remains last when the tertiary derivative formed from this primary derivative is decomposed by potash in such a manner as to eliminate two out of the three radicles.

The optical examination of the crystals of the tertiary hydroxylamines—all of which exhibit strong double refraction—shows that the metameric modifications have certain optical properties in common. In benzanisbenz- and anisbenzanishydroxylamine, the planes of the optic axes for all colours are perpendicular to the plane of symmetry; the second median lines coincide with the axis of symmetry, and horizontal dispersion takes place round the first median lines. In dibenzanis- and dianisbenzhydroxylamine, the planes of the optic axes for all colours have the same positions, but the first median lines coincide with the axis of symmetry, and crossed dispersion takes place round this axis. There is therefore a certain correspondence between the optical and chemical characters of these bodies, indicating a connection between their physical structure and chemical properties.

Tribenzhydroxylamine, $N(C^6H^5O)^3O$ (Lossen, *Liebig's Annalen*, clxxv. 282, 299; clxxxvi. 3, 34. O. Lehmann, *Zeitschr. f. Kristallographie*, i. 627. Klein a. Trechmann, *Liebig's Annalen*, clxxxvi. 76; *Zeitschr. Kryst.* i. 637). This compound is known in three modifications (α , β , γ), which are formed simultaneously by the action of benzoyl chloride on the potassium or silver salt of dibenzhydroxamic acid. With the former the action takes place at the temperature of the water-bath, and is completed almost instantaneously. As however the potassium salt decomposes spontaneously at this temperature, it is better to use the dry silver salt; 10 parts of this salt are drenched with 30 parts of dry benzene, and 4 pts. of benzoyl chloride diluted with 8 pts. benzene are added. The mixture, which at first forms a stiff paste, gradually separates into a precipitate and a liquid which leaves a small residue on evaporation. The precipitate, consisting of silver chloride, α and β tribenzhydroxylamine, and dibenzhydroxamic acid, is washed with ether, which takes up chiefly the α -modification, and then with boiling alcohol, which dissolves the β - and γ -compounds and the rest of the dibenzhydroxamic acid. The alcoholic solution treated with solution of sodium carbonate yields a precipitate consisting of the β - and γ -modifications, which may be purified by recrystallisation from ether or alcohol, the β -compound then separating in many-faced prisms or needles, the γ -compound (according to Steiner, *Liebig's Annalen*, clxxv. 240) in short thick crystals resembling rhombohedrons; the two kinds of crystals may be separated by hand-picking.

α Tribenzhydroxylamine melts at 100° , and is resolved by heating for an hour with hydrochloric acid of sp. gr. 1.05 into dibenzhydroxamic and benzoic acids. It is very soluble in benzene, and crystallises therefrom, also from oil [? petroleum], and from a state of fusion, without alteration. The crystals are monoclinic, exhibiting the forms OP , $\infty P\infty$, $+P\infty$, $-P\infty$, $+2P\infty$, ∞P , $\infty R3$. Cleavage very distinct parallel to $\infty P\infty$; less distinct parallel to OP . Axes, $a:b:c = 1.856:1:1.1418$. Angle $ac = 81^\circ 42'$. Plane of the optic axes $\infty R\infty$. Double refraction strong.

β Tribenzhydroxylamine melts at 141° – 142° , and is less soluble in benzene than the preceding modification. It crystallises in the monoclinic system. Axes $a:b:c = 0.8970:1:0.3004$. Angle $ac = 83^\circ 21'$. Observed forms: ∞P , $-P$, $R\infty$, $\infty P\infty$, $\infty R\infty$. Cleavage parallel to $\infty P\infty$. Plane of optic axes $\infty R\infty$. Double refraction, positive, strong. This is the modification described in *2nd Suppl.* pp. 155, 156.

γ Tribenzhydroxylamine melts at 112° , and forms short monoclinic prisms ∞P , OP , cleavable parallel to both faces. Axes, $a:b:c = 0.9257:1:?$. Angle $ac = 65^\circ 54'5'$. Plane of optic axes, $\infty R\infty$. Double refraction strong. Dispersion slight and inclined. This modification is resolved by alcoholic potash into the ethylic ethers of benzoic and dibenzhydroxamic acids.

With regard to the constitution of these isomeric derivatives, it has already been observed that Lossen regards the differences between them as affording proof that the three combining capacities, or quantivalencies, of a nitrogen-atom are each different one from the other. At the same time he observes that the occurrence of three modifications of α , β , γ of a given tri-substitution derivative of hydroxylamine may be explained by difference of position of the substituted radicles; thus, anisidibenzhydroxylamine, which contains the group C^6H^5 twice and C^6H^5O once, might exhibit the three following modifications:

Moreover, polymerisation may be supposed to take place by the nitrogen becoming pentadic, so as to give rise to di-hydroxylamine, $\begin{smallmatrix} HO \\ | \\ H^2 \end{smallmatrix} N = N \begin{smallmatrix} OH \\ | \\ H^2 \end{smallmatrix}$; and in this, the replacement of two hydrogen-atoms by a radicle A, and of a third by another radicle B, may give rise to nine different modifications, according to the relative positions taken up by these radicles.

Hydroxamic Ethers (Lossen, *Ber.* vi. 1392; vii. 841; *Liebig's Annalen*, clxxv. 284, 313. Pieschel, *ibid.* 305. Eiseler, *ibid.* 326. Rostoski, *ibid.* clxxviii. 213. Waldstein, *ibid.* clxxxi. 384. Lossen a. Zanni, *ibid.* clxxxii. 220). Lossen has shown that the di-derivatives of hydroxylamine containing two acid radicles, R, R' (which may be the same or different) may be represented by the general formula $R.NH.OR$, (p. 1075). These compounds are acids, in which the hydrogen-atom of the NH-group may be replaced by metals and alcohol-radicles, giving rise to normal salts and ethers.

Dibenzhydroxamic acid, $C^6H^5O.NH.OC^6H^5O$, has been already described (2nd Suppl. pp. 154, 662). Its *potassium salt* is decomposed by water into carbon dioxide, potassium benzoate, and (not $N^2C^{10}H^{10}O$ as formerly stated, but) symmetrical diphenyl-carbamide, or carbanilide, $CO(NH.C^6H^5)^2$, identical with that which is obtained by the several reactions given in vol. i. p. 756, and by heating urea with aniline (Baeyer, 1st Suppl. 398):

The proof that the diphenylcarbamide thus produced is really the symmetrical modification is afforded by the fact that when heated with strong hydrochloric acid to 180° , it is resolved into CO^2 and aniline:

(Lossen, *Ber.* vii. 841).

These results have been confirmed by Rotermund (*Liebig's Annalen*, clxxv. 257), who also finds that the reaction is the same with hot and with cold water; 1 mol. dibenzhydroxamic acid and 1 mol. NaHO form diphenylcarbamide; with 2 mols. NaHO the products are benzoic and benzhydroxamic acids.

Dibenzhydroxamic acid is resolved by distillation into carbon dioxide, phenyl isocyanate (and isocyanurate), benzoic acid, and benzanilide (Pieschel):

Ethyl Dibenzhydroxamate, $C^6H^5O.N(C^6H^5).OC^2H^5O$ (Eiseler, *loc. cit.*)—This ether is formed, together with other products, by the action of ethyl iodide on an ethereal solution of potassium dibenzhydroxamate. It crystallises in prisms melting at 58° , dissolves easily in alcohol and ether, and decomposes with violence at high temperatures. Heated with strong hydrochloric acid it yields hydroxylamine hydrochloride, benzoic acid, and ethyl benzoate:

Hot potash-solution converts it into benzoate and ethylbenzhydroxamate of potassium:

Ethylbenzhydroxamic acid, $C^6H^5O.N(C^6H^5).OH$, separated from the latter salt, is, according to Eiseler, an oily liquid. Lossen and Zauni, however, by commencing the preparation with pure ethyldibenzhydroxamate, have obtained this acid in limpid shining tables or prisms melting at 53.5° to 54.5° . It dissolves in water, alcohol, and ether. The solution of its potassium salt forms precipitates with metallic salts. By heating with hydrochloric acid it is resolved into ethyl benzoate and hydroxylamine hydrochloride (Eiseler).

Its *ethylic ether*, $C^6H^5O.N(C^6H^5).OC^2H^5$, formed by the action of ethyl iodide on ethylbenzhydroxamic acid dissolved in alcoholic potash, is a yellowish, aromatic, highly refractive liquid, insoluble in water, easily soluble in alcohol and ether. Dissolved in weak spirit and heated with a little hydrochloric acid, it is resolved into ethyl benzoate and ethyl-hydroxylamine:

Methyl Dibenzhydroxamate, $C^6H^5O.N(CH^3).OC^2H^5O$, formed like the ethyl-compound, is an oily liquid which solidifies at -15° . Potash converts it into methylbenzhydroxamic acid, $C^6H^5O.N(CH^3).OH$, which is resolved by hydrochloric acid into methyl benzoate and hydroxylamine:

Ethylene Dibenzhydroxamate, $C^6H^4[N(C^6H^5O)(OC^2H^5O)]^2$, crystallises in prisms, melts at 148° , is sparingly soluble in cold ether and alcohol, and moderately stable towards potash (Eiseler).

Ethyl Benzhydroxamate, $C^6H^5O.NH.OC^2H^5$, metameric with ethylbenzhydroxamic acid, is formed when benzhydroxamic acid (1 mol.) is left in contact for twenty-four hours with a highly concentrated solution of potassium hydroxide (2 mol.) and ethyl iodide (1 mol.), the mixture being frequently agitated:

The resulting solution is freed by filtration from potassium iodide, and carbon dioxide is passed through it for about an hour, whereupon the ethylic benzhydroxamate either

separates as an oil or remains dissolved, according to the degree of dilution of the liquid. In either case it is extracted by agitation with ether, and the ethereal solution, after drying with potassium carbonate, is left to evaporate. The residual mixture of an oil and a crystalline mass is pressed, and the crystals are purified by repeated crystallisation from alcohol.

The crystals thus obtained have a tabular habit, and appear to belong to the rhombic system. They have a faint aromatic odour, melt at 64° – 65° , dissolve easily in ether and in alcohol, less easily in water. The largest crystals, which have the form of thick tablets, from predominance of the pinacoids, are obtained from the alcoholic solution; the ethereal solution yields by spontaneous evaporation flat needles or concentrically radiate crystalline masses. Benzene, added to the ethereal solution, throws down the ethylic benzhydroxamate in the form of an oil.

This compound, like its isomeride, exhibits slightly acid properties. A molecule of it is dissolved by 1 mol. potassium hydroxide, and the resulting solution gives precipitates with silver, mercury, and lead salts. The *silver salt*, $(C^7H^5O)NAg.OO^2H^3$, is a white precipitate easily decomposed by heat (Waldstein).

This ether, heated in a sealed tube with excess of hydrochloric acid, is resolved into benzoic acid and the hydrochloride of ethylhydroxylamine:

The latter compound is produced in like manner, together with ethyl benzoate, from the ethylic ether of ethylbenzhydroxamic acid (p. 1080).

Ethylhydroxylamine hydrochloride, $N(C^2H^5)H^2O.HCl$, is a crystalline substance which deliquesces in the air and dissolves easily in absolute alcohol. It is precipitated from its alcoholic solution, on addition of ether, in large pearly laminae. When heated it melts and decomposes, evolving gas. Its solutions exhibit many of the reactions of hydroxylamine, reducing silver, mercury, and copper salts, and also chromic acid in alkaline solution. The *platinochloride*, $2[N(C^2H^5)H^2O.HCl]PtCl_4$, formed by mixing alcoholic solutions of the hydrochloride and platinum tetrachloride, is deposited as a yellow crystalline powder on adding ether to the solution. It dissolves easily in water and absolute alcohol, and crystallises therefrom in prisms on evaporation (Lossen a. Zanni.—Waldstein).

Methylic Ethylbenzhydroxamate, $C^7H^5O.N(C^2H^5).OOCH^3$, is prepared, like the corresponding ethylic ether, by the action of methyl iodide on ethylbenzhydroxamic acid dissolved in alcoholic potash (Lossen a. Zanni), or on the silver derivative of ethylic benzhydroxamate (Waldstein). It closely resembles its ethylic analogue, and is resolved by hydrochloric acid into ethyl benzoate and methylhydroxylamine:

Methylhydroxylamine hydrochloride, $N(CH^3)H^2O.HCl$, formed in the reaction just mentioned, closely resembles the ethyl-compound. It crystallises from a hot saturated solution in alcohol in flat prisms. The *chloroplatinate*, $2N(CH^3)H^2O.HCl.PtCl_4$, dissolves very easily in water and alcohol. It is precipitated from its alcoholic solution by ether as a crystalline powder, and is deposited from its solutions on evaporation in large flat orange-red prisms or tables.

Ethylic methylbenzhydroxamate, $C^7H^5O.N(CH^3).OO^2H^3$, prepared by the action of ethyl iodide on methylbenzhydroxamic acid dissolved in alcoholic potash, is a mobile liquid having an agreeable aromatic odour; when decomposed by hydrochloric acid, it yields methyl benzoate and ethylhydroxylamine:

Anis- and Dianishydroxamic Acids (Lossen, *Liebig's Annalen*, clxxv. 284). These acids are produced by the action of anisyl chloride on an alkaline solution of hydroxylamine hydrochloride. From the crude product, water extracts anishydroxamic acid and a small quantity of anisic acid, the rest of the latter, together with the dianishydroxamic acid, remaining undissolved. The first two acids may be separated, either by conversion into barium salts (the anishydroxamate being insoluble in water) or directly by means of ether, which dissolves the anisic acid with only a very small quantity of the anishydroxamic acid.

Anishydroxamic acid crystallises from boiling water in colourless laminae, which easily acquire a reddish tint from the presence of slight impurities. Its normal melting point is 156° – 157° , but it melts between 140° and 150° when kept for some hours at that temperature. It dissolves readily in alcohol, is nearly insoluble in ether, quite insoluble in benzene. Its solutions, even when slightly acid, produce a deep violet colour with ferric chloride. Its *acid potassium salt*, $N(C^6H^7O^2)HKO.N(C^6H^7O^2)H^2O$, is somewhat sparingly soluble and crystallises in flat needles (Lossen). When a solution of *lead acetate* is gradually added to a solution of this acid potassium salt, a

precipitate is formed which at first redissolves, but afterwards becomes permanent. A solution filtered from the precipitate formed in the first instance, was once observed, when left at rest, to deposit colourless shining needles having the same composition as the dense white precipitate, namely $\text{Pb}\left\{\begin{smallmatrix} \text{C}^2\text{H}^3\text{O}^2 \\ \text{N}(\text{C}^6\text{H}^7\text{O}^2)\text{HO} \end{smallmatrix}\right\}$. The crystallised salt cannot be recrystallised from water; when boiled with water it gives up a small quantity of lead and traces of anishydroxamic acid. When heated, it suddenly decomposes, with formation of acetic acid, and perhaps of amidanisoil (N. Hodges, *Liebig's Annalen*, clxxxii. 218).

An *aceto-benzhydromate of lead*, having the composition,

is obtained when a concentrated solution of lead acetate (6 grams to 40 c.c. H^2O) is mixed with a solution of 1 gram of potassium benzhydroxamate (Hodges).

Dianishydroxamic acid, $\text{C}^6\text{H}^7\text{O}^2 \cdot \text{NH} \cdot \text{OC}^6\text{H}^7\text{O}^2$, crystallises in needles melting at 142° – 143° , slightly soluble in ether, insoluble in benzene. By baryta-water in excess it is resolved into anisic and anishydroxamic acids (Lossen).

Ethyllic Benzanishydroxamate, $\text{C}^7\text{H}^5\text{O} \cdot \text{N}(\text{C}^2\text{H}^5) \cdot \text{O}(\text{C}^6\text{H}^7\text{O}^2)$, is formed by the action of ethyl iodide on an ethereal solution of potassium benzanishydroxamate. It crystallises in rhombic tablets, melts at 69° , and is resolved by potash into ethyl-benzhydroxamic and anisic acids:

and by potash into benzoic acid, anisic acid, and ethylhydroxylamine:

Ethyllic Anisbenzhydroxamate, $(\text{C}^6\text{H}^7\text{O}^2)\text{N}(\text{C}^2\text{H}^5) \cdot \text{OC}^6\text{H}^7\text{O}^2$, prepared in like manner, crystallises in prisms; melts at 79° ; is decomposed by potash into ethyl-anishydroxamic and benzoic acids, and by hydrochloric acid into benzoic acid, anisic acid, and ethylhydroxylamine (Eiseler).

Cinnamhydroxamic Acid, $\text{C}^9\text{H}^7\text{O} \cdot \text{NH} \cdot \text{OH}$, is formed, together with dicinnamhydroxamic and cinnamic acids, by the action of cinnamyl chloride on hydroxylamine in aqueous solution. It melts at 110° , dissolves slightly in cold, more freely in hot water, easily in alcohol and ether, but is insoluble in benzene. Its solution colours ferric chloride deep violet. The *acid potassium salt*, $(\text{C}^9\text{H}^7\text{O})\text{NHOK} \cdot (\text{C}^9\text{H}^7\text{O})\text{NH} \cdot \text{OH}$, and the corresponding *sodium salt*, form easily decomposable yellow crystals. The *barium salt* is a sparingly soluble yellow crystalline powder which, when heated, gives off carbon dioxide and ammonia, and yields traces of a basic compound.

Dicinnamhydroxamic acid, $\text{C}^9\text{H}^7\text{O} \cdot \text{NH} \cdot \text{OC}^9\text{H}^7\text{O}$, is slightly soluble in ether, insoluble in water, and crystallises in prisms or laminae which melt at 152° , and are not dissolved by baryta-water. Its salts, when once separated from aqueous solution, are no longer soluble in water. The potassium salt is decomposed by boiling with water, and converted for the most part into cinnamate. When the acid is heated to incipient carbonisation, a resin is formed, from which small quantities of a crystalline powder, $\text{N}^3\text{C}^{17}\text{H}^{11}\text{O}^4$, melting at 290° , may be extracted (Rostoski, *Liebig's Annalen*, clxxviii. 213).

HYDROXYL-UREA, $\text{CH}^3\text{N}^2\text{O}^2 = \text{CON}^2\text{H}^3(\text{OH})$ (1st Suppl. 725). Potassium and sodium derivatives of this compound are obtained, though not pure, by mixing its alcoholic solution with a solution of potassium or sodium ethylate, whereupon colourless and often crystalline precipitates are formed, which rapidly attract moisture from the air. The potassium salt, dried in a stream of air, appeared to have the composition $\text{CH}^3\text{KN}^2\text{O}^2 \cdot \text{CH}^4\text{N}^2\text{O}^2$. A *lead salt* is obtained by adding lead acetate to an aqueous solution of the potassium salt till the precipitate redissolves; the solution then deposits small colourless crystals having the composition $(\text{C}^2\text{H}^3\text{O}^2)^2\text{Pb} \cdot (\text{CH}^3\text{N}^2\text{O}^2)^2\text{Pb} \cdot \text{CH}^4\text{N}^2\text{O}^2$. A *cupric salt* is obtained by adding cupric acetate to the aqueous potassium salt, as a gummy precipitate which dries up to a shining green mass, and has nearly the composition $4\text{CH}^3\text{CuN}^2\text{O}^2 \cdot \text{C}^2\text{H}^3\text{O}^2$ (N. Hodges, *Liebig's Annalen*, clxxxiii. 314).

HYDROXYMETHOXYCINNAMIC ACID,

This is the constitution of ferulic acid, obtained from asafetida, and produced synthetically by digesting sodium-vanillin with excess of acetic anhydride and sodium acetate (p. 785).

HYDURILIC ACID, $C^8H^4N^4O^8$ (Murdoch a. Doeblner, *Ber.* ix. 1102). The ammonium salt of this acid is formed, together with oxalic acid, carbon dioxide, and carbon monoxide, by heating air-dried crystallised alloxantin for three or four hours to 170° in a sealed tube. On acidulating the crude product with hydrochloric acid, and submitting it to fractional evaporation, hydrurilic acid separates out first, and afterwards oxalic acid. When alloxantin is heated to 170° in contact with the air, the oxalic acid produced is resolved into CO , CO_2 , and water, and the hydrurilic acid remains in the free state, especially if the heating be prolonged. Alloxantin heated to 170° with water does not yield hydrurilic acid, inasmuch as the latter is decomposed by water at about the same temperature.

Air-dried crystallised alloxan is decomposed at 170° in the same manner as alloxantin; and experiment shows that it is not in the first instance resolved into alloxantin, parabanic acid, and carbon dioxide, but that the decomposition takes place in the manner represented by the equation:

Alloxan, heated to 170° in contact with the air, does not yield hydrurilic acid, since it gives up its water of crystallisation even at this temperature, and anhydrous alloxan is not capable of yielding hydrurilic acid.

When *hydrogen sulphide* is passed for several hours through a boiling aqueous solution of alloxantin, hydrurilic acid is found amongst the products of reduction.

HYGROPHILITE. A green mineral resembling lithomarge, occurring in shaly nodules in the sandstones and siliceous conglomerates of Halle on the Saal, and in the coal-mine of Wettin. Hardness = 2. Sp. gr. = 2.670 at 18° . Two analyses, (1) made by dissolving the mineral in hydrochloric acid; (2) by decomposing it with sodium carbonate, gave the following results, leading to the formula $2(RO.SiO^2) + 3(Al^2O^3.2SiO^2) + 5H^2O$:

	SiO ² (%)	Al ² O ³	FeO	CaO	MgO	K ² O	Na ² O	K ² O
(1).	48.784	31.920	3.145	1.065	1.718 (2)	5.673	1.364	9.015 = 102.684
(2).	48.061	32.193	3.383	1.241	1.718	5.673 (2)	1.364 (2)	9.015 = 102.648

(1) With trace of TiO_2 .

(2) Taken from No. 2.

(2) Taken from No. 1.

Hygrophilite is distinguished from the other minerals of the pinite group by its solubility in potash and in hydrochloric acid, its property of exfoliating in water, and its low specific gravity. The air-dried and pulverised mineral is capable of absorbing 17 per cent. water. At 300° the air-dried substance gives off 4.5 per cent. H^2O , and at a bright red heat the loss of weight amounts to 8.697 per cent., which, when account is taken of the simultaneous increase of weight due to the conversion of FeO into Fe^2O^3 , is equivalent to a loss of 9.037 per cent. water. Microscopical examination showed the existence of numerous green pores, from which gas-bubbles escaped when the mineral fell to pieces in water (Laspeyres, *J. pr. Chem.* [2], vii. 287; *Chem. Soc. Jour.* 1873, 1207).

HYOSCYAMUS. In the mother-liquors of henbane (*H. niger*), from which hyoscyamine has been separated, R. Buchheim has found an amorphous alkaloid which he designates as *Sikeraunne*.

On the Detection and Estimation of *Hyoscyamine*, see PLANT-BASES.

HYPERSTHENE. Des Cloizeaux (*Jahrb. f. Min.* 1874, 429) describes hypersthene crystals from a trachytic conglomerate from the Capucin (Mont Dore), agreeing exactly with the variety described by G. vom Rath as *amblystegite* (2nd Suppl. 55). They are accompanied by reddish needles of tridymite and zircon. Hypersthene has also been found, together with augite and oligoclase, in the lava of Santorin (Fouqué, *Compt. rend.* lxxxi. 220).

HYPOCHLOROUS ACID. See CHLORINE (p. 449).

HYPOGALLIC ACID. This name was given by Matthiessen a. Foster to a modification of dioxybenzoic acid, $C^7H^4O^4$, which, according to their experiments, was obtained by boiling hemipinic acid with hydriodic acid (iii. 239). According to Beckett a. Wright, however (*Chem. Soc. Jour.* 1876, i. 174), the product thus obtained is not a distinct acid, but a mixture of opianic and hemipinic acids, perhaps with addition of protocatechuic acid (see NARCOTINE).

HYPONITROUS ACID. See NITROGEN, OXYGEN-ACIDS OF.

HYPOPHOSPHORIC and **HYPOPHOSPHOROUS ACIDS.** See PHOSPHORUS, OXYGEN-ACIDS OF.

HYPOSULPHUROUS ACID. See SULPHUR, OXYGEN-ACIDS OF.

HYPOXANTHINE, $C^8H^4N^4O$. *Sarcine*.—This substance is formed by the action of pancreas ferment on blood-fibrin; also, though in much smaller quantity, by the simple decay of blood-fibrin (Salomon, *Ber.* xi. 574). It is also produced, together with leucine, tyrosine, xanthine, guanine, and carnine, in the decomposition of the albuminous constituents of yeast (Schützenberger, *Bull. Soc. Chim.* [2]. xxi. 204).

I

ICACIN, $C^{16}H^{76}O$. The crystalline resin of Conima or Incense-resin (p. 555).

ICE. Large masses of ice may be gradually penetrated at ordinary temperatures, and with the exertion of only slight pressure, by the meshes of fine wire-gauze. The ice thus penetrated has a structure similar to that of the wire-gauze, and incloses small air-bubbles disposed in columns. A block of ice fixed between two boards was in like manner traversed, without being permanently divided, by a loaded pendulous wire, the plane traversed by the wire being merely marked by a turbidity arising from small bubbles of air (J. T. Bottomley, *Pogg. Ann.* cxlviii. 492).

From experiments on the *plasticity* of ice, F. Pfaff (*ibid.* clv. 169) infers that the slightest pressure is sufficient to displace the particles of ice, if it acts continuously, and the temperature of the ice and of the surrounding medium is near the melting point.

On the *Optical Structure* of Ice, see Bertin (*Ann. Chim. Phys.* [5], xiii. 283; *Chem. Soc. Jour.* xxxiv. 632).

IDOCRASE. This mineral occurs between Drammen and Konerud in Norway, in a very decomposed sedimentary rock, crystallised and crystalline. The rock is penetrated by numerous hollow spaces formed by the weathering of corals, and the idocrase crystals line these hollows, particularly those formed by cyathophyllii. These crystals are occasionally 1 cm. in height; are always attached, and exhibit the combination $\infty P.P. \infty P\infty. 3P. 3P3.P \infty OP$. Smaller hollows, such as those formed by halysites, are filled with crystalline granular olivine and grass-green idocrase. Hyacinth-red garnets accompany the idocrase (Brögger, *Jahrb. f. Min.* 1876, 661).

IDRYL. This name was applied by Budeker to a mixture of hydrocarbons obtained by the dry distillation of an Idrian quicksilver ore (iii. 242). Goldschmidt, who has lately examined this product, finds it to be a mixture of anthracene, phenanthrene, pyrene, chrysene, and fluoranthene, for the last of which he retains the name 'idryl' (see FLUORANTHENE, p. 724).

IGASURIC ACID. See 2nd Suppl. 665.

IHLEITE. An iron sulphate, occurring, together with other minerals, in the graphite of Mugrau, Bohemia. It is amorphous, occurring either globular or reniform, exhibiting in section a confused reticulated structure composed of fine lamella and fibres, which, however, on microscopical examination, do not appear to be crystalline. Sp. gr. 1.812. It is soluble in cold water, but on warming it to 40° , a basic ferric sulphate separates out. An analysis of samples of this mineral yielded the following results, proving the constancy of the process of formation, viz.:—

	SO ³	FeO	Fe ² O ³	Al ² O ³	CaO	H ² O
1875	38.2	2.1	24.5	—	—	35.5 = 100.3
	37.4		26.1	0.3	0.4	35.6 = 99.8
1876	37.2	1.4	25.6	—	0.3	35.3 = 99.8

Ihleite appears, therefore, to be a combination of ferrous and ferric sulphates, represented by the formula $FeSO^4.9Fe^2S^3O^{12}+120H^2O$. The mineral which most nearly approaches it in composition is misy, which differs, however, from it in its lower percentage of water and higher percentage of sulphuric acid. Ihleite is of course a secondary product, formed by the oxidation of iron pyrites, the largest and best specimens being always found in the impure, hard, stony graphite (Schrauf, *Jahrb. f. Min.* 1877, 252).

ILMENTUM. See NIOBium.

IMIDOCAPRYLIC ACID. See CAPRYLIC ACID (p. 381).

IMIDOSULPHONIC ACID, $\text{NH}^+\text{S}^-\text{O}^6 = \text{NH}(\text{SO}^-\text{OH})^2$. Berglund (*Ber.* ix. 252), by acting on sulphuric hydrochloride, $\text{Cl.SO}^-\text{OH}$, with ammonia, has obtained a crystallised compound which he regards as the triammonic salt of this acid, $\text{N}(\text{NH}^+)^3\text{S}^-\text{O}^6$ or $\text{N}(\text{NH}^+)(\text{SO}^-\text{ONH}^+)^2$, and as identical with crystallised ammonium sulphamate, $\text{NH}^+\text{SO}^-\text{ONH}^+$ (v. 476; Rose's Parasulphatammon; Jacquelin's sulphamide, *Berz. Jahresb.* xxiv. 196). His reasons for assigning to it the more complex formula above given are that only two-thirds [$\frac{2}{3}$ three-fourths] of the nitrogen is given off by boiling with caustic alkalis, the remainder only on ignition with soda-lime,—and that numerous derivatives of the compound in question may be formed containing 2 at. S to 1 at. N.

Imidosulphonic acid is, however, not bi- but tri-basic, the hydrogen-atom attached to the nitrogen being replaceable by metals, as well as those which are present in the form of hydroxyl. The acid forms, therefore, two classes of salts, viz. 'neutral salts,' $\text{NH}(\text{SO}^-\text{OR})^2$ (better called *dimetallic*), and 'basic' or *trimetallic* salts, $\text{NR}(\text{SO}^-\text{OR})^2$. All these salts are distinguished by the peculiarly close attachment of the sulphur to the nitrogen, shown, in the case of the ammonium salt, by the fact that part of the nitrogen is given off only on ignition with soda-lime, and in the case of the rest, that the sulphur is only partly removed by chloride of barium, even after prolonged boiling.

The dimetallic imidosulphonates are, for the most part, easily soluble, and only the ammonium, potassium, and barium salts are crystallisable. The *potassium salt*, $\text{NH}(\text{SO}^-\text{K})^2$, which is but sparingly soluble, is identical with Frémy's sulphammonate (v. 482), and with the disulphammonate of Claus a. Koch (*1st Suppl.* 1047), to which, however, these chemists assign the formula $\text{NH}^+\text{S}^-\text{O}^6\text{K}^+$, differing by 2 at. H from that given by Berglund. The latter regards Claus's formula as inconsistent with the formation of the ammonium salt from ammonia and sulphuric hydroxychloride, and likewise with certain reactions of imidosulphonic acid. The alteration of the formula according to Berglund's views would, however, involve corresponding alterations in those of the other sulphammonic acids described by Claus a. Koch, a point which cannot be decided without further investigation.

The trimetallic imidosulphonates are much less soluble than the dimetallic salts; they are for the most part crystalline, and are converted into dimetallic salts by treatment with weak acids. The *ammonium salt*, $(\text{NH}^+)\text{N}(\text{SO}^-\text{ONH}^+)^2$, agrees in composition with Rose's formula $2\text{NH}^+\text{SO}^3$. The *potassium salt*, $\text{KN}(\text{SO}^-\text{K})^2 \cdot \text{H}^+\text{O}$, forms bulky crystals, probably tridlinic. The *sodium salt*, $\text{NaN}(\text{SO}^-\text{Na})^2 + 12\text{H}^+\text{O}$, forms large, micaceous, very efflorescent plates. The *barium salt*, $\text{BaN}^2[(\text{SO}^-\text{Ba})^2 \cdot 5\text{H}^+\text{O}]$, the *strontium salt*, $\text{SrN}^2[(\text{SO}^-\text{Sr})^2 \cdot 6\text{H}^+\text{O}]$, and the *calcium salt*, $\text{CaN}^2[(\text{SO}^-\text{Ca})^2 \cdot 6\text{H}^+\text{O}]$, are obtained as slightly soluble precipitates which quickly change to masses of small needles. The *silver salt*, $\text{AgN}(\text{SO}^-\text{Ag})^2$, is a white, slightly soluble, crystalline precipitate. The *lead salt*, $\text{PbNOH}(\text{SO}^-\text{PbOH})^2$, is a white precipitate which soon becomes crystalline. When decomposed by hydrogen sulphide, it yields imidosulphonic acid, which is very unstable.

Mercurimidosulphonates, $\text{HgN}^2(\text{SO}^-\text{R})^4 = (\text{RO.SO}^-\text{R})^2\text{N.Hg.N}(\text{SO}^-\text{OR})^2$.—These salts, in which the mercury is very strongly combined, may be regarded as salts of the acid $\text{HgN}^2(\text{SO}^-\text{H})^4$, which may be obtained in the free state by decomposing the barium salt with an equivalent quantity of sulphuric acid. $\text{HgN}^2(\text{SO}^-\text{K})^4$ crystallises from hot water in thin white very stable prisms; $\text{HgN}^2(\text{SO}^-\text{Na})^4 \cdot 5\text{H}^+\text{O}$ is more soluble than the potassium salt. $\text{HgN}^2(\text{SO}^-\text{K})^2(\text{SO}^-\text{Ag})^2 \cdot 3\text{H}^+\text{O}$ forms long unstable needles. $\text{HgN}^2(\text{SO}^-\text{Ba})^2 \cdot 5\text{H}^+\text{O}$ forms microscopic needles. $\text{HgN}^2(\text{SO}^-\text{Sr})^2 \cdot 15\text{H}^+\text{O}$ resembles the barium salt, but is more soluble. $\text{HgN}^2(\text{SO}^-\text{Mg})^2 \cdot 15\text{H}^+\text{O}$ solidifies from a syrupy solution in a radiate mass. $\text{HgN}^2(\text{SO}^-\text{Zn})^2 \cdot 15\text{H}^+\text{O}$ resembles the magnesium salt. $\text{HgN}^2(\text{SO}^-\text{Ni})^2 \cdot 15\text{H}^+\text{O}$ forms emerald-green bulky prisms. $\text{HgN}^2(\text{SO}^-\text{Co})^2 \cdot 15\text{H}^+\text{O}$ is a red radio-crystalline mass. $\text{HgN}^2(\text{SO}^-\text{Mn})^2 \cdot 10\text{H}^+\text{O}$ forms hard reddish unstable crusts. $\text{HgN}^2(\text{SO}^-\text{Cd})^2 \cdot 12\text{H}^+\text{O}$ forms hard, unstable, very soluble crusts. $\text{HgN}^2(\text{SO}^-\text{Cu})^2 \cdot 15\text{H}^+\text{O}$ forms rather unstable, very soluble, bluish, warty crystals. The basic mercury salt, $\text{HgN}^2(\text{SO}^+)(\text{Hg}^+\text{O})^2$, forms microscopic nearly soluble crystals.

Amidosulphonic acid, $\text{NH}^+\text{SO}^-\text{H}$. The dimetallic imidosulphonates are resolved by boiling with water into acid sulphates and amidosulphonates, the latter being also partly converted into double ammonium sulphates:

The amido- and imidosulphonic acids cannot be separated by simple crystallisation, but the separation is easily effected by precipitating the imido-acid with baryta-water, in the form of a basic salt. Barium amidosulphonate is accordingly easily prepared

by boiling the ammonium or barium salt of the imido-acid with water, till it exhibits a strong acid reaction; then supersaturating with barium hydrate; boiling the liquid continuously till all the ammonia is driven off; filtering; removing the excess of baryta by carbon dioxide; and strongly concentrating the filtered solution, whereupon the barium amidosulphonate is deposited in long beautiful needles which have a silky lustre and are very stable (Berghlund, *Ber.* 1876, 1896).

INDIAN BREAD. See Lycopodium.

INDICAN, $C^{11}H^{20}NO^{17}$. On the Formation and Excretion of this substance in the animal organism, see Nencki (*Ber.* vii. 1593; ix. 299; *Chem. Soc. J.* xxviii. 479); E. Salkowski (*Ber.* ix. 138; *Chem. Soc. J.* xxix. 950); Jaffé (*Chem. Centr.* 1877, 678; *Chem. Soc. J.* xxxiv. 442).

INDICATORS. On Indicators in Volumetric Analysis, see ANALYSIS (p. 83).

INDIGO. *Formation of Indigo-blue in plants.*—The formation of this substance, C^8H^6NO , from the juice of woad and other plants on exposure to the air, was formerly attributed to the oxidation of indigo-white, $C^{10}H^{12}N^2O^2$, supposed to exist in the juice in a state of solution. Schunck, however, pointed out that this could not be the case, as the sap of plants is always acid, and indigo-white dissolves only in alkaline liquids. He further showed (iii. 250) that woad (*Isatis tinctoria*) contains indican, $C^{26}H^{31}NO^{17}$, a glucoside which, when boiled with acids, splits up into indigo-blue and a saccharine substance called indiglucein:

Recently (*Manchester Memoirs*, [3], vi. 218 [1877]), Schunck has obtained indican from the leaves of *Polygonum tinctorium*, a plant used by the Chinese for the extraction of indigo, and from *Bleia Tankervillea*, an orchidaceous plant, the mode of preparation being similar to that formerly applied in the case of woad-leaves; and, lastly, indican has been detected by P. Michéa in the juice of the indigo-plant (*Indigofera tinctoria*). It may therefore be inferred that in all the plants known to yield indigo-blue, the formation of this substance is due to the decomposition of indican in the manner above mentioned. The cells of the fresh leaves of these plants do not contain any colouring matters except chlorophyll, and the conversion of indican into indigo-blue takes place only when the vitality of the cells is destroyed by cold, by organic lesions, such as the bites of insects, or by the action of chemical reagents. When the cut end of a sprig of *Polygonum tinctorium* was immersed in dilute hydrochloric acid, and the sprig was left for several days exposed to the sun and air, the acid was gradually absorbed, and passed upwards till it reached the uppermost leaves, its course being marked by a change of colour in the leaves from fresh green to dirty yellow, and afterwards to dark blue.

When an aqueous solution of indican is boiled or left to stand for some time, it undergoes a complete change, and if then decomposed by acids, yields, no longer indigo blue, but indigo-red and other products (comp. iii. 247). On one occasion an alcoholic extract of dried woad-leaves in which the indican had undergone partial decomposition by long standing, yielded, on evaporation, a quantity of a substance which exhibited all the properties of tyrosine. The formation of this body from indican may be represented by the equation:

Synthesis of Indigo-blue.—Considerable doubt appears to exist respecting the formation of this substance from liquid nitro-acetophenone, as announced by Emmerling a. Engler (*2nd Suppl.* 666). Wichelhaus (*Ber.* ix. 1106), following the directions given by these chemists, failed to obtain it. Emmerling a. Engler, on the other hand (*ibid.* 1422), maintain the correctness of their former statement, but add that, on repeating their experiments, they have not been able to reproduce the syrupy nitro-acetophenone from which the indigo-blue was obtained.

The synthesis of indigo-blue from compounds of the coal-tar group may however be effected in a different way, viz., through the medium of oxindole and isatin. Phenyl-acetic acid, $C^6H^5.CH^2.COOH$, added to fuming nitric acid warmed on a water-bath, is converted into ortho-nitrophenylacetic acid, $C^6H^4\begin{smallmatrix} CH^2.COOH \\ NO^2 \end{smallmatrix}$, which by reduction yields the corresponding amidophenylacetic acid, the anhydride of which, $C^6H^4\begin{smallmatrix} CH^2.CO \\ NH \end{smallmatrix}$, is identical with oxindole. This last compound may be converted by

the action of nitrous acid into nitrosoxindole, $\text{C}^6\text{H}^4 \begin{array}{c} \text{CH}(\text{NO})\text{CO} \\ \text{NH} \end{array}$, which by reduction yields amidoxindole, $\text{C}^6\text{H}^4 \begin{array}{c} \text{CH}(\text{NH}^2)\text{CO} \\ \text{NH} \end{array}$; this, when oxidised with ferric chloride, cupric chloride, or nitrous acid is completely converted into isatin, $\text{C}^6\text{H}^4 \begin{array}{c} \text{CO}\text{CO} \\ \text{NH} \end{array}$; and isatin may be converted into indigo-blue by heating it with a mixture of phosphorus trichloride and pentachloride,* whereupon hydrogen chloride is given off, and isatic chloride, $\text{C}^6\text{H}^4 \begin{array}{c} \text{CO}\text{CCl} \\ \text{N} \end{array}$, is formed, which, when reduced by heating it with phosphorus, or by treating its alcoholic solution with zinc-dust and acetic acid, yields indigo blue, $\text{C}^6\text{H}^4 \begin{array}{c} \text{CO}\text{CH} \\ \text{N} \end{array}$ (A. Baeyer, *Ber.* xi, 582, 1228, 1296).

Reaction with Sulphur-compounds.—E. Schaer (*Ber.* ix, 340) supposes that in the action of hyposulphurous acid, hydrogen sulphide, and hydrogen persulphide on indigo-blue, colourless molecular compounds are formed from which the indigo is regenerated by all the reagents (sulphurous acid for example) which destroy these sulphur-compounds. Indigo solution is decolorised by the compounds of hydrogen persulphide with strychnine (see *ALKALIDS*, p. 56).

Estimation.—A. Müller (*Amer. Chemist*, v, 128) estimates indigo-blue by the decolorising action of hyposulphurous acid. The titration of the acid with cupric sulphate, and the performance of the estimation with complete exclusion of air, are effected in the manner already explained with reference to the estimation of oxygen in blood (*2nd Suppl.* 200). Müller finds that 1 mol. CuSO_4 requires, to decolorise it, exactly the same quantity of hyposulphurous acid as 1 mol. of pure indigo-blue.

On the Compounds of Indigo-blue with Metallic Salts, see W. Skey (*Chem. News*, xxx, 33).

Dyeing and Printing with Indigo.—A new method of preparing an indigo-vat, founded on the rapid reduction of indigo-blue in alkaline solution to indigo-white by sodium hyposulphite, is described by Schützenberger a. De Lalande (*Bull. Soc. Chim.* [2], xx, 7). Into a solution of acid sodium sulphite of $30^\circ\text{--}35^\circ\text{Bm.}$ contained in a closed vessel, are introduced rolled strips of zinc-foil, or granulated zinc, in quantity sufficient to fill about a fourth part of the vessel, and yet to be distributed through the whole mass of liquid. After the action has gone on for about an hour, an excess of milk of lime is poured into the solution, whereby the dissolved zinc is precipitated. The filtered solution of sodium hyposulphite, Na_2SO_3 , thus obtained is mixed with ground indigo, and a sufficient quantity of lime or soda to hold the resulting indigo-white in solution.

The indigo-vat thus prepared is used cold for dyeing cotton, slightly warm for silk and wool. For printing, the above mentioned solution of indigo-white is thickened with gum and mixed with excess of sodium hyposulphite. With this colour, printing may be performed in contact with the air with the ordinary machines, the oxidation of the indigo-white being prevented by the excess of hyposulphite present. The printed cloths are hung up in the air for twelve to twenty-four hours, and when the colour has thereby been developed, they are finally washed with soap. This process, compared with the ordinary methods, is said to effect a saving of 56 to 60 per cent. of indigo.

Indigo Extract. The so-called 'Acid Extract of Indigo' is prepared by dissolving 5 pounds of Bengal indigo in 80 pounds of oil of vitriol, leaving the liquid at rest for five days, then adding 40 gallons of hot water, and filtering hot through felt. The resulting solution digested for six days with 40 pounds of common salt yields a precipitate which constitutes the acid extract. To obtain pure indigo-extract 100 lbs. of the acid extract are drenched with 12 gallons of water; the acid is immediately neutralised with soda; and the resulting precipitate collected on a filter. Bradford (*Chem. News*, xxxi, 29).

To estimate the value of such an extract, P. Hubert (*ibid.* 162) dries it at 100°

* Emmerling a. Engler obtained indigo-blue from isatin by heating the latter in a sealed tube with a mixture of phosphorus trichloride, acetyl chloride, and a little free phosphorus (*2nd Suppl.* 666); but, according to Baeyer, this method does not yield a satisfactory result, the product consisting chiefly of indigo-purpurin.

and incinerates it. According to Girardin, there are three sorts of extract to be distinguished, *single*, *double*, and *triple*. The mean composition of these is as follows:

	Water	Indigo	Salts
Simple Extract	89.0	4.96	5.7
Double „	85.0	10.20	4.8
Triple „	73.7	12.40	13.9

Hubert examined several such preparations made in Rheims, with the following results:

	1	2	3	4	5	6
Water	84.5	89.7	82.65	91.15	88.6	87.2
Indigo	10.6	5.6	9.55	6.05	8.2	8.4
Salts	4.7	4.7	7.80	2.85	5.2	4.4

A sure criterion of the value can however be obtained only by tinctorial experiments. For this purpose wool is dyed with a solution of 1 gram of indigo-carmines in a litre, and then more or less decolorised by a solution of permanganate containing 0.5 gram of that salt in the litre.

Indigo-red. According to observations by Nencki (*Ber.* vii. 1593), the urine of men and dogs, whose food was mixed with isatin, contained a colouring matter apparently identical with the indigo-red or urrhodin described by Heller.

Indigosulphonic Acid, $C^6H^5NO.SO^3$, or $C^6H^4NO.SO^3H$. A peculiar modification of commercial indigosulphonic acid (commonly called *indigosulphuric acid*) has been observed by S. Lupton (*Chem. News*, xxx. 215). The acid had assumed a chrome-green colour, and had deposited a purple sediment which dissolved in water with blue colour, and was not altered by sulphurous acid. The chrome-green solution, by which the violet end of the spectrum was considerably shortened, gave a dirty white precipitate with barium chloride, and was decolorised by bromine-water, and by potassium dichromate immediately, by dilute nitric acid only on boiling. Sulphurous acid instantly changed the colour of the solution to indigo-blue. The green liquid left, on evaporation, a green amorphous residue easily soluble in water and in alcohol (Berzelius' *Viridinsulphuric acid*?) A similar green coloration, accompanied by the separation of a purple precipitate, was observed on adding a few drops of a solution of potassium dichromate to a dilute solution of indigosulphonic acid mixed with hydrogen dioxide.

INDIUM. This mineral has been found by J. A. Tanner (*Chem. News*, xxx. 141) in mixtures of ore consisting mainly of calamine mixed with a considerable quantity of siliceous calamine (*Kieselzink*). A specimen from Wythe County, Virginia, showed a very faint indium line; another from Leadville, Tennessee, gave a distinct reaction. Calamine very rich in indium is found in the oxide mines in the Province of Bergamo (A. and G. de Negri, *Gazz. chim. ital.* viii. 120).

Spectrum.—Claydon a. Heycock (*Phil. Mag.* [5], i. 176), by passing the induction-spark between poles of indium, have obtained a spectrum of sixteen lines, including only the two more refrangible of the three known lines which are developed by the volatilisation of the chloride; the other fourteen lines correspond with longer durations of vibration.

Indium Platinochloride, $In^2Cl^6.5PtCl^4 + 36H^2O$, forms honey-yellow oblique four-sided prisms, with oblique end-faces. They quickly deliquesce on exposure to the air, and give off half their water at 100° .

INDOLE, $C^8H^7N = C^6H^4 \begin{smallmatrix} \nearrow CH^2.CH \\ \searrow N \end{smallmatrix}$. *Formation and Preparation.*—1. From

Indigo. Engler a. Jancke (*Ber.* ix. 1411) confirm the statement of Baeyer (*Liebig's Annalen*, [1869], *Suppl.* vii. 56) that, in preparing indole from indigo, it is more advantageous to convert the indigo into isatin, dioxindole, and oxindole, and reduce the oxindole with zinc dust, than to treat the indigo with tin and hydrochloric acid, and subject the yellow product to the action of zinc dust (comp. 1st *Suppl.* 733).

2. From Aniline-derivatives. Indole is formed when ethyl-aniline, diethyl-aniline, methyl-ethyl-aniline, ethyl-acetanilide, dimethyl-*o*-toluidine, or diethyl-*o*-toluidine is passed through a red-hot tube; the first yielding only traces of indole; the second, third, and fourth, rather more; the fifth, a moderately abundant product, and the last a considerable quantity. From the brown oily liquid which collects in the receiver, the indole may be separated by means of picric acid, with which it forms a crystalline compound decomposable by ammonia. Diethyl-*o*-toluidine thus treated yields from 3 to 5 per cent. of pure indole. Diethyl-*p*-toluidine yields none (Baeyer a. Caro, *Ber.* x. 692, 1262).

3. From Albumin. Commercial albumin is mixed with water, and the finely divided pancreas of an ox (carefully freed from blood and fat) having been added, the whole is kept at a temperature of 40° to 45° for sixty to seventy hours. The liquid is then left to cool, and strained through linen. It is next acidified with acetic acid and distilled on a sand-bath till only one quarter remains. The distillate is mixed with lime-water to alkaline reaction, and shaken up with an equal volume of ether. The clear ethereal solution leaves on distillation a reddish oil with the characteristic smell of indole. This oil, when mixed with a little water, solidifies to a crystalline mass, which, on recrystallisation from pure water, yields pure indole melting at 52° (Nencki, *Ber.* viii. 336). Kühne (*ibid.* 206) likewise obtained indole by digesting albuminoids with pancreatic infusion; by distillation of decomposed pancreatic juice; and by heating dry albumin to redness with eight times its weight of potassium hydroxide. According to Engler a. Janecke (*ibid.* ix. 1411), blood-albumin and egg-albumin treated by this last method yield 0.25 per cent. casein, and gluten only 0.1 per cent.; gelatin, and creatine only traces of indole. Hence it appears that the greater the proportion of loosely combined nitrogen in the proteid, the smaller is the quantity of indole producible from it; on the other hand it was found that the residues of blood-albumin, after treatment with baryta or hydrochloric acid, yielded scarcely any indole on distillation with potash.

Properties and Reactions.—Indole (from indigo) boils with partial decomposition at 245° – 246° , but volatilises completely without decomposition at 218° . Its vapour-density (determined in naphthalene-vapour, b. p. 218°) is 4.45, showing that the molecular formula is C^8H^7N (Nencki, *Ber.* viii. 1517). The indole obtained from other sources has the same vapour-density, the volumes occupied by equal weights being found by experiment to be, for indole from indigo (I), from blood-albumin (II and III), and from egg-albumin (IV),—the last three by fusion with potash—in the following ratios:

I	II	III	IV
1	: 0.995	: 0.923	: 0.908.

Nevertheless, the product obtained from albumin by fusion with potash is not identical, but isomeric, with that which is formed by reduction of indigo, or by pancreatic digestion of albuminoids, as it differs therefrom in melting point and in its behaviour with oxidising agents; for distinction therefore the product obtained by the action of melting potash on albumin is called pseudo-indole. The differences between the two modifications are as follows:

Indole melts at 52° ; pseudo-indole at 85° – 86° (Engler a. Janecke); 88° – 89° (Kühne; probably impure). Indole from indigo suspended in water and subjected to the action of a stream of ozonised oxygen, is converted into indigo-blue, together with resinous products (Nencki, *Ber.* viii. 1517). Indole is also oxidised to indigo-blue in the animal organism, indigo-blue appearing in the urine after subcutaneous injection of indole (Nencki, *ibid.* vii. 1593). Pseudo-indole treated with ozonised oxygen as above is converted into a yellowish-brown substance having an odour different from that of indole, and not yielding any blue insoluble colouring matter when treated with ether. Indole treated with chromic acid immediately yields a bulky violet-brown precipitate, which is insoluble in ether, chloroform, and benzene, dissolves sparingly and with red colour in alcohol and aniline, easily and with violet colour in concentrated hydrochloric acid. Pseudo-indole, treated with chromic acid, gives, only in concentrated solution and after some time, a reddish-yellow precipitate, which is nearly insoluble in ether, chloroform, and benzene, but dissolves with yellow colour in aniline and in hydrochloric acid. Pseudo-indole gives with nitrous acid a precipitate, which, when treated with alkalis, does not emit the odour of indole.

Another isomeride of indole is formed, together with a non-azotised body, by the action of ammonia on chloracetyl-benzene, $C^6H^5.CO.CH^2Cl$. When this compound is boiled with aqueous ammonia for about an hour, or heated with it to 140° – 150° in a sealed tube, it is converted into a deep red liquid which solidifies on cooling, whilst the whole of the chlorine remains in the aqueous solution in the form of sal-ammoniac. From this red product, ether separates two compounds, one of which remains undissolved when the red substance is digested with ether for a short time, while the other dissolves in the ether and separates slowly therefrom.

The former of these, which is formed in small quantity only (8 per cent. of the chloracetyl-benzene), is the iso-indole. It is insoluble in water, very slightly soluble at ordinary temperatures in alcohol, ether, benzene, carbon disulphide, and glacial acetic acid, and crystallises from the hot acetic acid solution, also from boiling alcohol, in serrated colourless laminae having a silky lustre, and consisting of aggregates of broad pointed needles. It melts at 194° – 195° , and sublimes in nacreous laminae. It dissolves in strong hydrochloric acid, and separates therefrom in the crystalline state,

partially on cooling, immediately on dilution (Staedel a. Rügheimer, *Ber.* ix. 563, 1758).

Nitroso-di-indole, $C^{16}H^{13}(NO)N^2$.—This compound, commonly called *nitroso-indole*, is not known in the free state, but its nitrate, $C^{16}H^{13}(NO)N^2.NO^3H$, is obtained by adding to an aqueous solution of indole (prepared by pancreatic digestion of albumin) a few cubic centimeters of hydrochloric acid, and a large quantity of nitric acid, freed by evaporation from too great an excess of nitrous acid, and distilling the mixture. This nitrate dissolves readily, and with dark colour, in alcohol, less easily in ether, and is nearly insoluble in water acidulated with nitric acid. It decomposes when dried in a vacuum, and detonates sharply when heated. Free nitroso-di-indole has not been obtained. The *hydrochloride* forms red, amorphous, very unstable flocks (Nencki, *Ber.* viii. 1670).

Hydrazo-di-indole, $(C^{16}H^{13}N)^2N^2H^2$ $\begin{array}{c} C^6H^5N-NH \\ | \\ C^6H^5N-NH \end{array}$, is readily formed by the

action of reducing agents, e.g. alcoholic ammonium sulphide, on the nitroso-compound. It dissolves in alcohol and in ether, crystallises in shining yellow needles, and melts at 140° to a deep blue mass which, at a higher temperature, gives off ammonia and chars. Hydrazo-di-indole dissolves with yellow colour in strong sulphuric acid, the solution turning red when heated. Acids and alkalis convert it into a dark-brown colouring matter, regarded by Nencki as a *zoindole*.

INDOLINE, $C^{16}H^{14}N^2$ (Schützenberger, *Compt. rend.* lxxxv. 147). This polymeride of indole is obtained by heating indigo-blue with 2 pts. barium hydrate, $1\frac{1}{2}$ zinc-dust, and 10 water to 180° . On exhausting the product with alcohol and evaporating, a dark-coloured resinous substance remains, brittle at ordinary temperatures, but softening even below 100° ; and on heating this resin with zinc-dust, indoline sublimes in long pale yellow shining needles. It melts at about 245° , is insoluble in water, but soluble in alcohol and ether, to which it imparts a bluish fluorescence. It possesses basic properties, and yields with acids crystallisable salts mostly insoluble in water.

The *picrate*, $C^{16}H^{14}N^2.C^6H^3(NO^2)^3O$, is slightly soluble in alcohol. Indoline dissolves in hot *hydrochloric acid*, and the solution forms with *platinic chloride* a brown granulo-crystalline precipitate. The solution of indoline in strong *sulphuric acid* exhibits a blue fluorescence, and, on exposure to the air, deposits indoline sulphate in brown crystals. Indoline is partly decomposed by sublimation, yielding crystals, some of which resemble anthracene, while others are like anthraquinone.

If the heating of indigo with baryta-solution be interrupted before the reaction is complete, the solution will be found to contain, together with indoline, a substance which, on exposure to the air, is deposited in red flocks having the composition $C^{16}H^{12}N^2O$. This body dissolves in alcohol, and separates therefrom in red crystalline granules; also in dilute hydrochloric acid, with red colour, and is precipitated by ammonia.

INK. According to R. Böttger (*N. Rep. Pharm.* xxiii. 47), an excellent black ink is obtained by triturating 1 pt. pyrogallol, 3 pts. finely pounded gum-arabic, and 3 pts. neutral ammonium vanadate, with a suitable quantity of cold rain-water.

Böttger (*Dingl. pol. J.* ccix. 176) describes an indelible ink prepared by triturating 1 dram of aniline black with a mixture of 60 drops of strong hydrochloric acid and $\frac{3}{4}$ oz. alcohol, and diluting the resulting deep blue solution with a hot solution of $1\frac{1}{2}$ drams of gum arabic in 3 ozs. of water. This ink does not attack steel pens, and is not destroyed either by acids or by alkalis. If the solution of aniline black be diluted with a solution of $\frac{3}{4}$ oz. shellac in 3 ozs. spirits of wine, an excellent varnish is obtained for wood and metals.

Coloured Inks.—A good red ink is said to be obtained by triturating carmine with water-glass solution, and adding sufficient of that solution to make the ink run well from the pen. The ink must be protected from the air, best in a bottle closed with a cork soaked in oil. The writing dries very quickly (*Dingl. pol. J.* ccix. 316).

The following coloured inks are described by C. H. Viedt (*ibid.* ccxiv. 167). Red ink may be prepared by dissolving 1 pt. anhydrous fuchsin in 150–160 pts. boiling water, and, if the ink runs too easily, adding a solution of 3 pts. gum-arabic in 6 pts. water. Blue ink is a solution of 1 pt. anhydrous aniline blue (*bleu de nuit*) in 200–250 pts. water. Violet ink is prepared by dissolving 1 pt. blue-violet aniline in about 300 pts. water. This ink is very sensitive towards ordinary copying ink made from logwood extract; if a pen which has been used for copying ink be dipped into the violet aniline ink just mentioned, the writing immediately becomes pale and granular. Green ink is prepared by dissolving 1 pt. iodine-green in 100–110 pts. water,

Yellow ink is best prepared by dissolving 1 pt. picric acid in 120–140 pts. water. As copying inks, these inks cannot be recommended. The characters made with them are indeed soluble in water, and may therefore be transferred to damp paper; but the writing is, for the most part, not strong enough to yield a legible copy. If the strokes are made very thick, they exhibit on drying the well-known metallic lustre of the aniline dyes.

INOSITE, $C^6H^{12}O^6$. H. Vohl, by treating this substance with strong nitric acid (sp. gr. 1·52), obtained *hexnitroinosite*, $C^6H^6(NO^2)^6O^6$ (iii. 276). Further experiments have shown that *trinitroinosite* is formed at the same time. Finely pulverised anhydrous inosite is added, with continual stirring, either to well-cooled strong nitric acid, or to a cooled mixture of 1 mol. nitric and 2 mol. strong sulphuric acid. In the latter case, the inosite is quickly converted into a sandy crystalline mass; in the former case, the same substance is precipitated on addition of sulphuric acid. By washing this product with water and dissolving it in boiling alcohol, a solution is obtained which, on cooling, deposits hexnitro-inosite in tablets and prisms; and the mother-liquor yields by spontaneous evaporation, first white concentrically grouped needles of trinitroinosite, $C^6H^9(NO^2)^3O^6$, afterwards a gummy mass, from which inosite is reproduced by the action of ammonium sulphide (*Berl. Ber.* vii. 106).

Fermentation of Inosite.—According to Hilger (*2nd Suppl.* 669), the lactic acid formed in the fermentation of inosite is ethylene-lactic (paralactic) acid; Vohl, on the other hand, finds that it is identical with ordinary lactic acid (*Ber.* ix. 984).

INSECT-POWDER. R. Rother (*Pharm. J. Trans.* [3], vi. 781) finds, in the insect-powder obtained from *Pyrethrum caucasicum*, *roseum*, &c. (1) a resinous, greenish-yellow acid, which he calls *Persicein*; (2) a light brown acid, *Persiretin*; and (3), an easily soluble acid, *Persicin*. This last, which appears to be the active principle of the powder, is a glucoside, easily split up by boiling with dilute acids into persiretin and sugar.

INSOLINIC ACID. See TEREPHTHALIC ACID.

INVERTIN. The sugar-inverting constituent of yeast. See FERMENTS (p. 784).

INVERT-SUGAR. See SUGAR.

IODINE. *Occurrence*.—According to H. Zenger (*Arch. Pharm.* [3], vi. 137), iodine is found, together with bromine, in fresh-water plants. According to A. Guyard (*Bull. Soc. Chim.* [2], xxii. 60), the iodine sometimes present in saltpetre is in the form, not of potassium iodate, but of sodium iodate or iodide, sometimes of sodium periodate.

According to Stanford (*Dingl. pol. J.* cccxvi. 85; *Chem. Soc. Jour.* xxxiv. 169), kelp contains about 0·16 per cent. of iodine. Seaweeds possess the power of taking the iodine from the sea-water, but in different degrees, as shown in the following table; they take up ten times more iodine than bromine. 100 parts of dried algae contain:

	Sarphat	Schweitzer	Godechens	Wallace	Stanford
<i>Laminaria digitata</i> . . .	0·135	—	0·625	0·4440	0·1535 0·2946
„ <i>saccharina</i> . . .	0·230	3·880	—	0·2880	0·2794
<i>Fucus serratus</i> . . .	0·124	0·058	0·177	0·0565	0·0856
„ <i>nodosus</i> . . .	—	—	0·074	0·0396	0·0572
„ <i>vesiculosus</i> . . .	0·001	—	—	—	0·0297
<i>Zostera marina</i> . . .	0·0005	—	—	—	0·0457
<i>Rhodomela pinnastroides</i> . . .	—	—	—	—	0·0378
<i>Hyderix siliquosa</i> . . .	—	—	—	—	0·2131
<i>Hymanthalia lorea</i> . . .	—	—	—	—	0·0892
<i>Chordaria flagelliformis</i> . . .	—	—	—	—	0·2810
<i>Cladophora glomerata</i> . . .	—	—	—	—	—

According to Sonstadt, the iodine in sea-water is in the form of calcium iodate, 1 part of which is contained in 250,000 parts of the liquid (*2nd Suppl.* 671); and since the equivalent weight of calcium iodate is $\frac{I^2O^2Ca}{2} = \frac{342}{2} = 171$, it follows that

1 pt. of iodine is contained in $250,000 \times \frac{171}{127} = 336,610$ parts of sea-water.

Preparation.—The manufacture of iodine (and bromine) from the mother-liquor of

kelp, as now practised in Glasgow,* is described by Mr. Stanford (*loc. cit.*) as follows: The liquor, having a density of 85 to 95 Twaddle, is mixed with one-seventh of its weight of oil of vitriol (145 Tw.), and left for 24 hours, whereby the sulphur-compounds contained in it are decomposed, and sulphur is precipitated. The liquor is then distilled with manganese dioxide in an iron still having a leaden cover and two arms connected with two series of stoneware cells, in which the iodine condenses in hard masses. After all the iodine has passed over, more manganese dioxide is added, the leaden arms are connected with another condensing apparatus, either of lead or earthenware, and the bromine is collected therein.

Reactions.—With Chlorine. (i. Sodini (*Gazz. chim. ital.* 1876, 321), from experiments on the manner in which the action of chlorine on iodine in presence of water is affected by the quantity of the latter, finds that, to ensure the complete conversion of the iodine into iodic acid, according to the equation,

there must be at least 20 pts. of water present to 1 pt. of iodine. With a smaller quantity of water, the quantity of iodic acid formed decreases, and a corresponding amount of iodine chloride is produced; and when only the theoretical quantity of water indicated by the preceding equation is employed, scarcely a trace of iodic acid is produced.

With Ozone. According to J. Ogier (*Compt. rend.* lxxxv. 957), this reaction yields, besides iodic acid, an intermediate product having the composition I^2O_3 (p. 1095).

With Palladium Chloride and Potassium Ferrocyanide. When iodine in alcoholic solution or in fragments is added to an aqueous solution of potassium ferrocyanide, it is not precipitated on addition of palladium chloride, but the yellow colour of the liquid changes to a green, which becomes particularly bright on heating, and is due to the formation of palladium ferrocyanide. A solution of potassium ferrocyanide likewise dissolves iodine, which then also is no longer precipitated by palladium chloride. In these solutions iodine cannot be detected by means of starch; neither can it be separated from bromine and chlorine by means of palladium chloride in presence of potassium ferrocyanide (S. Kern, *Chem. News*, xxxiii. 184).

Alteration of Iodine tincture.—This tincture (alcoholic solution), when kept for some time, is found to contain hydriodic acid, the quantity of which may be determined by diluting the tincture largely with water, so as to precipitate the greater part of the iodine, then treating the filtrate with barium carbonate, and estimating the dissolved barium iodide. A tincture ten years old was found to contain 1.12 per cent. hydriodic acid (P. Carles, *Pharm. J. Trans.* [3], vi. 88).

Detection and Estimation.—On the estimation of Iodine by means of soluble Thiocyanates, see HALOGENS, p. 923. On the estimation of Iodine in Organic Compounds, see p. 924; also Brügelmann (*Zeitschr. anal. Chem.* 1877, pp. 1–21; *Chem. Soc. Jour.* xxxi. 739).

For the estimation of iodine in cuprous iodide, Ulex (*Arch. Pharm.* [3], v. 524) expels the iodine by means of ferric chloride, and receives it in a solution of potassium iodide, the operation being conducted in an apparatus which allows of the aspiration of a stream of air through the liquid during the ebullition, whereby the process is greatly accelerated. Or the cuprous iodide is decomposed with zinc powder, and the soluble zinc iodide thereby produced is titrated by Mohr's method with silver solution and neutral potassium chromate.

For the exact estimation of iodine in urine, A. Hilger (*Zeitschr. anal. Chem.* 1873, 342; 1874, 476) acidulates 40 c. c. of the urine with hydrochloric acid, and determines the iodine by means of a standard solution of palladium chloride, 10 c. c. of which are equivalent to 0.00119 iodine, the strength having been determined by means of potassium iodide. The titration is best performed by measuring out 10–20 c. c. of the palladium solution, heating it on the water-bath in a flask with ground stopper, and adding the urine-solution, previously brought to a determinate volume, till the whole of the palladium is precipitated, the completion of the process being ascertained by the testing of small filtered samples. The presence of phosphates and sulphates does not interfere with the determination.

Iodides. 1. *Hydrogen Iodide* or *Hydriodic acid*.—On the Direct Formation and Dissociation of this compound, see CHEMICAL ACTION (p. 428). On its Heat of Formation, see pp. 952, 963.

Preparation.—For the preparation of gaseous hydrogen iodide, A. Bannow (*Berl. Ber.* vii. 1498) introduces red phosphorus into a tubulated retort, and adds to it, by means of a dropping funnel, a solution of 2 pts. iodine in 1 pt. hydriodic acid of sp. gr. 1.7. The evolution of gas begins without external heating, but after the whole

* The process described in vol. iii. p. 290, as practised in Glasgow, has been abandoned for many years.

of the liquid has been added, the action must be assisted by a gentle heat. The quantity of the solution must be so regulated that the phosphorus and iodine may be present in the ratio of P^2 to I^3 . If heat be applied too soon, a considerable sublimation of phosphonium iodide will take place.

Kolbe (*J. pr. Chem.* [2], xv. 172) finds that the method of preparing aqueous hydriodic acid, recommended by Vigier and copied into many text-books, which consists in pouring 15 pts. of water on 1 pt. of amorphous phosphorus, adding 20 pts. of iodine, and driving over the resulting hydriodic acid by heating [the reaction being represented by the equation $P^2 + 5I^2 + 5H^2O = P^2O^5 + 10HI$ (1st Suppl. 738)], always yields a dilute and strongly iodised acid, and that a better product is obtained by the older method of first preparing phosphorus iodide with 1 pt. amorphous phosphorus and 10 pts. iodine, and decomposing this compound with water.

The following process is recommended by W. Stevenson (*Chem. News*, xxvi. 201) for preparing hydriodic acid, iodic acid, and the greater number of iodides and iodates. 3 pts. iodine are dissolved in a solution of 2 pts. barium hydrate in 4 pts. boiling water, and the liquid, after it has become neutral and colourless, is filtered. The insoluble barium iodate thus obtained serves for the preparation of iodic acid and metallic iodates, and the soluble barium iodide for that of hydriodic acid and iodides.

On the reaction of Hydriodic acid with Ethers, see p. 741.

Carbon Iodide or Tetriodomethane, CI^4 (see p. 404).

On the Periodides and Sulphatoperiodides of the Cinchona-bases, see pp. 479, 486, 489-491, and 493.

Iodine Bromide, BrI . This, according to Bornemann, is a crystalline body having the colour of iodine; melting at 36° ; distilling with partial decomposition; subliming in fern-like groups of crystals; and dissolving in water with much less separation of iodine than that which takes place with iodine chloride. The hydrate, $BrI \cdot 5H^2O$, described by Löwig (iii. 293) does not exist.

Iodine Chloride (Bornemann, *Liebig's Annalen*, clxxxix. 184). To prepare the monochloride, ICl , chlorine was passed over iodine contained in a retort, till crystals of the trichloride made their appearance, and the red-brown liquid was distilled into glass tubes which were immediately sealed. The contents of those which contained small quantities of the trichloride solidified after a while, yielding very fine crystals of the mono- and tri-chloride, whereas those of the tubes in which there were no crystals of the trichloride did not solidify, even in a freezing mixture. When, however, they were opened, their contents solidified after a while, with the exception of those which contained free iodine as well as ICl , a result which agrees with an observation made by Brenken (*Berl. Ber.* viii. 489) that the crystallisation of ICl is facilitated by ICl^3 , but retarded by free iodine. Iodine monochloride is decomposed by water, as observed by Trapp and by Schützenberger (iii. 293) with formation of iodic and hydrochloric acids and separation of iodine. The quantity of chlorine required to dissolve iodine suspended in water increases with the proportion of water present, and for the complete conversion of the iodine into iodic acid, at least 20 pts. of water must be present to 1 pt. of iodine. In more concentrated solutions the passage of chlorine is attended with the separation of iodine trichloride as well as of iodic acid.

Hydrogen-iodine Chloride, $ICl.HCl$, is a yellow, volatile compound, formed, according to Schützenberger (*Compt. rend.* lxxxiv. 389), together with iodic and hydrochloric acids, by the action of water on the chloride of iodine, and may be extracted from the aqueous solution by ether. The formation of this body is the cause of the stability of iodine monochloride in water containing hydrochloric acid, observed by Gay-Lussac (iii. 293).

Schützenberger has also examined the action of water on various systems of iodine chlorides comprised between the limits ICl^5 and ICl . Each of these systems may be regarded as a mixture of the two components ICl^5 and ICl , the former of which is resolved by water into iodic and hydrochloric acids: $ICl^5 + 3H^2O = IO^3H + 5HCl$. If now the quantity of hydrochloric acid thus formed is equal to or greater than that which is required to convert the ICl into the compound $ICl.HCl$, which is stable in water, the monochloride ICl will not be decomposed. In the contrary case, however, it will suffer decomposition just as if it were alone, that is to say, it will be resolved by the water into iodic acid, hydrochloric acid and a corresponding quantity of free iodine, till the hydrochloric acid thereby produced is sufficient to convert the rest of the monochloride into the stable compound $ICl.HCl$:

Iodine trichloride may accordingly be regarded as a compound of ICl^5 and ICl , and will give up half its iodine in the form of iodic acid. The system, $4ICl^2 = ICl^5 + 3ICl$,

will in like manner give up one-fourth of its iodine as iodic acid. The system $\text{ICl}^3 \cdot 5\text{ICl}$ is the most highly iodised system that can be decomposed without separation of iodine.

Trichloride, ICl^3 .—Christomanos (*Berl. Ber.* x. 434) prepares this compound by the action of chlorine on hydrogen iodide:

Pure hydrogen iodide, obtained by gradually adding iodine to a mixture of amorphous phosphorus with a few drops of water gently heated in a retort, is passed through a calcium chloride drying-tube into a tall cylinder or flask filled with dry chlorine. At the first contact of the two gases, a dense white cloud of hydrogen chloride is formed, in which float innumerable golden-yellow spangles of iodine trichloride. When the hydrogen iodide is in excess, the fumes have a reddish-violet colour, and the spangles of trichloride then assume a still more brilliant appearance. Generally, if the two gases are tolerably pure, the hydrogen iodide takes fire in the chlorine. Violet fumes of iodine are then set free, which immediately combine with chlorine to form brilliant golden-yellow crystals of trichloride, whilst the hydrogen burns with bright red-flame in the iodine vapour. The sides of the cylinder speedily become covered with yellow crystalline scales of the trichloride. If after this the current of hydrogen iodide be continued, the crystals assume a darker colour, becoming orange and brown, and finally deliquescent, owing to the following reaction:—

The process forms a very striking lecture experiment.

Iodine trichloride is a lemon- to orange-yellow solid, very easily decomposable. It can be preserved only in an atmosphere of chlorine. In the air it volatilises perceptibly, even at -12° . It is less volatile in carbon dioxide, especially when cooled to -12° , but it still loses weight distinctly, and at the same time an odour of carbonyl chloride, COCl^2 , is perceptible. When heated to 100° in an open glass tube it is instantly decomposed into free chlorine and iodine monochloride, which latter boils rapidly at that temperature. In an atmosphere of chlorine the trichloride melts at 33° . It dissolves in water. Strong sulphuric acid throws down from the concentrated aqueous solution a yellow powder; but the same acid dissolves the trichloride with yellow colour. The trichloride dissolves in potash, forming iodide, chloride, iodate, and chlorate. In an atmosphere containing ammonia it emits dense white fumes. An excess of ammonia immediately converts it into nitrogen iodide, sal-ammoniac, and ammonium iodide. The trichloride dissolves in benzene with dark cherry-red colour. It is immediately decomposed by carbon bisulphide, sulphur chloride being formed. It oxidises solutions of sulphur dioxide and ferrous sulphate when boiled therewith. Potassium and phosphorus take fire in contact with it. The trichloride volatilises in a current of hydrogen in the cold without acting upon it; but on gentle heating, hydrogen chloride and liquid iodine monochloride are formed.

With regard to the melting point, Lothar-Meyer (*Ber.* x. 648) observes that the fusion of iodine trichloride is merely a consequence of its dissociation, which depends upon pressure, presence of chlorine, &c., so that the melting point 33° observed by Christomanos must have been determined by accidental conditions. The beginning of the decomposition may take place, according to circumstances, at 25° or above 80° .

The specific gravity of iodine trichloride cannot be determined by any of the customary methods, on account of the facility with which this compound volatilises and decomposes; in fact it maintains a constant weight only at comparatively low temperatures in an atmosphere of chlorine or carbon dioxide. The following method of determining the specific gravity, which may be applicable also in the case of other easily decomposable bodies, is described by Christomanos (*Berl. Ber.* x. 782; *Chem. Soc. J.* xxxii. 697). A thin-walled glass vessel furnished with two glass taps, and holding about a litre, is filled with chlorine and weighed, the chlorine then expelled by carbon dioxide, and the vessel again weighed. The iodine trichloride is next introduced into the vessel, chlorine passed through, and another weighing made. The resulting increase of weight is equal to the weight of the iodine trichloride less that of the chlorine which it displaces. The chlorine is then displaced by carbon dioxide, and the vessel is again weighed, whereby the weight of the trichloride is obtained less that of an equal volume of carbon dioxide which it displaces; and as the weights of the equal volumes of chlorine and carbon dioxide thus displaced stand to one another in a known proportion, the weight of a volume of chlorine equal to that of the iodine trichloride, and the weight of the trichloride itself, can be determined by calculation. Hence also the weight of the trichloride compared with that of an equal bulk of water, that is to say, its specific gravity, can be found. The number found by Christomanos was 3.1107; but as the experiments were made with a very imperfect apparatus, this number is regarded as only approximate.

Oxides and Oxygen-acids of Iodine. *Iodine Trioxide* or *Iodous Oxide*, I_2O_3 , is formed, together with the pentoxide, which is the ultimate product, by the action of ozone on iodine. It is a light-yellow, extremely light powder, which deliquesces to a syrup in moist air, and is resolved, on addition of more water, into free iodine and iodic acid. Heated to 125° – 130° , it decomposes violently, with evolution of iodine and free oxygen, leaving a small white residue of iodic oxide, which is decomposed at a higher temperature into iodine and oxygen (J. Ogier, *Compt. rend.* lxxxv. 957).

Iodic acid, IO^3H . *Reactions, Detection, and Estimation.*—Iodates in solution are reduced to iodides by the action of the copper-zinc couple (Thorpe, *Chem. Soc. J.* 1873, 541).

According to Jacquemin (*Compt. rend.* lxxvii. 211), small quantities of iodic acid or its salts may be readily detected by means of *pyrogallol*, which instantly turns them brown and produces a precipitate of purpuro-gallin (1st *Suppl.* 977). As pyrogallol does not act in a similar manner on the acids of chlorine and bromine, or on nitric acid, this test may be used for the detection of iodic acid in nitric acid, and of iodates in potassium iodide solution, urine, and other liquids.

Action of Phosphorus.—Sonstadt (*Chem. News*, xxviii. 288) employs for the detection of small quantities of iodates—in sea-water for example—carbon disulphide containing in solution a small quantity of phosphorus. An excess of phosphorus must be avoided, as it would destroy the coloration by converting the reduced iodine into hydriodic acid. According to Corne (*J. Pharm.* [4], xxii. 425), the separation of iodine from iodates in solution may also be effected by addition of a few drops of water in which phosphorus has been kept, the effect being due to the presence of phosphorous acid in the liquid, inasmuch as it is not produced by a piece of clean phosphorus. Polacci, on the other hand (*Gazz. chim. ital.* 1873, 474) ascribes the reduction to the direct action of the phosphorus; he finds, moreover, that it is produced by amorphous phosphorus. If the liquid is alkaline, it must first be neutralised. Corne (*J. Pharm. Chim.* [4], xxiv. 216), from further experiments maintains the correctness of his former view.

Iodic and Periodic acid may be separated by the different behaviour of their barium-salts to ammonium carbonate, the iodate being easily converted by digestion with ammonium carbonate, even at ordinary temperatures, into barium carbonate and ammonium iodate, whereas the periodate when similarly treated remains unaltered (Kämmerer, *Zeitschr. anal. Chem.* 1873, 377).

Constitution and Basicity of Periodic Acid.—Thomsen, from his experiments on the heat of neutralisation of periodic acid, inferred that, of the five hydrogen-atoms in the ordinarily assumed molecule of this acid, H^5IO_6 , two only are normally basic; in other words that the acid must be regarded as pentahydric (or pentatomic) and bibasic (2nd *Suppl.* 681). The same view is taken by Basarow (*Berl. Ber.* vi. 92), who represents periodic acid by the formula $(\text{HO})^3\text{IO}$, in which the iodine is septivalent, two of the five hydroxyl-groups being acid, the other three alcoholic.

Sodium Periodate.—A crystalline periodate of sodium is precipitated when an iodide or iodate is heated with a hypochlorite and excess of alkaline hydrate, in presence of sodium salts. As this precipitation takes place only when sodium salts are present, it may be used as a test for sodium (T. Fairley, *Rep. Br. Assoc.* 1875, [2], 42).

IODOFORM, CHI_3 . This compound is produced, together with acetic acid, by the action of iodine and ammonia on monobromacetone (Sokolowsky, *Berl. Ber.* ix. 1687).

To prepare iodoform, R. Rother (*Pharm. J. Trans.* [3], iv. 593) heats 32 pts. iodine, 32 potassium carbonate, 16 alcohol of 95 per cent. and 80 water, till the mixture becomes colourless; then decants the clear liquid; collects the separated crystals of iodoform; and mixes the filtered liquid with 16 to 24 pts. hydrochloric acid and 2 to 3 pts. potassium dichromate. The liquid is then neutralised with potassium carbonate, and 32 pts. more of that salt are added, together with 6 pts. iodine and 16 alcohol. The reaction having been completed at the heat of the water-bath, the product is treated as above, whereby a fresh quantity of iodoform is obtained. The object of the treatment with potassium chromate and hydrochloric acid is to set free the iodine present as potassium iodide by the action of the chlorine thereby evolved, and thus render it available for the reaction.

On the Crystalline Form of Iodoform, see Dogiel (*N. Petersb. Acad. Bull.* xx. 337).

IRIDIUM. On alloys of Iridium and Platinum, and on the Separation of these two Metals, see PLATINUM.

IRIS ROOT. The crystalline odoriferous principle obtained by distilling this root with water has been examined by Flückiger (*Arch. Pharm.* [3], viii. 481), who

finds that it consists of crystals of myristic acid saturated with a fragrant oil. The myristic acid does not appear to be present in the root in the free state, but to be separated by the process of distillation from a compound existing therein.

IRON. *Occurrence.*—The metallic iron found by Nordenskiöld near Disen Bay, in Greenland (2nd Suppl. 796), and supposed to be of meteoric origin, has been examined by Steenstrup, who infers, from its mode of occurrence and its structure, that it is of terrestrial origin, an opinion in which Rammelsberg concurs (*Zeitschr. geol. Ges.* xxviii. 225; *Jahrb. f. Min.* 1877, 91; *Chem. Soc. J.* xxxii. 578).

On Meteoric Iron, see METEORITES.

On the occurrence of Iron ores in various countries, and the minerals accompanying them, see *Jahresh. f. Chem.* 1875, 1265.

Physical Properties.—On the influence of Heat, and of the passage of an Electric Current, on the Electric Conductivity of iron and steel, see ELECTRICITY (p. 718). On the Heat-conductivity of iron, see HEAT (p. 1017).

Influence of Magnetisation in the Molecular Structure of Iron.—Faraday showed that iron loses its magnetism at a high temperature, and recovers it at a certain point as the temperature falls. W. F. Barret (*Phil. Mag.* [4], xlvii. 51) finds that at this particular temperature an iron wire experiences an alteration of structure attended with sudden elongation, and a change of place of the metal in the thermo-electric scale; at the same time it emits a sound, and glows more brightly for a short time, just before its incandescence ceases altogether. The thermic and electric conducting powers of the wire appear to be altered at the same time. Barret also observes that a very hard and tough iron can be produced by the action of a strong electromagnet on the metal while in a state of fusion.

Occlusion of Gases by Iron.—Iron precipitated by the voltaic current from a solution of neutral ferrous chloride and sal-ammoniac (shining brittle nodules which scratch glass) gives off hydrogen when immersed in water or other liquid. By exposure to the air it loses only a portion of the absorbed gas. In hot water the evolution of gas from the iron is very rapid, and is sometimes attended with an audible sound. The occluded gas is given off when the iron is heated in a vacuum. One vol. iron thus treated gave off 235.8 to 248 vol. hydrogen. The iron, after it has been heated, takes up no more hydrogen, even when it is employed as the negative electrode of a voltmeter. The hydrogenised iron is very hard and possesses considerable coercitive power (Chailletot, *Compt. rend.* lxxx. 319).

According to O. Reynolds (*Institut.* lxxiv. 270), iron takes up hydrogen when acted upon by dilute sulphuric acid. Iron or steel thus treated becomes shortened and brittle, increases in weight, and gives off hydrogen when immersed in water.

On the Occlusion of Gases by Cast Iron and Steel, see IRON METALLURGY (p. 1112).

Influence of various Solutions on the Rusting of Iron.—A. Wagner has examined the action produced on strips of iron by water containing various salts, in presence of air free from carbon dioxide, and of air containing that gas, at various temperatures; also in sealed tubes from which air was expelled.

The experiments show that pure water in presence of air causes iron to rust; that if carbon dioxide is also present, the rusting is more rapid; that the production of rust is materially increased by the chlorides of magnesium, ammonium, sodium, potassium, barium, and calcium, the first mentioned being the most active in this respect; that iron immersed in evaporated river-water rusts more slowly than iron in distilled water; that the presence of oils or fats greatly diminishes the rapidity of rusting; and that alkalis prevent the rusting entirely. Magnesium chloride solution in the absence of air attacked iron at a temperature of about 100°; the chlorides of sodium, potassium, barium, and calcium were without action under the same circumstances.

Compounds of Iron.

Alloys. An alloy of iron and Chromium containing 74 per cent. Cr, 25 per cent. Fe, and 1 per cent. foreign matter, has been obtained by reducing chrome-iron ore (from the Ural) with charcoal; it has a silvery fracture, and the hardness of diamonds. In some trials alloys capable of welding were formed; they contained 96.4 per cent. iron, 2.3 chromium, 1.3 lime and silica, and traces of carbon (*S. Kern, Chem. News*, xxii. 136, 265).

An easily fusible alloy, which filled the moulds well, was found to contain 79 per cent pig-iron, 19.5 tin, and 1.5 lead (*Kern, loc. cit.*)

On alloys of Iron and Manganese, see IRON METALLURGY (pp. 1108–1111). On alloys of Iron and Copper, see COPPER (p. 566).

Amalgamation.—An amalgam of iron is easily obtained by bringing cleansed iron in contact with sodium- or ammonium-amalgam, and when it has become covered with

a silvery coating, dipping it into acidulated water; the sodium- or ammonium-amalgam is then decomposed, and the mercury penetrates the iron. An iron plate is also quickly amalgamated when made to serve as the negative electrode of a battery with mercury and acidulated water. The best results are, however, obtained by the use of zinc-amalgam. The mercury is covered with dilute sulphuric or hydrochloric acid, and the iron is placed in the liquid, together with some pieces of zinc, whereupon it quickly becomes covered with mercury. The quantity of mercury thus precipitated on the iron is very small; nevertheless, it does not merely form a superficial deposit, but penetrates deep into the iron, modifying its chemical and physical properties. Amalgamated iron, like amalgamated zinc, is less easily attacked by acids than the metal in its ordinary state.

Cyanides. See pp. 611–616.

Nitride, $\text{Fe}^{\text{e}}\text{N}^{\text{e}}$. This compound has been found by Silvestri (*Pogg. Ann.* clvii. 165) in silvery-lustrous deposits on the lavas of Etna. It may be formed artificially by heating the lava first in a stream of hydrogen chloride, to decompose it, and then in a stream of dry ammonia gas; also, though less easily, by the action of sal-ammoniac vapours on the ignited lava. On fusing it with sulphur, sulphide of iron is formed and nitrogen is evolved.

Frémy (*Compt. rend.* lii. 321) assigns to the artificial compound the formula $\text{Fe}^{\text{e}}\text{N}^{\text{e}}$; by Stahlschmid (*Pogg. Ann.* cxxv. 321) it is regarded as $\text{Fe}^{\text{e}}\text{N}^{\text{e}}$, and by Rogstadius (*J. pr. Chem.* lxxxvi. 307) as $\text{Fe}^{\text{e}}\text{N}^{\text{e}}$. The natural product heated in a stream of hydrogen yields metallic iron and ammonia, in quantities which show that the composition of the nitride is 90.86 per cent. iron, and 9.14 nitrogen, agreeing with Frémy's formula.

Silvestri considers it very probable that this iron nitride, for which he proposes the name 'Siderazote,' has played a very important part in volcanic processes, as it appears that the metallic-shining compound is peculiar to blocks of lava possessing sharp edges, found in the neighbourhood of craters, and in the middle of lava streams. Lava may possess the property of absorbing nitrogen under certain conditions of temperature, and thus give rise to the formation of ammonium chloride, which is found so largely as a product of the fumaroles in crevices and holes. The decomposition of this ammonium chloride in presence of ferruginous lava may explain the presence of hydrogen amongst the products of volcanic action.

Oxides. Ferric oxide prepared from the oxalate, when heated for half an hour to 350° in a current of hydrogen, furnishes the magnetic oxide; if it be heated for twenty minutes to 500° , ferrous oxide is produced in the pyrophoric state. Ferrous oxide thus prepared decomposes water, slowly at ordinary temperatures, more rapidly at 100° . In contact with nitric acid, it exhibits vivid incandescence. With carbon dioxide at 500° it forms carbon monoxide and magnetic oxide of iron: $3\text{FeO} + \text{CO}^2 = \text{Fe}^{\text{e}}\text{O}^4 + \text{CO}$, a reaction which explains why ferrous oxide cannot be obtained by heating the carbonate, unless the heat be very gentle. Pyrophoric ferrous oxide displaces a part of the ammonia in ammonium sulphate, forming ammonio-ferrous sulphate. Carbon dioxide has no effect on it at the ordinary temperatures, nor does exposure to a temperature of 450° in an atmosphere of nitrogen deprive it of its pyrophoric properties.

If ferric oxide be reduced by hydrogen at 700° , non-pyrophoric metallic iron is produced. Carbon monoxide produces the same effect as hydrogen, forming magnetic oxide at 350° , pyrophoric ferrous oxide at 500° , and metallic iron at 700° to 800° .

The same results are obtained when the reductions are effected at the same temperature, but for different lengths of time; thus, at 440° , ferrous oxide is obtained after six hours, and metallic iron after twelve hours' reduction; at 350° magnetic oxide is obtained after one hour, ferrous oxide after ten hours, and metallic iron after thirty-six hours (*H. Moisson, Compt. rend.* lxxiv. 1296).

Ferric Oxide, $\text{Fe}^{\text{e}}\text{O}^{\text{e}}$.—A. Frenzel (*Jahrb. f. Min.* 1874, 685) accidentally obtained small rhombohedrons of iron-glance, slightly magnetic and having a metallic lustre, by igniting a precipitate of ferric hydrate.

Ferric Oxide from Meteoric Iron.—Ignited ferric oxide prepared from meteoric iron is attracted by the magnet, whereas the oxide prepared from ordinary iron does not exhibit this property after ignition; when dried at 110° it is slightly attracted, but this property is feeble; the higher the temperature at which the oxide has been dried. With the sesquioxide prepared from meteoric iron the case is exactly the reverse. The magnetic properties of the oxide thus prepared are due to the presence of small quantities of nickel or cobalt-salts; and when these have been removed by four successive precipitations and redissolutions in sodium acetate, the ferric oxide exhibits all the properties of that which is obtained from terrestrial sources. On the other hand by adding small quantities of cobalt or nickel (or both) to a ferric salt,

and precipitating with ammonia, an oxide is obtained having all the properties of that which is prepared from meteoric iron. It is possible that the presence of the nickel or cobalt may give rise to the formation of $\text{Fe}^{\text{Ni}}\text{O}^{\text{Ni}}$, or that, as suggested by C. F. Chandler, the oxide of cobalt or nickel may unite with the ferric oxide to form the compounds, $\text{Fe}^{\text{Co}}\text{CoO}^{\text{Co}}$ and $\text{Fe}^{\text{Ni}}\text{NiO}^{\text{Ni}}$, analogous to $\text{Fe}^{\text{Ni}}\text{O}^{\text{Ni}}$ (J. L. Smith, *Amer. Chemist*, v. 356).

Reduction of Ferric Oxide by Carbon.—J. Parry (*Chem. News*, xxvii. 313) found that when pure ferric oxide was heated in a vacuum with pure carbon, obtained by calcination of white sugar, no gas was evolved at 100° , but that between the melting points of lead and copper 77 per cent. of the oxygen in the ferric oxide was removed in seventeen hours, slowly at the lower temperatures, with formation chiefly of carbon dioxide, rapidly at the higher temperatures, the gas then evolved consisting chiefly of carbon monoxide. These facts seem to show that solid carbon may play some part in the chemistry of the blast-furnace.

Reduction by a mixture of Carbon Dioxide and Cyanogen.—This mixture at high temperatures exerts a strong reducing action, stronger indeed than that of a mixture of CO^2 and CO . With 1 vol. CN and 6 vol. CO^2 at 685° – 710° F., the ferric oxide is deprived of 79.9 per cent. of its oxygen, yielding 56.3 per cent. metallic iron. If the proportion of CO^2 be increased to 15 vol., only 6.5 per cent. of metallic iron is obtained, and with 30 vol. CO^2 the yield of iron is reduced to 0.9 per cent. Part of the carbon formed unites with the reduced iron.

Ferric Hydrate. *Limonite*, $\text{Fe}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{H}}$ or $2\text{Fe}^{\text{H}}\text{O}^{\text{H}}\cdot 3\text{H}^{\text{O}}$, occurs at Big Lick, Roanoke County, Virginia, in narrow veins having the lustre and translucency of goëthite. These veins, which traverse the ordinary compact limonite, are dark blood-red by transmitted, nearly black by reflected light. Lustre between adamantine and waxy. Streak yellowish brown. Hardness somewhat above 5. Sp. gr. 3.76 at 15° .

Composition.—A. Direct result of analysis. B. After deduction of phosphoric acid and of 2.68 per cent. $\text{Fe}^{\text{P}}\text{O}^{\text{P}}$ as $\text{Fe}^{\text{P}}\text{O}^{\text{P}}$, also of the water given off at 100° . C. Values calculated from the formula $\text{Fe}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{H}}$:

	$\text{Fe}^{\text{O}}\text{O}^{\text{O}}$	$\text{Mn}^{\text{O}}\text{O}^{\text{O}}$	$\text{AlP}^{\text{O}}\text{O}^{\text{O}}$	$\text{P}^{\text{O}}\text{O}^{\text{O}}$	SiO^{O}	H^{O}	
A (found)	81.52	0.11	0.26	2.38	0.51	14.95	= 99.73
B (corr.)	85.61	—	—	—	—	14.39	= 100
C (calc.)	85.56	—	—	—	—	14.44	= 100

Of the 14.95 per cent. H^{O} , 1.70 goes off at 100° , 0.93 at 150° , 3.60 at 200° , 5.01 at 250° , and 3.74 at a red heat (Mallet, *Sill. Am. J.* [3], ix. 460).

Compound of Ferric Oxide with Lime. $\text{Fe}^{\text{O}}\text{O}^{\text{O}}\cdot\text{CaO}$ or $(\text{FeO}^{\text{O}})^2\cdot\text{CaO}$. This body is formed when a mixture of 190 pts. iron and 66.5 lime is heated to whiteness for several hours in a platinum crucible standing in a muffle, and the mixture is left to cool slowly. It is thus obtained in crystals often an inch long, and having a strong metallic lustre. Still larger crystals of the same compound are obtained by igniting 1000 grains of hematite with 1000 grains of chalk. It is magnetic, has a sp. gr. of 4.693, and yields a red-brown powder (J. Percy, *Phil. Mag.* [4], xlv. 455).

Ferroso-ferric Oxide, Magnetic Oxide, $\text{Fe}^{\text{O}}\text{O}^{\text{O}}$.—A mixture of this oxide with corundum, forming a thick bed at Sheep's Hill near Cruger on the Hudson, is described by J. Kempland (*Amer. Chem.* iv. 321; *Jahresh. f. Chem.* 1874, 1078). Being a very basic and therefore very refractory mineral and rich in ferric oxide, it is well adapted for the fettling of puddling furnaces, and as an oxidising material in the Bessemer converter.

Ferroso-ferric Oxide from Aniline residues.—The residue left in the preparation of aniline by the action of ferrous acetate on nitrobenzene consists of magnetic iron oxide, $\text{Fe}^{\text{O}}\text{O}^{\text{O}}$, agreeing in composition with the native oxide from Cornwall and Dannemora, as shown by the following analysis:

$\text{Fe}^{\text{O}}\text{O}^{\text{O}}$	FeO	Graphite	SiO^{O}	$\text{P}^{\text{O}}\text{O}^{\text{O}}$	S and Mn
67.00	30.05	1.23	0.78	0.62	traces = 99.68

(J. Spiller, *Berl. Ber.* vi. 1384).

Oxysalts of Iron. See the several acids.

Phosphide. On triferrous phosphide, $\text{Fe}^{\text{P}}\text{P}^{\text{P}}$, produced by the action of phosphine on a solution of a ferrous salt, see 2nd Suppl. 949.

Sulphides. The *Monosulphide*, FeS , may be prepared by heating a mixture of 2 pts. iron pyrites and 1 pt. iron-filings to redness for half-an-hour in a hessian crucible (C. Méhu, *Russ. Zeitschr. Pharm.* 1876, 546).

The *Sesquisulphide* or *Ferric Sulphide* is precipitated as a hydrate, $2\text{Fe}^{\text{S}}\cdot 3\text{H}^{\text{O}}$, by the action of yellow ammonium sulphide on a solution of ferric chloride containing free chlorine or a small quantity of sodium hypochlorite. As thus

obtained, it is a green flocculent precipitate, becoming almost black after washing on the filter. On mixing it, after drying, with a white powder, such as chalk, the green colour is again distinctly seen. The sesquisulphide is soluble in ammoniacal water, and is precipitated therefrom on dilution: it dissolves also in alcoholic ammonia, forming a perfectly clear, emerald-green solution which can be filtered. In a mixture of ammonium sulphide and very dilute ammonium thiosulphate, it is but slightly soluble. It dissolves in hydrochloric acid, with evolution of hydrogen sulphide and formation of ferric chloride (Phipson, *Chem. News*, xxx. 139).

Bisulphide, FeS_2 . Iron pyrites.—Observations on the formation of pyrites in recent times have been made by Daubrée (*Compt. rend.* lxxxi. 584; *Chem. Soc. Jour.* xxix. 533). He points out that, frequent as the formation of iron sulphide may be, it is but rarely that the product is a true pyrites, that is to say, a crystalline, metallicallly lustrous sulphide, capable of resisting the action of acids. Amongst localities in which true pyrites has been formed in historic times, may be especially mentioned the warm springs of Bourbonne-les-Bains (Dép. Haute Marne) and of Hamman-Meskoutin in the province of Constantine, Algeria. At the former locality, pyrites is found in small granules mixed with the sand near the source of the spring, and as a coating on quartz-grains and remains of flint implements, whereby its recent origin is sufficiently indicated, also in small cavities in the lime between the tiles of an old conduit, which likewise contains crystals of calcspar. The reaction in this case appears to be similar to that observed by Ebelmen between calcium sulphate and ferric oxide, in presence of organic matter, whereby iron bisulphide and calcium carbonate were produced. Daubrée also mentions the occurrence of pyrites in a fissure of a ship's timber which, before being used for building, had lain for some time in a basin receiving the contents of two sewers, whereby reducing and sulphuretted compounds were probably introduced into the water.

Detection and Estimation of Iron, and Analysis of its Compounds.

The smallest trace of iron in a nickel-salt may be easily detected by mixing the slightly acidulated solution with *potassium thiocyanate*, and agitating with ether. A rose tint in the ethereal layer indicates with certainty the presence of iron (Böttger, *N. Rep. Pharm.* xxiv. 621).

Estimation of Ferric Oxide and Alumina in presence of Phosphoric Acid.—To the liquid containing phosphoric acid, alumina, and oxide of iron, an excess of calcium chloride is added, and then ammonia, which throws down tricalcic phosphate, alumina, and ferric oxide. The precipitate is ignited, weighed, and dissolved in hydrochloric acid; the phosphoric acid is determined by means of uranium in one portion of the solution, and the iron by stannous chloride in another. The phosphoric acid is calculated into tricalcic phosphate, and the iron into Fe_2O_3 , and the difference between the united weights of these compounds and that of the original precipitate gives the alumina. If sulphuric acid is present, it must be separated by baryta before the addition of ammonia. The presence of baryta in the filtrate does not affect the results, provided sufficient calcium chloride is added to precipitate all the phosphoric acid, as $\text{P}^{+}\text{O}^{+}(\text{CaO})^2$ (H. Pellet, *Bull. Soc. Chim.* [2], xxvii. 106).

Volumetric Estimation. 1. With *Sodium Thiosulphate* (iii. 385).—To render this method exact, it is desirable that the iron solution should be as nearly neutral as possible, since an excess of acid would decompose the thiosulphate. J. M. Crafts (*Bull. Soc. Chim.* [2], xx. 50) employs for the titration: (1). A $\frac{1}{10}$ -normal solution of thiosulphate prepared by dissolving 12.4 grams of the air dried salt in a litre of water. 2. A $\frac{1}{20}$ -normal solution of ferric chloride, which serves for the exact titration of the thiosulphate solution, and is best prepared by dissolving the required quantity of iron containing a known amount of carbon in hydrochloric acid, with addition of a little nitric acid, and evaporating down till a drop taken out just dissolves in water without turbidity.

For the estimation of iron in ores, the pulverised ore is digested with strong hydrochloric acid, with addition of a little nitric acid, to convert the whole into ferric salt, and the solution is freed from excess of acid by neutralisation with sodium carbonate, or better by cautious evaporation. It is advisable to use 1.4 grm. of the ore and dilute the solution to half a litre. The number of c.c. of thiosulphate solution required for the decomposition of 100 c.c. of the iron solution, will then give the percentage of metallic iron in the ore. The first titration serves for the approximate estimation of the quantity of thiosulphate required; in the subsequent operations, about 20 per cent. more of the thiosulphate is taken, and the excess determined by back-titration in the usual way with iodine and starch. The operation is somewhat impeded by the presence of considerable quantities of sulphates, phosphates, and in general of any acids which readily form precipitates with the iron. The presence of atmospheric oxygen in the water used does not create any difficulty.

2. With *Permanganate*.—Parnell (*Chem. Soc. Jour.* xxvi. 27) recommends that the estimation of iron by permanganate be performed by candle or gas light, so that the disturbing influence caused by the yellow colour of the resulting ferric salt on the exact recognition of the end of the operation may as far as possible be eliminated. A solution of 3 pts. ferric chloride in 400 pts. of water is colourless by candle-light, but the slightest trace of permanganate added to it produces a perceptible coloration. For the titration of the permanganate solution, Parnell recommends *arsenious acid*, as it can easily be obtained quite pure, and the inconvenience arising from the slowness of the action towards the end of the oxidation, and from the brown coloration of the liquid resulting from the formation of manganic oxide, may be obviated by addition of a slight excess of a standard solution of a ferrous salt, the excess of ferrous oxide in which can be very exactly determined by back-titration with permanganate solution.

A simple method of estimating iron in ores, *without the use of weights*, is described by W. N. Hartley (*Chem. Soc. Jour.* xxviii. 410). A suitable quantity of the ore is counterpoised by pure iron wire; the ore and wire are dissolved in separate quantities of acid; the two solutions are made up to equal volumes; and $\frac{1}{50}$ of the total volume of each is taken for the analysis, whereby the error in weighing is reduced to $\frac{1}{50}$. The two ferric solutions are then reduced by granulated zinc, and titrated with permanganate. If then m and n denote the quantities of permanganate solution used for the solution of the ore and of the wire respectively, the percentage x of iron in the ore is given by the equation:

$$x = \frac{m}{n} \cdot 100.$$

3. With *Potassium Dichromate*.—The titration of ferrous salts with a standard solution of potassium dichromate is regarded by Riley (*Chem. Soc. Jour.* xxxii. 25) as the best of all methods for the volumetric estimation of iron. W. L. Howie (*Pharm. J. Trans.* [3], vi. 480) points out that it is apt to give too high a result, if sugar is present, and the titration is performed in a hydrochloric acid solution. In such cases, as in the analysis of *Ferrum carbonicum saccharatum*, he recommends that the iron salt be dissolved, not in hydrochloric, but in phosphoric acid, since, in presence of this acid, the dichromate is not reduced by sugar.

4. With *Stannous Chloride*.—To the method of estimating iron by means of standard solutions of stannous chloride, recommended by Fresenius and others (iii. 385), two objections have been raised, viz.: First, that the solution of stannous chloride rapidly decomposes, and has constantly to be re-standardised; secondly, that the results are not constant, the same weight of ore requiring varying amounts of standard solution. The first objection is met by keeping the standard solution in a bottle to which the air can have access only through a wash-bottle of potassium pyrogallate. When the solution is kept in this manner, the variation in four weeks is under 0.1 p.c. The second objection is untenable, since, when the solution is strongly acid and hot, the limits of error can be confined to 0.05 p.c. The extreme sharpness, and above all the rapidity of the operation, render it very advantageous, especially in mining practice (Uelsmann, *Zeitschr. anal. Chem.* xvi. 50). See also Stock and Jack (*Chem. News*, xxx. 221; xxxi. 63); Esilmann (*ibid.* 221); C. W. Hinman (*Sill. Am. J.* [3], xiv. 478; *Chem. Soc. Jour.* xxxiv. 608).

Carnelley (*Chem. News*, xxx. 257) estimates iron in well-water colorimetrically by adding to a measured volume of the water, after oxidation of the iron by permanganate solution and sulphuric acid, a known quantity of solution of *potassium ferrocyanide*, and comparing the tint of the resulting blue liquid with that of another, prepared by adding a titrated iron solution to the same quantity of potassium ferrocyanide dissolved in a correspondingly large volume of distilled water.

Separation of Iron from Uranium. According to E. Bureker (*J. Pharm. Chim.* [4], xxvii. 347), the method of separating these metals based on the precipitation of the iron with ammonium carbonate (v. 944) is not very exact, as, after a short time, the double carbonate of uranium and ammonium is likewise deposited, and is very difficult to remove from the precipitate. Better results are obtained by the following method given in Rose's *Traité d'Analyse Quantitative*. The solution of ferric and uranic salt is precipitated by ammonia; the precipitate, after ignition and weighing, is heated in a current of hydrogen, and the reduced iron is dissolved out by dilute hydrochloric acid, brought to the state of ferric salt by nitric acid, and precipitated by ammonia.

On the separation of Iron from *Uranium* and *Chromium*, see p. 458.

Analysis of Cast Iron and Steel.

An elaborate memoir on the estimation of the several constituents of iron and steel has been published by M. Boussingault (*Ann. Chim. Phys.* [5], v. 148). 1. To estimate the carbon, the finely-pulverised metal is triturated with 16 to 20 times its weight of mercuric chloride, and the insoluble mixture of carbon and mercurous chloride which remains after boiling the whole with hydrochloric acid, then washing and drying, is placed in a platinum boat, and heated to dull redness in a stream of hydrogen in order to drive off the mercurous chloride. The residue of carbon-compounds and graphite remaining in the boat is then weighed and heated, first over a lamp to burn away the carbon-compounds, afterwards in a stream of oxygen to burn the graphite. The accuracy of the determination may be increased by receiving the carbon dioxide produced by the combustion in a weighed absorption apparatus, as in organic analysis. This method, besides showing the form in which the carbon is present in the iron, has the further advantage of rendering visible extremely small quantities of carbon, even a small fraction of a milligram being easily recognised on the bottom of the platinum boat. The accuracy of the result is not impaired by the presence of nickel, copper, or chromium, since these metals, like the iron, are converted into chlorides, and pass into solution. The presence of tungsten, however, creates a difficulty, as this metal remains behind together with the carbon and the mercurous chloride, and is converted into oxide during the combustion of the carbon, thereby compensating wholly or partially the loss of weight. Moreover the tungstic acid formed at a red heat may burn a portion of the graphite to carbon dioxide. Hence, when the proportion of tungsten is considerable, it is best to estimate the carbon by direct combustion and weighing of the carbon dioxide.

Silicon.—To obtain an exact estimation of this element, especially when its amount is very small, the analysis must be made in the dry way, inasmuch as liquid reagents almost always contain traces of silicon, which may also be imparted from the glass or porcelain vessels in the process. If, on the other hand, the comminuted iron be first oxidised on the platinum boat in a muffle furnace, and then ignited in a stream of dry hydrogen chloride, pure silica will be left in the boat.

Phosphorus is estimated by dissolving the iron in nitric acid, evaporating, and calcining the residue, fusing the resulting oxide with sodium carbonate, boiling the melt with water, acidulating with nitric acid, and precipitating with an ammonio-ceric salt. The precipitate of cerium phosphate is then decomposed by oxalic acid, and the phosphoric acid in the filtrate is determined as ammonium-magnesium phosphate. The phosphoric acid may also be precipitated from the nitric acid solution by ammonium molybdate.

Sulphur is determined by passing the gas evolved on treating the iron with dilute sulphuric acid into a solution of silver nitrate, whereby the whole of the sulphur is precipitated as silver sulphide.

Manganese.—For the estimation of this metal, Boussingault finds that the iron (as ferric salt) may be completely precipitated by sodium acetate. When the quantity of manganese is very small, the nitric acid solution may also be treated with lead dioxide, and the resulting red solution titrated back with mercurous nitrate, the strength of which has been determined by means of an iron solution containing a known amount of manganese.

The precipitation of manganese as peroxide by the electric current is not to be recommended, on account of the time which it takes, and the various disturbing influences which affect the result.

For the estimation of the iron itself, Boussingault gives the preference to the method with permanganate; and for the detection of copper he recommends the known process founded on the separation of copper and iron by ammonia, and the extremely delicate reaction with ferrocyanide.

On the analysis of Carburetted Iron see also C. H. Piesse (*Chem. News*. xxix. 57 and 110; *Chem. Soc. J.* xxvii. 711); A. H. Allen, *Chem. News*. xxix. 91 and 120); H. Uelsmann, *Dingl. pol. J.* ccxx. 534; *Jahresb. f. Chem.* 1876, 999).

The following methods relate to the determination of special constituents:

J. Parry (*Amer. Chemist*, iv. 257) estimates the carbon in pig iron by dissolving the metal in solution of cupric sulphate, burning the dried residue of copper and carbon with cupric oxide, and instead of absorbing the carbon dioxide in a potash apparatus, passing it, by means of a Sprengel pump, into a graduated cylinder, and measuring it, with the necessary corrections for pressure, temperature, and moisture.

Uelsmann (*Dingl. Pol. J.* ccxx. 534), after dissolving the iron in a solution of cupric chloride, oxidises the carbon with chromic acid, as recommended by Ullgren

(*Liebig's Annalen*, cxxiv. 59), in an apparatus connected with a cooled receiver, the operation being assisted by heat, and the evolved carbon dioxide absorbed by soda-lime.

For the estimation of carbon in spiegeleisen, Riley (*Chem. Soc. J.* xxxii. 1) dissolves the metal in cupric chloride, and, after complete solution of the iron and of the precipitated copper, collects the carbon, &c., on an asbestos filter, and burns the carbon with cupric oxide in a current of oxygen. For high percentages of carbon Riley considers that colorimetric determinations are not satisfactory.

For the estimation of phosphorus, Uelsmann (*Dingl. pol. J.* ccxviii. 492) regards the method of precipitation with molybdic acid as the only one capable of affording exact results in the analysis of pig iron, steel, &c. The best way of proceeding, as proposed by Eggertz (*J. pr. Chem.* lxxix. 496), is to weigh the precipitate directly, as when dried at 110°–120° it always contains the same quantity of phosphorus (1.63 per cent.), provided the process be carried out under uniform conditions. It is especially important that no acid, except nitric acid, be present, and that the precipitate be quickly formed.

Koschelt (*Chem. Centr.* 1877, 487) prepares a molybdic solutida by dissolving 1 part of pure molybdic acid together with 1 part of caustic potash in 6 parts of water; adding, after cooling, a solution of $\frac{1}{3}$ part of tartaric acid in 2 parts of water, followed by addition of $7\frac{1}{2}$ parts of nitric acid; heating the whole to boiling; and filtering while hot. About 1 gram of the iron is dissolved in the smallest possible quantity of nitric acid (the solution should not measure more than 50 c.c.), and the filtered liquid is allowed to flow into about 30 c.c. of the molybdic solution placed in a basin on the water-bath. After complete precipitation, the whole is warmed for a short time; and the precipitate is collected on a weighed filter, washed with dilute nitric acid (2 : 3) and alcohol, dried at 120°–130°, and weighed: it contains 1.73 per cent. of phosphorus. Cairns (*ibid.*) precipitates the ferric phosphate with ammonia, redissolves, precipitates with ammonium molybdate, redissolves, reprecipitates, again dissolves, and finally precipitates with magnesia mixture.

A spectroscopic method of estimating phosphorus in iron and steel is given by J. Alleyne (*Institut*, 1875, 253), depending on the fact that when an electric spark is made to pass between iron electrodes, the presence of phosphorus may be recognised by certain characteristic lines, which disappear completely when the atmospheric air surrounding the electrodes is replaced by an atmosphere of hydrogen, and reappear when oxygen is again admitted into the tube, the quantity of oxygen required to reproduce them being inversely proportional to the amount of phosphorus in the iron.

Sulphur may be estimated by dissolving the iron in dilute sulphuric acid, and passing the gas, which contains hydrogen sulphide if sulphur is present, into an alkaline solution of lead oxide, whereby the sulphur is precipitated as lead sulphide, which may then be oxidised to sulphate. The operation should be conducted in an atmosphere of hydrogen, since, if air is passed for a long time through the alkaline lead solution, the precipitated lead sulphide becomes oxidised and dissolves in the alkaline liquid (Fresenius, *Zeitschr. anal. Chem.* 1874, 39). J. Moffat Johnson (*ibid.*) uses, instead of the alkaline lead solution, a solution of bromine in hydrochloric acid, whereby the hydrogen sulphide is immediately converted into sulphuric acid. Th. M. Drown (*Amer. Chemist*, iv. 423) effects the oxidation of the hydrogen sulphide by passing it through at least three bottles containing solution of potassium permanganate (1 : 200).

Aluminium and Chromium. For the determination of these metals the following method is given by A. Blair (*Sill. Am. J.* [3], xiii. 421). Five grams of iron or steel borings are placed in a half-litre flask with 20 c.c. of hydrochloric acid diluted with three or four times its volume of water, and the flask is closed with a valved stopper. If necessary, heat is applied, and when the iron is dissolved, the valved stopper is replaced by a solid one, and the flask cooled. The flask is then about three-fourths filled with water and a slight excess of barium carbonate (free from sulphate) added gradually. The flask should be thoroughly shaken several times, loosening the stopper occasionally to allow the carbonic acid to escape, and left over-night. The liquid is then quickly filtered, and the precipitate washed with cold water and dissolved in hydrochloric acid; the solution diluted; the sesquioxides of iron and chromium precipitated with ammonia; and the excess of ammonia expelled by boiling. The precipitate is washed, dried, and fused with 3 grams of sodium carbonate and 0.5 gram of nitre, the heat being continued till all the nitre is decomposed; the fused mass is dissolved in water; and the solution filtered from the ferric oxide, is evaporated with hydrochloric acid and alcohol. The chromic oxide which remains is then dissolved in hydrochloric acid, the solution filtered from silica, and the chromium precipitated in the usual way.

For the determination of aluminium in steel, the first part of the process is the same as for chromium, as far as the washing of the precipitate obtained with barium carbonate, which in this case is dissolved in hydrochloric acid and the barium precipitated with sulphuric acid; the barium sulphate is then removed and the excess of acid expelled by evaporation. The ferric oxide, alumina, and chromic oxide, are separated by ammonia, ammonium sulphide, and citric acid. The chromium (if any) is converted into alkaline chromate by fusion with sodium carbonate and nitre; the mass is dissolved in water; and, without filtering, potassium chlorate and hydrochloric acid are added, and the solution is evaporated to dryness in the water-bath, keeping the chlorate in excess. The residue is redissolved in water; a slight excess of ammonium carbonate is added; the solution boiled till all smell of this salt is removed, then filtered, and mixed with excess of hydrochloric acid; and when the greater part of the chlorate is decomposed, a little alcohol is to be added and the chromium precipitated as before. The alumina obtained by precipitation with ammonium carbonate is apt to be contaminated by silica and lime (from the citric acid), from which it can be separated by dissolving in hydrochloric acid, evaporating to remove silica, redissolving in hydrochloric acid, and precipitating with ammonium carbonate, care being taken to remove all excess of carbonate by boiling.

Manganese. S. Peters (*Chem. News*. xxxiii. 35) estimates manganese in iron and steel by a colorimetric method. 0.1 gram of the metal is dissolved at boiling heat in 3 to 4 c.c. of nitric acid (sp. gr. 1.2); lead dioxide (0.2–0.3 gram) is then added, the liquid is boiled for two or three minutes and filtered; the filtrate is poured into a burette and diluted to 50–60 c.c.; and the tint of this liquid is compared with that of a solution of permanganate containing 0.01 gram manganese in a cubic centimeter. If the two have the same depth of colour, the necessary data for calculation are obtained.

For the estimation of manganese in *spiegeleisen* and *ferromanganese*, the two following methods are given by E. Riley (*Chem. Soc. J.* xxxii. 1–12).

1. *Direct Method.*—About a gram of finely comminuted *spiegeleisen* is dissolved in nitric acid (sp. gr. 1.2), and small quantities of potassium chlorate and hydrochloric acid are added to decompose the carbon-compounds produced by the reaction. The solution diluted to about a litre and neutralised with sodium or ammonium carbonate is then heated with sodium or ammonium acetate (preferably with the ammonium salt), the resulting basic ferric acetate is left to settle; the solution is filtered; the precipitate redissolved in hydrochloric acid; and the process repeated in order to ensure a complete separation of the iron and manganese. The united filtrates are evaporated to half a litre, and mixed after cooling with 2 to 4 c.c. of bromine and agitated; excess of ammonia is added; the liquid gently heated for about an hour, then boiled for five minutes; the precipitate is left to settle; the liquid is filtered; and the filtrate is evaporated and tested for manganese. Lastly the precipitate is dried and heated to redness for half an hour in a muffle or over a Bunsen burner, and finally over a gas blowpipe. It then consists of *manganoso-manganic oxide*, Mn^2O^4 .

Indirect Method.—About a gram of finely crushed *spiegeleisen* is dissolved in hydrochloric, or better in dilute sulphuric acid; the liquid is diluted with recently boiled distilled water; and the iron is estimated volumetrically with bichromate or permanganate; to the amount thus obtained 5 per cent. is added for carbon and impurities; and the difference is regarded as manganese. The result thus obtained is generally too low by 0.6 to 0.8 per cent., the error arising from the formation—during the dissolution of the iron—of oily hydrocarbons and soluble organic matter, which act more or less on the oxidising solution, thus rendering the amount of iron too high, and consequently that of manganese too low. The method however is for the most part sufficiently accurate for technical purposes, and it has the great advantage of being very expeditious, an hour being sufficient for its completion, whereas the direct method takes five or six hours. The indirect method may however be rendered much more exact, though at some sacrifice of time, by dissolving the *spiegeleisen* in nitric acid, evaporating to dryness, and heating the residue to destroy the carbon-compounds. The oxides of iron and manganese are then to be dissolved in hydrochloric acid, and the solution largely diluted with water, reduced with sodium sulphite, and titrated as before. The results of the indirect method, thus modified, agree very nearly with those of the direct method.

W. Galbraith (*Chem. News*, xxxiv. 47) dissolves 1 gram of *spiegeleisen* in nitric acid in a small round-bottomed flask, evaporates to dryness, and heats the residue for ten minutes at a cherry-red heat. A weighed quantity of ferrous or ammonio-ferrous sulphate is added, after cooling, together with a little dilute hydrochloric acid; the liquid is heated, with agitation; and when the whole is dissolved, the quantity of unoxidised iron is determined by titration with potassium dichromate. From this the

amount of manganese present may be calculated. Riley is of opinion that this method does not yield exact results.

Estimation of Manganese in Manganiferous Iron Ores.—These ores sometimes contain small quantities of baryta, zinc oxide, potash, soda, and silica. 1 gram of the ore, dried at 100°, is dissolved in hydrochloric acid, the silica separated by filtration, and the greater part of the free acid evaporated off. The solution is diluted to $\frac{1}{2}$ litre, left at rest for four hours, and treated with a few drops of sulphuric acid to precipitate the baryta; then diluted to 1 litre, mixed with ammonium acetate, neutralised with ammonia, heated to the boiling point, left to clarify, and filtered; and the precipitate, redissolved in hydrochloric acid, is again precipitated by ammonia after addition of ammonium acetate. The basic ferric acetate thus precipitated is left to settle, collected on a filter, and washed three or four times with boiling water containing a few drops of ammonium acetate. Lastly, the filtrate is evaporated to half a litre, mixed when cold with 2 to 4 c.c. bromine, and otherwise treated as above described for the analysis of spiegeleisen. The ignited manganoso-manganic oxide must be tested for barium, zinc, calcium, &c. Chlorine may be used instead of bromine for the oxidation of the manganese, but there is no advantage in this alteration of the mode of proceeding (Riley, *Chem. Soc. J.* xxxii. 12).

The following process for the analysis of manganiferous iron ores is given by A. Fimaro (*Gazz. chim. ital.* vii. 286). 2 or 3 grams of the finely powdered mineral are dissolved in hydrochloric acid, and the solution evaporated to dryness after adding a drop or two of nitric acid to peroxidize the iron; the residue is heated with a small quantity of hydrochloric acid, diluted, and filtered from the separated silica, which is ignited and weighed; the solution containing the iron and manganese is exactly neutralised with ammonia, and precipitated with a slightly acid solution of ammonium benzoate or succinate; and the precipitate, which contains the iron and alumina, is collected, washed first with water, then with dilute ammonia, and finally dried, ignited, and weighed. The iron and alumina in this precipitate may then be separated and determined in the usual manner. The manganese is precipitated as sulphide by sulphide of ammonium, and determined as manganoso-manganic oxide in the usual way. If the mineral contains copper or zinc, these must be removed by passing sulphuretted hydrogen through an acetic solution, previously to the precipitation of the iron. The magnesia and lime are determined in the filtrate from the manganese sulphide. This process is said to be especially valuable when the manganese is not in very minute quantity, and preferable to the separation by means of—1. Ammonia and ammonium chloride. 2. Barium or calcium carbonate. 3. Sodium acetate and chlorine or bromine, or hypochlorite. 4. Lead oxide. 5. Conversion into sulphates.

On the separation of Iron and Manganese by means of Sodium Acetate, see also Stöckmann (*Zeitschr. anal. Chem.* xvi. 172) and Krämer (*ibid.* 334); also *Chem. Soc. J.* xxxii. 805.

Classen (*Berl. Ber.* x. 1316) separates iron from manganese, cobalt, nickel, and zinc, by treating the concentrated solution of the metals with a solution of potassium oxalate (1 : 6), and excess of strong acetic acid, whereby the oxalates of manganese, nickel, cobalt, and zinc are precipitated, leaving the iron in solution. The filtrate (with the washings) is concentrated on the water-bath, and rendered alkaline by sodium carbonate; the precipitate which forms is dissolved in concentrated oxalic acid; the solution precipitated with acetic acid as before; and the precipitate first obtained is washed with concentrated acetic acid, or a mixture of equal parts of acetic acid, alcohol, and water. It may still retain a trace of iron, which may be separated by a repetition of the process.

IRON METALLURGY. 1. **Cast or Pig Iron.** 1. *Chemistry of the Blast Furnace.*—*Temperature of the Blast.*—H. Valéris (*Bull. Acad. Roy. Belgique*, [2], xxxix. No. 4, April 1875) has calculated the temperature to which the blast must be raised in order to obtain the greatest heat in the furnace. By former experiments he had found that carbon burning in the open air produces a temperature of 1678°, half of it burning to dioxide, the other half to monoxide. Carbon monoxide in burning produces a temperature of 2231° C. In both cases it is assumed that the quantity of air supplied is such that its oxygen just suffices for complete combustion. When, however, carbon monoxide burns under this condition, only $\frac{1}{3}$ of it is burnt to CO², the other $\frac{2}{3}$ remaining unaltered. The burning of CO in the air cannot raise the temperature higher than 2231°, as at higher temperatures cooling takes place in consequence of the dissociation of CO². From these considerations, it is easy to calculate to what height the temperature of the blast must be raised, in order to obtain this maximum of temperature. Suppose that 1 kilogram of pure carbon is to be burnt; this will require 12 kilograms of air of the temperature x . Since now the

specific heat of air = 0.2375, the quantity of heat required to be added to the air, which is to be used for the combustion, will be $12 \cdot 0.2375 \cdot x$ heat-units. Now the products of combustion, consist of 1.83 CO₂, 1.166 CO, 6.99 N and 3 air; and as the specific heats of the first three are respectively 0.2169, 0.245 and 0.244, the rise of temperature produced in the air will be expressed by the fraction :

$$\frac{12 \cdot 0.2375 \cdot x}{\frac{1.85 \cdot 0.2169}{\text{CO}_2} + \frac{1.166 \cdot 0.245}{\text{CO}} + \frac{6.99 \cdot 0.244}{\text{N}} + \frac{3 \cdot 0.2375}{\text{Air}}} = \frac{2.85 \cdot x}{3.12}$$

This temperature of the air is added to the temperature of combustion of the carbon in the air, so that the sum represents the maximum temperature, viz. :

$$1678 + \frac{2.85 x}{3.12} = 2231^\circ;$$

whence it follows that $x = 605^\circ$. In practice this amount is not sufficient, since the fuel burnt is not pure carbon; and hence it is that good results have been obtained by heating the air even to 800° . By the use of air at 600° , there is a saving of about $\frac{1}{5}$ of the carbon that would be required if cold air were used.

Use of Lignite in the Blast furnace.—Experiments on iron smelting with a mixture of coke and lignite are described by v. Frey (*Dingl. pol. J.* cxxvii. 71). It was found that 33 per cent. of the coke might be replaced by crude lignite (a poor variety from Lieschau) without any deterioration in the quality of the dark brown Bessemer iron produced in the furnace, and with a considerable saving of expense for fuel. The following table shows the composition of the iron made with coke alone, and with the mixture of coke and lignite :

from	Pig-iron smelted with :	Fe	Combined Carbon	Graphite	Si	Mn	S	P	Cu
Prevali	66.6 p. c. Fünfkirchen Coke	88.251	0.450	3.860	2.231	5.098	0.082	0.012	0.016

Kalán	25 p. c. Ostran Coke	—	—	—	up to 3.020	1.820 to 3.060	0.010 to 0.030	trace	—
	25 „ Fünfkirchen Coke								
	25 „ Hard Charcoal								
	25 „ Crude Lignite								

The construction and working of a lignite blast furnace at Friedrichshütte in Bohemia are described by A. Kerpely (*Dingl. pol. J.* cccix. 322; *Jahresb. f. Chem.* 1876, 1060).

Use of Quick Lime in the Blast furnace.—The introduction of quick lime into the furnace in place of the raw limestone generally used might be expected to effect a considerable saving of fuel, seeing that a large quantity of heat is expended in expelling the carbon dioxide from the raw limestone, and further that a certain quantity is absorbed during the reduction of this carbon dioxide to monoxide. The actual saving effected is, however, less than that which is indicated by theory. Experiments have indeed shown that the use of burnt lime in the smaller blast furnaces is attended with a somewhat greater production, a better quality of iron, and also at times with a trifling saving of fuel, but in the larger and newer furnaces this is not the case. The reduction by carbon monoxide of many easily reducible ores begins at 200° , and the products of this reduction are carbon dioxide, iron, and a certain quantity of carbon. Carbon dioxide also, at a certain temperature, is reduced by carbon to monoxide. At 410° the carbon dioxide begins to reoxidise the iron reduced at the lower temperature, and this oxidation increases with the rise in temperature, so that at a bright red heat a mixture of carbon dioxide and monoxide in equal volumes will extract from sesquioxide of iron only one-third of its oxygen, whilst metallic iron at the same temperature will take up from such a mixture two-thirds of the oxygen which it would contain as sesquioxide. By the use of burnt lime the heat in the furnace is certainly increased, and the presence of this heat is made known by a rise in the temperature of the escaping gases. This increase in temperature, however, induces a greater formation of CO in proportion to CO₂, perhaps through the oxidising power of the latter being increased, and, therefore, more carbon monoxide being necessary for the reduction, or perhaps through the carbon dioxide being more easily reduced by the carbon. Whichever may be the true explanation, the result remains the same, viz., an absorption of heat, which means a waste of fuel, so that the gain on the one hand is neutralised by a loss on the other. (I. L. Bell, *Engineering*, Sept. 1875, p. 203; *Dingl. pol. J.* cccxviii. 260.)

Composition of Gases and Slags from the Alfreton Blast-furnace.

	Carbon	Hydrogen	Oxygen	Nitrogen	Silica	Alumina	Potash	Limestone	Magnesia	Iron

On Reiser's proposed method of using gaseous fuel and mineral fuel from the more recent formations, in blast furnaces, see *Dingl. pol. J.* ccxviii. 176; *Jahresb. f. Chem.* 1875, 1023.

Gases and Slags.—W. Kent (*Engineering and Mining Journal*, April 1875, p. 228; *Dingl. pol. J.* ccxviii. 332) has calculated the composition of the gases and slags from blast furnaces, basing his calculation on the obvious principle that whatever is introduced into the furnace must leave it in some form or other, either as gas, or as crude iron, or as slags. The table on p. 1106 shows the result of the calculation for the Alfreton blast furnace, from data furnished by Dr. Percy.

Formation of Chlorine-compounds in Blast-furnaces.—In several German iron works, viz. the Concordia works at Benndorff, the Sophia works at Wetzlar, and the Main-Weser works at Lollar, much damage has been done to the furnaces by the formation of chlorine-compounds. At the Concordia works it was noticed that the iron plates of the furnace were destroyed, and that the pumice placed in compartments in the throat of the furnace to absorb the gases, had assumed a yellowish-brown colour from the formation of ferric chloride, and partly caked together. Fused salts, chiefly potassium chloride, likewise exuded through the walls of the furnace. Similar observations were also made at other works. Now chlorides do not occur in iron ore or in limestone, and they are not likely to be derived from the building material of the furnace. The source of them must therefore be looked for in the coke with which the furnaces were fed; and in fact the liquid obtained by lixiviating an average sample of 35 kilos. of this coke gave by analysis:

43.54 grms.	NaCl	=	.1209	per cent.	on the coke.
1.38	„ KCl	=	.0038	„ „ „	
.72	„ MgO.SO ³	=	.0020	„ „ „	
9.76	„ KO.SO ³	=	.0271	„ „ „	
3.92	„ KS	=	.0108	„ „ „	
9.58	„ CaS	=	.0266	„ „ „	
<hr/>					
68.90 grms.	salts	=	.1912	per cent.	on the coke.

Consequently a furnace consuming daily about 50 tons of coke would at the same time receive 60.47 kg. NaCl and 1.91 kg. KCl, which together would be capable of yielding 38.73 kg. HCl, so that the decomposition of only a small proportion of these chlorides would be sufficient to account for the damage done to the furnaces.

The analysis above quoted agrees moderately well with those of many lime-springs, the only difference being that the former exhibits a larger proportion of sulphates. Now such waters are known to exist in the Westphalian coal-districts, and their use for quenching the coke would account for the presence of chlorides therein; and, in fact, since the use of these waters at the Concordia works has been discontinued, the destructive action above described has no longer been noticed (*Chr. Meineke, Dingl. pol. J.* ccxvii. 217).

Analysis of White Fumes from a Blast-furnace near Longwy.—The ores used in this furnace are ferruginous oolite, with a matrix of clay-slate. They are reduced with coke, and with a blast heated to 500°–600°, in order to obtain black or grey pig-iron, like that from Scotch furnaces. Owing to the high temperature of the blast, a dense white smoke is evolved which incrusts the walls of the work. The portion of this crust which is soluble in water consists largely of potassium sulphate, but no sulphide; but the insoluble part evolves sulphuretted hydrogen on treatment with an acid. On analysis, the deposit was found to have the following composition:

Portion soluble in Water.							
K ² SO ⁴	K ² CO ³	KCl	Soluble SiO ²				
37.82	3.90	1.52	0.12		= 43.36		
Insoluble portion.							
SiO ²	CaO	Al ² O ³	FeO	MnO	MgO	S	
22.98	15.88	9.62	4.00	0.16	0.36	not det.	= 53.00
Hygrometric Water							= 3.20
							<hr/>
							99.56

The following is the percentage composition of the insoluble portion (exclusive of sulphur) compared with that of the slag:

	SiO ²	CaO	Al ² O ³	FeO	MnO	MgO	K ² O	S	H ² SO ⁴	
Insoluble.	43.3	30.0	18.1	7.6	0.3	0.7	—	—	—	= 100
Slag.	33.0	43.7	14.6	3.6	1.9	1.7	0.7	0.2		= 99.4

As the slag is more basic than the insoluble portion of the fume, it would appear that the latter is mixed with free silica; and on examination, it was found to contain fibrous silica, probably evolved as silicon sulphide, which, on exposure to moist air, was converted into fibrous silica. The potassium sulphate was probably due to the oxidation of volatilised potassium sulphide (L. Gruner, *Compt. rend.* lxxxii. 559).

Limit of the Carburation of Iron.—M. Boussingault (*Compt. rend.* lxxx. 850) infers, from experiments made by himself and by others, that the highest amount of carbon that iron can take up is 4.1 per cent., answering to the formula Fe^3C . This compound may exist in the fused state, but undergoes dissociation, partly at least, on cooling, as shown by the appearance of graphite in the mass, so that the solidified iron may be regarded as a mixture of Fe^3C with free iron and free carbon. The transformation of grey into white cast-iron appears to be due simply to the manner of cooling the metal, rapid cooling producing the white, and slow cooling the grey variety.

2. *Silicon in Pig-iron.*—The form in which silicon exists in pig-iron has been investigated by E. H. Morton (*Chem. News*, xxix. 107). When the iron is dissolved in a dilute acid, the silicon remains in the form of silica; and the same result is obtained on heating Bessemer pig with fuming sulphuric acid or with iodine in sealed tubes, the air of which has been previously displaced by hydrogen or carbon dioxide, the formation of silica being attended, in the one case, with the formation of sulphur dioxide, in the other, when iodine is used, with deoxidation of carbon dioxide. The residue obtained on treating pig-iron with fuming sulphuric acid consisted of crystallised and amorphous silica, but did not contain a trace of free silicon; neither was any silicon found in the residue left when the pig was dissolved in hydrofluoric acid. From these results Morton infers that the silicon in pig-iron is chemically combined, not merely mechanically mixed. When siliceous iron is decomposed by acids or by iodine, the silicon appears to be oxidised at the moment of liberation; free silicon is not affected by these oxidising agents. When pig-iron containing silicon is heated in a stream of hydrogen, the silicon is volatilised; and by subsequently passing the gas into dilute potash-solution, acidulating this liquid, evaporating to dryness, and estimating the silica in the usual way, it was found that a pig-iron containing 4.612 per cent. silicon yielded to hydrogen 0.344 per cent., while a second specimen containing 4.704 per cent. Si yielded to hydrogen 0.494 per cent. Free silicon does not unite with hydrogen, so that in this case also it appears that a compound of iron and silicon is decomposed by the hydrogen.

Investigations on iron rich in silicon have been made by Troost & Hautefeuille (*Ann. Min.* 1874, iv. 1). Iron of this description is employed in the Bessemer process, not only because it determines a higher temperature in the converter, but because the refining of it is not attended with so great a loss by sparkling as is the case in the refining of ordinary pig-iron. The emission of sparks is occasioned chiefly by the escape of gases contained in the pig-iron, but siliceous iron is very poor in gases, and when refined in a current of air, presents an appearance similar to that of lead in cupellation.

Pig-iron, heated in an apparatus made of refractory silicates, always yields carbon monoxide, and at the same time takes up silicon; this shows that iron carbide has the power of decomposing silicates and separating the silicon from them:

	Si	C
A pig-iron originally containing	0.21	5.32 per cent.
contained, after 48 hours heating in a porcelain crucible	0.87	5.20 "
" 24 " " gaize "	1.07	3.20 "
Globules of metal which penetrated into the gaize contained	3.40	— "
A cast-steel originally containing	0.10	1.54 "
contained, after 24 hours heating in a hessian crucible	0.26	0.24 "
" " " " gaize "	0.80	0.70 "

These results show that, to fuse iron without introducing silicon into it, the fusion must be effected in vessels of lime or magnesia. On the other hand, iron rich in silicon gives up a certain portion of that element when heated in a lime crucible.

In the blast-furnace the absorption of silicon takes place only after the combination of the iron with the carbon; that is to say, it begins in the boshes of the furnace, and is completed in the hearth. It is especially from the silicates of the alkali-metals that iron takes up the largest quantity of silicon. By fusing together crude potash, charcoal, iron filings, and silica, a regulus was obtained containing 15.16 per cent. silicon and 2.94 per cent. carbon.

3. *Manganiferous Cast iron.*—The varieties of these alloys, containing not more than about 26 per cent. manganese, are known as *Spiegeleisen*; those with higher proportions of manganese are named *Ferromanganese*. The following

tables (p. 1110) contain analyses of spiegeleisen. Table I. by E. Riley (*Chem. Soc. Jour.* xxxii 7).—Table II. analyses of Carniola spiegeleisen by the Carniola Company at Laibach, to which are appended determinations of the carbon by Riley.

According to Riley's analysis in Table I., the percentage of carbon increases on the whole with that of the manganese. The analyses by the Carniola Company show rather the contrary result; but Riley's analyses of the same spiegeleisens likewise show an increase of carbon on the whole from about 15 to 50 per cent. manganese, though there is a decrease in the carbon between the samples containing 35 and 40 per cent. manganese. In the ferromanganese containing 73 per cent. Mn, the percentage of carbon is higher than in any of the spiegeleisens. (For methods of analysis, see pp. 1103, 1104).

Spiegeleisen is largely produced in Germany, Russia, and Sweden, and the ores from which it is obtained are of very different and peculiar characters. In Germany it is produced solely from spathic iron ores containing manganese; in Russia from manganese oxides containing iron; and in Sweden by fluxing a mixture of knebelite and manganiferous garnet (combined silicates of iron and manganese). An important point with reference to these ores is that, if the iron and manganese oxides are not in actual combination as carbonates or silicates, they are in a state of very intimate mixture: for whenever pure manganese ores are added to the blast furnace mixture, with the view of obtaining spiegeleisen rich in manganese, the result is always a failure, only a small fraction of the added manganese combining with the iron, while the greater portion is carried off in the slag. To produce pig-iron rich in manganese, the manganese must therefore be added to the mixture in the form of a compound containing iron; the reduction process is thereby facilitated, since a mixture of the oxides of manganese and iron is more easily reduced to the metallic state, and is thus enabled to unite with the iron of the charge. With manganese alone there is a great tendency for this metal to pass into the slag as a silicate, from which it cannot be profitably recovered. To prevent this, the heat should be as great as possible, and the reducing power of the furnace almost complete. The oxides of manganese are much less easily reduced, and require more time and a much higher temperature than those of iron. In the production of spiegeleisen, the following points should be especially observed:—

1. The manganese ore used should contain a large proportion of iron, in order to secure the easy reduction of a large portion of manganese.

2. The furnace charge should be basic, *i.e.*, an excess of limestone, or, better, of burnt lime, should be used.

3. The draught of the furnace should be much slower than in the ordinary process, in order to give more time for the reduction of the manganese.

4. The furnace temperature should be as high as possible, the air employed as hot as possible; and as coke bears a stronger pressure of air and develops a greater heat, it is preferred to wood charcoal in this process.

At Filipstad, in Sweden, spiegeleisen has been made by using native oxides of manganese, especially Hausmannite, which contains 72 per cent. manganese. The iron produced contained only 4 per cent. manganese, the excess of the metal passing away in the slag.

The ores employed in Germany for the manufacture of spiegeleisen are found in veins of the Devonian formation, on the east bank of the Rhine. They are spathic ironstones, which consist of carbonate of iron intimately mixed with carbonate of manganese. They further contain more or less copper and iron pyrites, with traces of galena and zinc blende, and frequent occurrence of quartz. Analyses of the products of three different mines gave the following results:—

	Stahlberg	Kirschenbaum	Huth
	p. c.	p. c.	p. c.
Iron	41.70	42.58	42.21
Manganese	8.16	6.46	8.70

The well-known foliated texture of spiegeleisen depends more upon the amount of carbon contained in it than upon the amount of manganese. This structure is also better developed if the iron, after running off, is covered over with slag, so as to allow it to cool more slowly.

The following analyses show the percentage composition of spiegeleisen manufactured with coke in Germany.

	C	Si	S	Cu	Mn	Fe
(1)	4.129	0.458	0.015	0.219	8.706	85.929
(2)	5.04	0.41	0.08	0.16	7.57	86.74

(Forbes, *Journal of the Iron and Steel Institute*, Feb. 1872).

The New Jersey Zinc Company manufactured in 1874 from three furnaces 4,070 tons of spiegeleisen having the following composition (*Dingl. pol. J.* ccxvii. 154):—

Fe	Mn	Si	C	P
83.250	11.586	0.867	4.632	0.166
83.22	11.67	0.99	4.02	0.19

The function of manganese in iron metallurgy is explained by Troost a. Hautefeuille (*Compt. rend.* lxxxii. 265) as follows: Manganese unites readily with the impurities of iron, giving rise to compounds whose formation is attended with the evolution of a quantity of heat greater than that which is evolved in the formation of the corresponding iron-compounds. These manganese-compounds unite with oxygen more readily than iron-compounds, manganese even taking oxygen from the oxides of iron. At the same time the manganese in oxidising develops an amount of heat which greatly facilitates the formation of slag.

On the Decarburization of Spiegeleisen, see W. Raymond (*Dingl. pol. J.* ccxx. 60; *Jahresb. f. Chem.* 1876, 106).

4. *Manufacture of Pig-iron containing Manganese and Phosphorus* (Le Chatelier, *Dingl. pol. J.* ccxvi. 342).—Near Liège there occurs an iron ore which yields a pig-iron containing 4 per cent. of phosphorus, and when this ore is mixed with a manganiferous iron ore, found near Nassau, containing 15 per cent. manganese and 33 per cent. of iron, a pig is obtained, which easily gives up the phosphorus in puddling. At Grevigné, 1,000 kilos. of coke, 1,500 kilos. of ordinary, and 500 kilos. of manganiferous ore are used for an iron containing manganese; and for ordinary pig-iron, 1,000 kilos. of coke, 850 kilos. of lime, and 2,500 kilos. of ordinary ore. Three different sorts of pig-iron are manufactured, one containing more than 6 per cent. of manganese, which, when broken across, shows mirror-facets; another with 3 to 6 per cent. of manganese, but with facets so small as hardly to be visible; and the third contains less than 3 per cent. of manganese. The slags are green in the interior, and brown on the outside. They contain $\frac{1}{2}$ to $\frac{1}{3}$ of the amount of manganese in the ore. If much lime is added, a white pig is formed, rich in manganese.

The following are analyses of these pig-irons and their slags:

On the Conversion of this Pig-iron into Wrought Iron and Steel, see p. 1116.

5. *Iron containing Copper*.—Wrought iron containing some tenths per cent. of copper is known to be red-short; nevertheless, some of the best irons from Siberia have been found to contain from 0.01 to 0.03 per cent. of copper. Some specimens of steel contained 0.2 per cent., but the steel was not brittle, and had been used with success for the manufacture of steel axles. Specimens of cast iron from the blast furnaces of the South Ural mountains showed that the presence of copper in cast iron may amount to a higher percentage than in steel or iron, without altering the quality of the metal. The following is the composition of this peculiar sample of cast iron:

Fe	Cu	Sn	Co	Si	Ni	C	Mn
83.514	8.123	1.252	0.501	0.952	0.125	3.001	2.312

= 99.780

(S. Kern, *Chemical News*, xxxiv. 78).

Leithner (*Dingl. pol. J.* cccxi. 349) utilises the residues from the cuprififerous pyrites which have been used in sulphuric acid works to generate sulphurous acid, for the preparation of a cuprififerous iron to be employed in the precipitation of 'cement-copper.' The burnt pyrites is freed as far as possible from sulphur by a second roasting close to the blast-furnace, then mixed with lime and smelted. The cuprififerous pig-iron thus obtained yields up its copper to the solutions from which it precipitates the copper.

6. *Malleable Cast Iron* (2nd Suppl. 696).—The chemical changes which take place in the manufacture of this kind of iron by heating ordinary cast iron in a bed of smithy scales, have been examined by Russell Davenport (*Mechanics' Magazine*, 1872, p. 392; *Dingl. pol. J.* ccvii. 51). The samples examined were a quarter of an inch thick, and were analysed both before ignition and after each of two heatings. The following numbers represent mean percentages:

Casting No 1	Before ignition	After first ignition	After second ignition
Silicon	0.445	0.438	0.449
Phosphorus	0.315	0.327	0.315
Manganese	0.529	0.585	0.525
Sulphur	0.059	0.067	0.083
Total carbon	3.43	1.51	below 0.10
Casting No. 2			
Silicon	0.585	0.614	0.614
Phosphorus	0.280	0.290	0.295
Manganese	0.585	0.616	0.575
Sulphur	0.105	0.147	0.162
Total carbon	3.48	0.43	below 0.10

These numbers show that the proportions of silicon, phosphorus, manganese, and sulphur in pig iron are not essentially altered by ignition; the slight increase of sulphur is derived from the fuel. The carbon is wholly removed by heating the iron to redness in contact with ferric oxide, the burning out of the carbon proceeding from without inwards. After the first heating the castings exhibit a black nucleus surrounded by a white crust nearly free from carbon. In the dark nucleus (technically called the 'heart') graphite was recognised, although the pig-iron was originally free from it. After the second ignition the entire ingot had become white. Many of the castings after ignition were extremely brittle, and exhibited a coarsely crystalline texture; nevertheless they were not found to differ chemically in any respect from good iron.

7. *Solution of Gases in Cast Iron*.—J. Parry (*Amer. Chem.* vi. 107) finds that grey cast iron absorbs hydrogen to the amount of 20–22 times its bulk. On ignition in a vacuum, the hydrogen is given off, together with CO and CO₂. When volatile metals (zinc, cadmium, bismuth, magnesium, and even cobalt) are heated in a vacuum with iron, their vapours are taken up by the iron. On again heating the iron in a vacuum, the volatile metal is given off and deposited as a sublimate on the side of the tube.

Parry (*ibid.* iv. 254) has also examined the gases absorbed by spiegeleisen, white and grey pig-iron, bar-iron, and steel during the processes of manufacture. By heating these several forms of iron in the vacuum of a Sprengel pump, it was found that:

- 50 grams of spiegeleisen yielded in three hours 12 c.c. gas at 15° and 760 mm.
- 50 grams white pig gave in 6½ hours, 13 c.c. gas.
- 37 grams of bar-iron gave in two hours, 9.4 c.c. gas.
- 4.75 grams grey pig gave in two hours, 15.81 c.c. gas.
- 10 grams steel gave in two hours, 18.4 c.c. gas.

Percentage Composition of the Gases.

	CO ^a	CO	H	N
From Spiegeleisen	0.942	17.87	81.105	—
„ White pig	6.800	2.32	84.000	6.88
„ Bar iron	9.920	34.262	54.100	1.718
„ Grey pig	1.600	5.200	89.700	3.250
„ Steel	16.550	24.352	52.610	6.488

The experiments of Troost a. Hautefeuille (*Compt. rend.* lxxvi. 482, 562) on the action of iron carbide on siliceous compounds (p. 1110) show that, in order to study the absorption of gases by iron, it is necessary to employ a vessel free from silicon; they therefore employed vessels made of carbon.

Cast iron raised to a high temperature in a carbon boat in an atmosphere of hydrogen undergoes tranquil fusion; there is no disengagement of gas and no projection of the metal. But if, after it has remained for some time in this atmosphere, the pressure of the hydrogen be rapidly diminished, the disengagement of gas is rendered evident by the projection of globules of metal and particles of graphite, and if the temperature be allowed to fall at the same time, the metal solidifies during the disengagement of gas, and the surface of the ingot is rough. The solubility of hydrogen in cast iron is much diminished by the presence of phosphorus or silicon (especially the latter) in the metal. Carbon oxide is much less soluble than hydrogen in cast iron, more especially in highly carburetted iron.

These results were confirmed by extracting the gases dissolved or enclosed in pig-iron. A cylinder of the metal weighing 500 grams heated to 800° in a vacuum gave off in 190 hours 16.7 c.c. of gas consisting of

Carbon dioxide	Carbon oxide	Hydrogen	Nitrogen
0.6	2.8	12.3	1.0

The greater part of the carbon oxide was disengaged in a few hours, while the hydrogen was much more forcibly retained.

The same cylinder of cast iron was afterwards heated to 800° for 48 hours under a pressure of 770 mm. (1) in hydrogen, and (2) in carbon oxide, and after each operation placed in a vacuum for 170 hours. The gases extracted in the two cases were—

	Carbon oxide	Hydrogen	Nitrogen
(1.)	1.1	44.0	1.5 = 46.6 c.c.
(2.)	14.7	1.5	0.7 = 16.9 „

Hence the order of solubility is the same as in the fused metal.

To ascertain the effect of different proportions of carbon in the metal on the solubility of the gases, comparative experiments were made with cast steel and soft iron. Cylinders of these metals, each weighing 500 grams, when heated to 800° in a vacuum, gave off the following gases:

	Carbon dioxide	Carbon oxide	Hydrogen	Nitrogen
Cast steel	0.05	1.4	0.5	0.25 = 2.2 c.c.
Soft iron	2.20	10.8	4.4	1.1 = 18.5 „

These cylinders were heated to 800° (1) in hydrogen, and (2) in carbon oxide, and afterwards placed in a vacuum, as in the case of the cast-iron cylinder. The gases extracted were—

		Carbon oxide	Hydrogen	Nitrogen
From cast steel . .	{ (1.)	0.9	6.4	0.5 = 7.8 c.c.
	{ (2.)	2.0	0.8	0.4 = 3.2 „
From soft iron . .	{ (1.)	0.6	10.0	3.3 = 13.9 „
	{ (2.)	18.7	0.2	0.1 = 14.0 „

Steel retains the last traces of hydrogen much more forcibly than cast iron, notwithstanding that when saturated with the gas it gives off a portion at the ordinary temperature, in this respect resembling palladium. Soft iron retains carbon oxide more forcibly than it retains hydrogen, contrary to what is observed with cast iron and steel.

The evolution of gases from pig-iron has also been examined by A. Ledebur (*Chem. Centr.* 1873, 810), who attributes it to three causes: 1. Gases absorbed by the iron in the blast-furnace are given off in consequence of the reduction of pressure which takes place when the furnace is tapped. An alteration in the constitution of the metal during cooling may also give rise to the escape of dissolved gases. The greater the proportion of graphite in pig-iron, the smaller is the quantity of gas which it gives off. Iron rich in carbon takes up chiefly gases containing a large proportion

of hydrogen; iron poor in carbon, especially in combined carbon, takes up chiefly gases in which the carbon predominates. 2. Evolution of gases also takes place in consequence of the contact of the melted iron with the air. The movement observed on the surface of the cooling iron is well known to be due to oxidation, a crust of ferroso-ferric oxide, silica, and oxides of manganese forming on the surface, breaking up, and being continually reproduced. This very basic slag may act upon the fused carburetted iron in such a manner as to give rise to the formation of carbon oxide. 3. Gases may be produced by the action of the fused iron on the sides of the mould. Even very carefully dried moulds contain small quantities of water, which is converted into vapour as the iron runs into the mould, and the steam passing through the molten iron gives rise to the formation of hydrogen, hydrocarbons, and hydrogen sulphide. The presence of this last gas is shown by the frequently observed occurrence of sulphur dioxide in the combustion of the gas which escapes from the iron.

Gases from Spiegeleisen.—This alloy, in flowing from the blast-furnace, gives out a much larger quantity of gas than ordinary pig-iron. The latter runs into the channels with vivid sparkling, and gives out only a few gas-bubbles, in solidifying, whereas spiegeleisen appears to be covered with a film of gas, and gives out a large quantity at the moment of solidification. The gas burns like hydrogen, not like carbon dioxide. The appearance just described may be imitated by slowly fusing 200 grams of spiegeleisen in a lime crucible under the oxyhydrogen flame, then adding to the very hot bath 100 grams more, and removing the cover from the crucible as soon as this latter quantity is melted. In this case also, the shining metal-bath appears to be covered with a veil of gas, which may most readily be seen by placing the eye on a level with the specular surface of the metal. Gas-bubbles are then seen to escape from time to time from the metal, and for a moment increase the height of the flame. At the moment of solidification, the metal spits and gives off a considerable quantity of hydrogen. Spiegeleisen, after solidification, retains a much larger quantity of gas than ordinary pig-iron. 500 grams of the two heated in a vacuum to 800° gave:

	Pig-iron	Spiegeleisen
Carbon Dioxide	0.6 c.c.	0.0 c.c.
„ Monoxide	2.8 „	0.0 „
Hydrogen	12.3 „	27.0 „
Nitrogen	1.0 „	2.5 „
	16.7	29.5

The carburetted manganese obtained by reduction of the oxide by charcoal in a lime crucible, absorbs, when heated to redness in a flame of hydrogen, a larger quantity of this gas than iron containing an equal proportion of carbon. Hence it appears that manganese increases the capacity of iron for absorbing hydrogen, but diminishes its power of absorbing carbon monoxide (Troost & Hautefeuille, *Compt. rend.* lxxx. 909).

8. *Absorption of Heat by Pig-iron, Slags, and Steel at High Temperatures.*—The following numbers denote units of heat absorbed by a unit-weight of the substance; they were determined with a water-calorimeter, and represent minima, inasmuch as small losses of heat were unavoidable. 1. The several varieties of grey pig, as they run from the furnace, take with them only 280 to 285 heat-units, but while in the hearth they often contain from 300 to 310 units. 2. White pig under the same circumstances contains 20 units less. 3. Grey pig at its solidifying point contains 244 to 245 units, and immediately after solidification 221 to 222 units. 4. White pig at its solidifying point retains 225 to 235, and immediately after solidification 192 to 203. The several varieties of white pig have therefore a latent heat of 32 to 34 units, the grey only 23 units. 5. The slags contain $\frac{10}{100}$ as much heat as the iron, in the case of grey iron therefore 500, and in that of white iron 450 heat-units at the moment of tapping. 6. The latent heat of the slags is about 50 units. 7. Bessemer steel obtains by refining 30 heat-units more than pig-iron; fused steel often contains only 300 units. 8. The melting points of these varieties of iron and steel, as determined by Gruner, agree with those observed by Pouillet:

White pig-iron melts at	1050°–1100°
Grey siliceous pig-iron	1200°
Cast steel	1350°–1400°
White pig-irons running from the furnace have a temperature of	1250°–1300°
Grey pigs have a temperature of	1350°–1450°
Bessemer steel attains in the converter, at the moment of refining, a } temperature of at least	1500°

(L. Gruner, *Ann. Min.* [7], iv, 224; *Dingl. pol. J.* ccxii. 527).

II. Wrought Iron. 1. *Refining of Pig-iron.*—A. Warner purifies pig-iron by subjecting it in the fused state to the action of a mixture of soda (sodium carbonate) and lime, using for each 1 per cent. of silicon to be removed, 20 kg. soda and an equal quantity of lime to a ton of iron. The lime being divided and distributed by the melting soda comes into intimate contact with the iron, and abstracts its silicon and sulphur. The action, which is energetic, lasts for twenty to thirty minutes, and two slags, consisting of silicates and sulphides, collect on the surface, below which the iron is tapped off. Iron thus refined contains only 0.04 per cent. sulphur and 0.10 to 0.14 silicon (*Dingl. pol. J.* ccxvi. 490; *Engineering*, 1875, 132).

According to a later communication by E. Rigo (*Dingl. ccxviii. 125*), Warner endeavours to effect the removal of silicon and sulphur by means of various mixtures of sodium carbonate and infusible substances. He uses: *a.* 2 pts. by weight of soda and 3 pts. of ferric oxide; 1 ton of pig-iron of 1 per cent. silicon requires 40 kilos. of the mixture — *b.* 1 pt. of soda and 2 pts. of oxide of manganese, 40 kilos. being required for 1 ton — *c.* 3 pts. of soda and 2 pts. of slaked lime; 1 ton of iron requires for every per cent. of silicon 38.5 kilos. of the mixture — *d.* 1 pt. soda and 2 pts. of fluor spar this flux, however, cannot in general be recommended, though it answers well in special cases. Sodium carbonate, owing to its price, is added only in quantity absolutely necessary to obtain the desired object of bringing the action of the cheaper and specially refining agents into full operation.

2. *Puddling.*—A report on the progress of Mechanical Puddling (*2nd Suppl. 697*) has been published by P. Tunner (*Dingl. pol. J.* ccxiii. 123). Riley a. Henley have adapted a principle, first laid down by J. v. Ehrenwerth, to the construction of a mechanical puddling furnace, in which a horizontal circular chamber revolves round a vertical axis under an arch similar to that of the ordinary puddling furnace. A great improvement in this furnace has been made by Pernot, who inclines the circular chamber towards the working door in such a manner that during the rotation part of the inclined hearth remains uncovered by the iron and slag. This part of the movable hearth, which projects into the hot air-stream, is subjected to powerful oxidation, but the oxidised products are immediately taken up by the bath of metal, slag, &c. With Pernot's furnace, the stirring, or puddling, properly so called, is performed by machinery, but the bolting up is effected in the ordinary way. At the works of Petin a. Gaudet in St. Chamond, a furnace thus constructed yielded in a week (with eleven 12-hour shifts), 500 centners of puddled iron, whereas an ordinary hand-puddle furnace yields only 240 centners. 1000 kg. wrought iron were produced from 1030 kg. pig-iron (in the ordinary puddle-furnace, 1200 kg. of pig would be required); and the consumption of coal was reduced from 1500 to 1200 kg.

On Danks' puddling furnaces, see J. M. Drown (*Engineering and Mining Journal*, xvi. No. 5; *Chem. Centr.* 1874, 107).

A new method of converting pig-iron into wrought iron and steel is described by F. C. Knowles (*Monit. scient.* [3], iv. 334). He endeavours to obviate the chief inconveniences of the ordinary puddling process (great loss of heat, waste of iron by burning, imperfect purification of the iron) by separating the heating from the chemical process: (1). By the production of a very basic slag containing not more than 30 per cent. silica; (2) by the use of caustic soda and pure ferric oxide, with the view of removing sulphur and phosphorus from the iron; (3) by the use of sodium nitrate or permanganate as oxidising agent. Gaseous fuel is used, consisting of carbon monoxide mixed with air heated to 500°. The carbon oxide is either obtained from the furnaces in which the iron is remelted with coke or anthracite, or it is produced by passing carbon dioxide obtained by ignition of limestone over red-hot coke; or, lastly, by the action of water-vapour on charcoal. The carbon oxide and air are mixed in such proportions as just to burn the whole of the carbon to dioxide. This carbon dioxide may be reconverted into the monoxide, and the alternation repeated till the mixture becomes too rich in nitrogen, after which the heat of the burning gases may be utilised for heating boilers, lime-kilns, &c.

The iron in the fused state is brought into the furnace, which is made of cast iron and has its walls kept cool by a stream of water. To avoid presenting too much silica to the slag, this furnace has no lining of fire-clay, but is lined internally with a kind of enamel made of ferrous or manganous oxide, emery or bauxite, and a small quantity of caustic soda: this lining is said to be very durable. Powdered ferric oxide (hematite) is introduced into the furnace, together with the melted metal, and the mixture of carbon oxide and air is introduced through the bottom of the furnace, whereby a sufficiently uniform mixture of the contents is effected. As soon as the silicon of the pig has been converted by this treatment into a slag, the latter is removed and replaced by a mixture of caustic soda and manganiferous iron ore free from silica. The pig-iron having been freed by these reagents from carbon, sulphur, and phosphorus, is run into moulds, then cooled by water, and worked under rolls, hammers, &c.

Manufacture of Wrought Iron and Steel from Pig-iron containing Phosphorus and Manganese (p. 1111).—The iron is refined in puddling furnaces, the waste heat being used for heating steam-boilers. The charge used is a mixture of manganiferous iron with white pig, made from somewhat purer ore than that which yields ordinary pig-iron, and usually contains less than 1 per cent. of phosphorus. When the iron contains not more than 5 per cent. of manganese, it is sometimes puddled alone, but it is more generally mixed with white iron containing less than 1 per cent. of phosphorus. The charges consist of 200 to 225 kilos.; for best sheet iron, 175 kilos. of spiegeleisen containing 7 per cent. of manganese and 50 kilos. of white pig, or 50 kilos. of German spiegeleisen containing 12 per cent. of manganese and 175 kilos. of white pig-iron; and for second quality, pig-iron with 5 per cent. of manganese. The action is carried on at a high temperature, and at such a rate that only four charges of 900 kilos. of pig-iron are refined in twelve hours. The loss of iron amounts to 5 per cent. The production of 1 pt. of fine-grained iron requires the consumption of 1 pt. of coal. The manganese facilitates the purification of the iron, chiefly by forming fusible slags. The strongly basic properties of the manganous oxide are said also to promote the formation of acids from the impurities in the iron. †

At the Terre-Noire Works near St. Etienne in France rails are manufactured from iron containing phosphorus. A white iron (not steel) is produced by melting pig-iron with old rails,—both irons must be poor in silicon,—removing the impurities by oxidation, and reducing the oxidised iron by the use of an alloy of iron and manganese containing from 40 to 60 per cent. of the latter metal. Almost the whole of the carbon is then removed, and a product is obtained which makes excellent rails (*Chem. Centr.* 1876, 709).

On the separation of Carbon, Silicon, Sulphur, and Phosphorus, in the Refining and Puddling Furnace, and on the Bessemer Converter, see J. L. Bell (*Journal of the Iron and Steel Institute*, 1877, 390; *Dingl. pol. J.* cccxxv. 264, 357; *Chem. Soc. J.* xxxiv. 95).

3. *Preparation of Malleable Iron and Steel direct from the Ore.*—The rotatory furnace invented for this purpose by Dr. C. W. Siemens, and the mode of working it, have already been described (*2nd Suppl.* 701–704). In the *Journal of the Iron and Steel Institute*, 1875, Dr. Siemens has given an account of the results obtained at the Towcester Works, where three rotatory furnaces have been erected. About 30 cwt. of ore mixed with 9 cwt. of small coal having been charged, the furnace is rotated for 2½ hours; the slag is then tapped, and the speed of rotation increased to ball up the iron. The balls formed contain about 70 per cent. of iron and 30 per cent. of cinder, but it is found that the particles of iron are pure metal, although the slag may contain 6 per cent. or more of phosphoric acid and from 1 to 3 per cent. of sulphur. The bulk of the cinder is removed by shingling, but sufficient remains to impart to the fracture a dark appearance without any sign of crystalline texture. The metal in being worked shows what may be termed ‘slag-shortness.’ By repiling and reheating, crystalline iron of great purity and toughness is produced.

The following table shows the composition of some of the irons produced:—

	1	2	3	4	5	6	7

1. Hammered iron.—2. Iron from Canadian ore.—3. Iron from Towcester ore.—4. The same well rolled.—5. The same badly rolled.—6. The same badly hammered, containing slag.—7. Chatterley.—8. Towcester iron, rolled.—717 Si corresponds to 1·54 per cent. of slag.—9. Iron from Indian ores. ·932 Si corresponds to 2 per cent. of slag.—10. Phosphorus in Towcester iron.—11. Homogeneous iron, from Towcester iron.—12 and 13. Towcester iron, rolled.—14. Towcester iron-bloom, containing 3·17 per cent. slag.—15. Iron, fractured bloom, crystalline texture, slag 1·58 per cent.—16. Iron, fractured bloom, texture fibrous and dull, slag 2·61 per cent.—17 and 18. Iron remelted in the refinery.

Attempts to prepare malleable iron and steel by Siemens' method at Privali are described by v. Frey (*Dingl. pol. J.* ccxvii. 69).

Blair's method of preparing malleable iron direct from the ore is described by P. Tunner (*ibid.* ccxvi. 304; *Jahresb. f. Chem.* 1875, 1017).

4. *Fibrous Iron*.—H. Le Chatelier observes (*Compt. rend.* lxxxii. 1057) that when fibrous iron is heated to dull redness in a stream of chlorine, there remains, after the volatilisation of the iron chloride, an extremely thin, greenish-white network composed of threads of slag, and to the enclosure of these threads in the mass of iron he attributes its fibrous structure. This network of threads appears to be formed when the slag is difficult of fusion and the iron is puddled at a comparatively low temperature. Fibrous iron smelted with charcoal from the Jura was found to contain 0·7 per cent. of this slag; fibrous charcoal-iron from Belgium yielded 1·3 per cent.

5. *Cause of Brittleness in Wrought Iron*.—F. Kick (*Dingl. pol. J.* ccxiii. 358) observes that the molecular change in wrought iron which results in brittleness is brought about, not only by frequent agitation, but also by sudden cooling from a high temperature. Boiler plate 10 mm. thick heated not quite to redness, and then quickly cooled in water, exhibited a crystalline layer 1 mm. thick on each side of the nucleus, which had remained fibrous. Kick is of opinion that this change of structure may lead to the bursting of steam-boilers.

On Homogeneous Iron and the degree of Homogeneity to be expected in Iron produced by various systems of Puddling and subsequent Working, see *Engineer*, May 11, 1877, and *Chem. Soc. J.* xxxiv. 253–257; also *Dingl. pol. J.* ccxxvi. 394; *Chem. Soc. J.* xxxiv. 257.

6. *Burnt Iron* (2nd Suppl. 700).—According to H. Caron (*Compt. rend.* lxxvii. 836) burnt iron may be regenerated, that is to say, restored to the state of malleability, by plunging it, while red-hot, into a saturated solution of common salt, till its temperature is reduced to about 110°.

7. *Soft Iron*.—J. A. Cabell (*Chem. News*, xxx. 142) has analysed iron found in crystalline granules on the wall of a welding furnace, in which Heaton steel had been heated for forging. This iron was soft, easy to file and saw, did not become hard by sudden cooling, and showed indeed all the properties of bar iron. Sp. gr. 7·86. Its composition was remarkable, as shown by the following analysis

C	Si	S	P	Fe
1·121	0·024	0·037	0·436	98·882 = 100.

8. *Spongy Iron* (G. Lunge, *Dingl. pol. J.* ccxix. 325).—The preparation of this kind of iron, which is extensively used for the reduction of cement-copper, requires the uniform heating of an extended porous mass. This is effected by heating the ore and reducing agents in a reverberatory furnace having a very wide horizontal sole. Vertical partitions divide the over-arched heating space into three parts, each provided with two working doors in the side walls. These divisions are filled through doors in the arched roof, on which the materials have been previously warmed, and they are emptied by pipes passing downwards from the working doors in the sole; these pipes may be connected with conically widening collecting vessels which can be tightly closed. The grate, situated 1·422 m. below the fire-bridge, admits of a thick layer of fuel and thereby ensures a constant reducing flame. The fire-gases, after leaving the furnace, pass over the sole, composed of chamotte tiles, and finally arrive at the reducing furnace. The furnace, which is raised to a bright red heat, admits of the introduction in each division of 20 ctr. of dry 'purple ore' (impure ferric oxide from the copper extraction) mixed with 6 ctr. of comminuted and sifted coal to reduce it. The process is completed in nine to twelve hours in the first division, in eighteen hours in the second, in twenty-four hours in the third division, and requires in these intervals repeated working of the materials with closed furnace doors. The spongy iron, after cooling in the collecting boxes, is ground, sifted, and used for the precipitation of copper.

9. *Bronzing of Iron*.—For this purpose Ph. Hep recommends, in place of a film of ferric oxide, which is difficult to produce, the formation of a film of ferroso-ferric oxide. This is produced by smearing the surface of the iron with linseed oil, and then heating it, or if a strong heat is inadmissible, dipping the uniformly oxidised article into water at 100°. Still more quickly is the bronzing produced in an acid bath of ferric chloride. The ferroso-ferric oxide which forms after a while attaches itself closely to the surface on immersing the object in hot water, and after drying may be rubbed in with linseed oil or wax. It is true that objects bronzed with ferroso-ferric oxide are liable to rust after some time, but the bronze-surface does not peel off, and the rust is easily brushed off.

Iron surfaces may also be protected by forming cuprous sulphide upon them. For this purpose the objects, after being cleaned, are dipped in solution of cupric sulphate, and as soon as a thin film of copper is formed on them, they are rinsed with water, and treated with a slightly acid solution of sodium thiosulphate, whereby a black deposit of cuprous sulphide is formed. The surface, after drying with blotting paper, and treatment with the burnishing stick, exhibits a steel-blue shimmer, and withstands satisfactorily the action of atmospheric agents.

10. *Coating of Iron with other Metals*.—(1). With Copper. The following methods are described by A. Gaudoin (*Dingl. pol. J.* cxviii. 50). *a*. The required quantity of copper is fused in a crucible; the metal bath is covered with a flux of cryolite and phosphoric acid; and the iron, after being heated to the temperature of the bath, is dipped into it.—*b*. A mixture of 1 pt. dry chloride or fluoride of copper, and 5 or 6 pts. of cryolite, to which 'a certain quantity' of barium chloride may be added, is fused, and the iron, after being cleansed with acid, is dipped into this bath. The deposition of the copper may be accelerated by a voltaic current.—*c*. For the coppering of iron in the wet way, a strongly acid solution is required. An excellent bath for the purpose is made by dissolving cupric oxalate and a large excess of potassium bi- or quadroxalate in a ten to fifteenfold quantity of water. In this case also the aid of the current is advantageous.

On the Coppering of Cast Iron Rollers for Calico-printing, by Electrolytic deposition, see G. Schäffer (*Bull. Soc. industr. de Mulhouse*, xlv. 120; *Jahresb. f. Chem.* 1874, 1093; *Chem. Soc. J.* xxviii. 196).

(2). With Zinc. The iron is first cleansed with dilute sulphuric acid, and immersed for a time in water mixed with milk of lime. It is then dipped, first into a solution of zinc chloride (prepared by saturating common hydrochloric acid with zinc) containing a quantity of sal-ammoniac equal to $\frac{1}{30}$ per cent. of the weight of the zinc chloride. In this solution the iron becomes covered with a thin coating of zinc, the thickness of which may be increased by immersing the dried iron in fused zinc till it has acquired the temperature of the bath (*Dingl. pol. J.* cxvii. 340). On the 'galvanisation' of iron, see also F. A. Thum (*ibid.* ccxvi. 339).

(3). With Nickel. The bath used consists of a 5 to 10 per cent. solution of zinc sulphate containing a quantity of nickel sulphate sufficient to give it a bright green colour (Böhm, *Ber.* 1876; *Jahresb. f. Chem.* 1876, 1103). According to Hess (*Dingl. pol. J.* cxvii. 256) the nickel bath used by Plazanet consists of 87.5 grams nickel sulphate, 20 ammonium sulphate, 17.5 citric acid, and 2 litres of water. According to Boden (*ibid.*), a nickel bath much used in France is prepared by dissolving 4 pts. nickel nitrate in 4 pts. aqueous ammonia, and 150 pts. water holding in solution 50 pts. of acid sodium sulphite. With the aid of a very feeble current the deposition is completed in a few minutes. There is no necessity for interrupting the process in order to clean the surface and thereby ensure the desired thickness of the deposit; the nickelled objects merely require to be dried in sawdust.

(4). With Tin. Iron tacks may be tinned by triturating zinc chloride with a considerable quantity of oil; heating the mixture in a swinging pot; then adding the tacks, together with the requisite quantity of tin; after a few seconds the tinned tacks are withdrawn by means of a wire net and thrown into water (*J. Wiley, Berl. Ber.* vii. 1465).

(5). With Gold and Silver. To obtain iron capable of being directly silvered or gilt, Delatol (*Dingl.* ccxv. 471) adds to 1,000 pts. of cast iron, 12 pts. nickel, and 0.5 pt. manganese. Objects made of this alloy require merely to be cleansed with milk of lime, and may then be plunged into the following baths.

<i>Gold-bath.</i>		<i>Silver-bath.</i>	
Water	100 pounds.	Water	100 pounds.
Sodium Bicarbonate . .	4½ "	Sodium Bicarbonate . .	2 "
Sodium Pyrophosphate .	1½ "	Silver Chloride or Nitrate .	2 oz. "
Auric Chloride . . .	¼ oz.	Potassium Cyanide . .	6 "
Sodium Cyanide . . .	1 "	Hydrocyanic Acid . .	10 drops.
Hydrocyanic Acid . .	2 drops.		

11. *Etching of Iron and Steel.*—The action of acids on various kinds of iron and steel produces markings which give an insight into the structure of the metal, its composition, and the manner in which it has been worked. A convenient etching fluid is composed of 1 pt. hydrochloric acid, 1 pt. water, and a trace of antimonious chloride (one drop of a strong solution of the latter to a litre of the dilute acid.) The surface to be etched, having been previously rendered even by filing or grinding, is surrounded with a ridge of wax about $\frac{3}{8}$ -inch high; the acid is poured into the space thus marked off; and the progress of the etching is observed every half-hour, the acid being renewed if necessary. When the etching is complete, the surface is washed, first with alkaline and then with pure water, and protected from rusting by a coating of Dammar varnish. The addition of antimony chloride to the etching liquid serves also to prevent too rapid rusting.

Soft fibrous iron thus treated is etched so uniformly that the surface remains light-coloured and with a faint lustre, but little carbon separating out; imperfect spots or ash-cavities however are brought to light. *Fine-grained iron* exhibits a similar aspect, the etched surface being generally more uniform, but darker in colour. *Coarse-grained and cold-short iron* is strongly attacked by the acid; the etched surface under the acid becomes black in ten minutes; and after thirty minutes a black deposit may be washed off it, the metal itself however remaining black and being marked with numerous small holes. *Malleable cast-iron* is very strongly and uniformly etched. *Puddle-steel, cement-steel, and Bessemer steel* yield uniform light-grey etch-surfaces, in which the lines of separation of the layers and imperfect spots show themselves, the finest capillary fissures being brought to light by the etching. *Grey pig-iron* yields a dark-grey uniform etching. *Soft iron* distinctly shows the white constituents as light-grey markings on the dark ground formed by the grey pig. The application of this etching process to finished goods shows the kind of metal of which they are made and the manner in which it has been worked. The mode of packing in the forge may in like manner be recognised in the finished pieces (F. Kick, *Dingl. pol. J.* ccxii. 40).

III. *Steel. Preparation from Cast Iron. Bessemer Process.*—Cast iron for this purpose should be rich in silicon, but as free as possible from sulphur and phosphorus. Only a few ores yield pig-iron of this description; the best is red hematite, then come brown hematite, magnetic iron ore, and lastly clay iron ore, in so far as this last can be used for making Bessemer steel (W. Baker, *Chem. News*, xxvii. 25).

P. Tunner (*Dingl. pol. J.* ccxv. 507) observes that a large proportion of silicon in pig-iron certainly facilitates the Bessemer process by raising the temperature of the furnace; but that, on the other hand, it is scarcely possible to obtain steel free from silicon by the use of pig-iron containing that element in large proportion. If the product is to be used as unhardened steel, the presence of silicon is not objectionable, but it greatly interferes with the hardening of steel. Tools and articles of similar description should therefore never be made of Bessemer steel prepared from siliciferous iron; steel for such purposes is best prepared by casting.

Rochussen a. Daelen prepare steel from pig-iron by lining the Bessemer converter with ferric oxide (pulverised ore), which supplies at least half the oxygen required to burn out the carbon; consequently the quantity of air required to be blown into the converter is less than in the original process, and the quantity of steel obtained is increased by the reduction of iron from the furnace lining. The temperature of the furnace is at least as high as when no ferric oxide is used, and is indeed increased by the combustion of the carbon oxide resulting from the mutual action of the ferric oxide and the carbon of the iron. As the carbon oxide is not formed till the metal bath has become strongly heated by the combustion of the silicon, a larger quantity of air is required in the latter stages of the process than at the beginning. To ensure this, the tuyere-holes at the bottom of the converter are closed at first by the furnace lining, and it is only when this lining melts that the blast has full play (*Engineer* April 1873, p. 249; *Dingl. pol. J.* ccix. 416).

H. Schwarz observes that, in working the Bessemer process, it sometimes happens that the usual appearances indicating the end of the operation present themselves before the oxidation of the carbon is really complete. This happens most frequently when the charge becomes too hot, and Schwarz considers it probable that under these circumstances the temperature of dissociation of carbon dioxide is reached, so that the oxygen of the air passes through the molten iron without combining with the carbon.

Use of Ferromanganese and Spiegeleisen in the Bessemer process (F. Gautier, *Dingl. pol. J.* ccxxii. 48).—The ferrosiferrous oxide formed in the Bessemer process when no manganese is employed, passes into the steel and renders it red-short, whereas manganese, if present, reduces the ferrosiferrous to ferrous oxide which, together with the manganous oxide formed at the same time, readily passes into the slag. A certain quantity of manganese is nevertheless found in the steel produced, and it is not yet ascertained how far the improved quality of the product is due to its presence. In the Bessemer and Siemens-Martin processes, from 1 to 10 per cent. manganese is added to the steel in the form of Spiegeleisen. The use of this alloy is however attended with an increase in the proportion of carbon in the product, and to avoid this, manganese alloys containing 75 per cent. manganese, prepared at the Terre Noire works, have lately come into use. Gautier is of opinion that the addition of 1 per cent. manganese in this form to the molten mass is sufficient for the preparation of the softest steel: for, as was first observed by Bessemer, the manganese removes from the steel, not only ferrosiferrous oxide, but likewise the greater part of the carbon. A specimen of steel prepared with ferromanganese showed a somewhat narrower range of elasticity and a somewhat smaller coefficient of tenacity than steel obtained with spiegeleisen; on the other hand its extensibility was more than three times as great as that of spiegeleisen steel. Now Mallet has shown that the constructive value of steel for parts of machinery, plates, &c., is measured by the product of the coefficient of tenacity into the final expansion: hence it follows that, for the uses just mentioned, ferromanganese steel is decidedly preferable to spiegeleisen steel, notwithstanding the greater tenacity of the latter. The product just mentioned is for hard steel, 305; for soft ferromanganese steel, 700; for ordinary iron, 105. It is recommended to add the ferromanganese red-hot to the mass in the converter, since such a mass added in the cold state might give rise to dangerous spitting.

The association of carbon with silicon greatly interferes with the preparation of soft steel, whereas steel not containing carbon forges readily even if it contains 7·5 per cent. silicon. *Sulphur*, if present in the raw material even to the amount of 1 per cent., may be removed almost completely, during the smelting in the blast furnace, by a copious addition of lime or manganese.

2. *Phosphorised Steel*.—The proportion of *phosphorus* in steel containing 0·5 per cent. carbon must not exceed 0·05 per cent., otherwise the steel will not roll well. The removal of the carbon from such steel by the use of ferromanganese is especially desirable, since it has been found that steel containing as much as 0·4 per cent. phosphorus may be rendered soft and tenacious, provided that the proportion of carbon in it is reduced to a mere trace. Phosphorised steel becomes softer by rolling, its granular texture changing at the same time into fibrous. The presence of a somewhat considerable proportion of manganese, up to 1 per cent., in phosphorised steel increases its power of resisting shocks. A so-called manganese-steel, very poor in carbon, may be prepared by the Bessemer or Siemens-Martin process, if 1·5 per cent. manganese in the form of ferromanganese be added to 60–75 per cent. of the fused metal; the product is a steel containing 1 per cent. manganese, and at most 0·5 per cent. carbon. Such steel is very flexible, and exhibits great resistance to shocks.

A. Greiner (*Rev. scient.* 1874, xxxv. 623; *Dingl. pol. J.* ccxvii. 33) describes the manufacture of phosphorised steel at the Königin-Marien Works at Kainsdorf near Zwickau, and at the Max Works near Schwandorf in Bavaria. The pig-iron used at Zwickau contains on the average 2·50 per cent. silicon, 0·04 sulphur, 0·10 to 0·12 phosphorus, 2·6 to 4 manganese, and 3·5 carbon; that of the Max Works contains 0·10 per cent. phosphorus (minimum), and 4 per cent. manganese. These pig-irons, when remelted in the cupola, take up an additional quantity of phosphorus from the ash of the coke, which at the Max Works sometimes contains from 0·33 to 0·4 per cent. phosphorus. The reaction between the blast and the metal in the converter is very violent, and the converter is therefore made higher than usual, in order to prevent the slag from being forcibly thrown out. The steel decarburised by the blast towards the end of the refining operation contains so much manganese, that the addition of spiegeleisen may be dispensed with, and the metal run off directly at the moment of completion.

The spectroscopic recognition of the completion of the process is more difficult in

the case of manganese pig than in the ordinary operation of refining, partly from the intense brightness of the flame produced by the oxidation of the manganese, and partly from the thick smoke of brown oxides arising from the liquid mass. Towards the end of the operation, however, the black lines towards the blue end of the spectrum disappear, and those in the green become fainter; then the latter disappear, while those in the yellow become faint, and so on. When all these absorption-bands have vanished, and the spectrum has again become continuous, the decarburisation is known to be nearly completed. The blast may then be continued a minute or two longer; a sample of the contents of the converter—metal and slag—taken out on the end of an iron rod; the colour of the slag is examined, and the hardness of the metallic globules tested by hammering. If the slag is black on the outside, the steel is very soft; a brown colour of the slag also indicates soft steel; orange, half-hard; and dark-yellow, hard steel. A globule of soft steel may be hammered out to a plate without any cracks on the edges; but the harder the steel, the deeper and more numerous will be the cracks.

At the Marien Works, two converters holding 5 tons each yield in 24 hours and 14 tappings, 33 tons of manganese steel, about 10 per cent. of the metal being lost by burning. The steel contains from 0·4 to 0·7 per cent. silicon, 0·06 sulphur, 0·10 to 0·15 phosphorus, 0·4 to 0·7 manganese, and about 0·15 carbon. Steel containing more than 0·20 per cent. phosphorus is brittle.

The chief use of the phosphorised steel above described is for the manufacture of rails. For this purpose the ingots are rolled to covering plates of 40 to 50 mm. thickness, and of the breadth of the packet of rails, and under these covers the rails of coarse-grained phosphorised iron are placed, whilst above, a flat bar of fibrous iron is brought to form the foot of the iron rail. The coarse-grained iron serves to combine the steel head with its basis of fibrous iron. A packet so composed endures a welding heat very well, and in rolling exhibits a very close resemblance to ordinary railway iron. A 'mixed' rail is thus obtained, which when carefully made is very durable.

Phosphorus makes steel cold-short, and diminishes its elasticity as regards drawing or bending strain. Good steel, containing 0·45 to 0·60 per cent. carbon, may be elongated without breaking, to the extent of 9 to 10 per cent. of its original length, whereas steel containing 0·25 to 0·38 per cent. phosphorus breaks when stretched only to the amount of 3 to 4 per cent. A steel prepared from pig-iron containing 0·69 per cent. phosphorus was found to be as brittle as glass. These defects are remedied to a certain extent by the presence of manganese, this metal removing the ferric oxide present in the decarburised bath, thereby rendering the metal capable of welding, and restoring its extensibility.

3. *Cementation Steel*.—The changes which iron undergoes in its conversion into steel by cementation have been studied by M. Boussingault (*Compt. rend.* lxxviii. 1458). The iron was weighed before and after cementation. Iron smelted from spathic iron ore and hematite in the Ria Works (East Pyrenees) was subjected to cementation in two pieces. One piece weighed 4949·54 grams before and 4994·20 grams after cementation, it had therefore gained 44·65 grams. The corresponding numbers in the second piece were 5124, 5199·6, and 75·6. The analysis of the metal gave—

	Before cementation	After cementation	
		No. 1.	No. 2.
Iron	99·100	98·200	97·650
Combined carbon	0·118	0·995	1·512
Silicon	0·105	0·107	0·120
Sulphur	0·012	0·006	0·005
Phosphorus	0·100	0·125	0·130
Manganese	0·222	0·220	0·218
Undetermined	0·343	0·347	0·365
	100·000	100·000	100·000

In both cases, the increase of weight exceeded the weight of the carbon fixed, and the silicon, phosphorus, and undetermined matters which were acquired, weighed more than the iron and sulphur lost.

A second experiment was made on a bar of Swedish iron. After cementation, the blistered surface was covered with graphite. The metal itself was of silvery whiteness.

The results of the analysis were as follows :

	Weight of the bar	Iron	Carbon	Silicon	Sulphur	Phos- phorus	Man- ganese	Under- ter- mined
Before cementation	2000.45	1089.45	6.00	0.32	0.30	1.14	1.80	1.44
After cementation	2026.22	1089.14	32.01	0.61	0.10	1.32	1.42	1.62
Differences . .	+ 25.77	- 0.31	+ 26.01	+ 0.29	- 0.20	+ 0.18	- 0.38	+ 0.18

The increase of the weight of the bar was slightly less than the weight of the carbon fixed.

A slight loss of iron always occurs in cementation: this was found to be the case even in an experiment with pure iron. Boussingault attributes this loss to the volatilisation of ferric chloride formed from the metallic chlorides which are always present in the ash of charcoal; moreover, the powdered charcoal used for the cementation always takes up a small quantity of iron. The combination of the iron with carbon is always attended with elimination of sulphur, which also goes on to a greater extent in the refining of the crude steel, *e.g.* by remelting. The best steel contains nothing but iron and carbon; all other constituents of wrought iron must be removed, or should remain in the steel in inappreciable quantities only.

H. St. Claire Deville (*Compt. rend.* lxxviii. 1464) is of opinion that the blisters on the surface of crude cementation steel are due to hydrogen which is absorbed during the cementation and afterwards given up. Berthelot (*ibid.* 1465) considers that iron, like palladium, is capable at a dull red heat of forming with hydrogen a chemical compound, which is decomposed at a higher temperature. The deposition of graphite on the surface of the crude steel is attributed by Berthelot to the decomposition of a compound of iron and carbon, which is perhaps formed by direct combination of its elements, or may be produced by the agency of hydrocarbons.

4. *Cast Steel*.—On the preparation of cast steel by the Bessemer and Martin processes, see Noblet (*Revue universelle des Mines*, xxxiii. 33; *Dingl. pol. J.* ccx. 197; *Jahresb. f. Chem.* 1873, 1004).

On the use of Alloys of Silicon and Manganese in the preparation of Cast Steel, see S. Kern (*Chem. News*. xxxv. 226; *Chem. Soc. J.* xxxii. 522).

5. Mushet's 'Special Steel.' This steel contains, according to Heeren (*Dingl. civ.* 477), 8.3 per cent. tungsten and 1.73 manganese; according to Gintl a. Janowsky (*ibid.* civ. 271), 8.813 to 8.741 tungsten and 2.575 to 2.480 manganese; according to Gruner (*ibid.* civ. 316), 7.98 per cent. tungsten, together with 1.40 carbon and 0.24 silicon: he supposes that Mushet obtained it by fusing pure cementation steel with metallic tungsten. Heeren and Gruner find that Mushet's steel in its original state has the hardness of good glass-hard steel; when subjected to the process by which ordinary steel is hardened, it becomes softer, and cracks in all directions. It may be forged at a red heat, and must be brought into the required shape by forging, as it cannot afterwards be filed. It also possesses a degree of toughness which renders it well adapted for the manufacture of cutting instruments. According to Kick, on the other hand (*ibid.* civ. 488), this steel is very difficult to work, and tools made of it soon lose their edge. According to Kellerbauer (*ibid.* civ. 488), the only advantage that Mushet's steel possesses over other kinds is that it does not require hardening; on the other hand, its utility is greatly limited by the difficulty of working it.

Alloys resembling steel may be prepared by fusing iron with nickel and tungsten in the following proportions:

Soft iron	Tungsten	Nickel
93	6.5	0.5
95	4.5	0.5
97	2.5	0.5

As a flux may be used a fused mixture of 36 parts boric oxide, 32 sand, and 32 calcium carbonate (H. Levallois, *Dingl.* ccx. 235).

6. *Hardening of Steel*.—H. Caron (*Compt. rend.* lxxvii. 836) recommends for this purpose the use of water at about 55° C. Steel plunged into water at this temperature does not crack, as it often does when hardened with cold water.

A. Jarolimek (*Dingl. pol. J.* ccxxi. 436) observes that thin steel wires are completely hardened by immersion, not only in boiling water, but likewise in boiling oil, and in melted lead or tin, and even in melted zinc, provided that they are dipped in the zinc-bath for a short time only, whereas they lose their hardness by prolonged immersion therein. Hence Jarolimek concludes that the hardening of steel depends

on sudden cooling below 500° , whereas tempering or softening is completed within lower limits of temperature. The fitness of a liquid for hardening steel depends upon its heat-conducting power and heat capacity, water being, especially for the last reason, preferable to all other liquids, although the film of vapour formed at the same time round the glowing steel tends by its low conductivity to retard the cooling of the steel. This inconvenience may, however, be obviated by immersing the red-hot steel in a stream of hot water spray, the water being then rapidly converted into vapour, and the vapour at the same time quickly removed. Steel thus treated acquires the hardness of glass. The *tempering* of steel is also easily effected by this process, either by diminishing the force of the spray or by removing the steel into the more diffused part of it.

To protect steel objects from oxidation during the hardening process, Ph. Rust (*Dingl.* ccxxi. 284) coats them with a thin paste of 2 parts charcoal, 1 part yellow prussiate and glue, after which they may be heated to redness in a charcoal fire and hardened.

On the Hardening of Steel, see further F. Dietlen (*Dingl.* ccxxi. 518; *Jahresb. f. Chem.* 1876, p. 1069); also Garman a. Siegfried (*Dingl.* ccx. 472; *Jahresb.* 1878, 1005).

On the Influence of Heat on the Hardening of Steel, see Metcalf (*Dingl.* ccxxix. 92; *Chem. Soc. J.* xxxiv. 1019).

For the regeneration of burnt steel, Kolicke (*Dingl.* ccviii. 463) recommends a mixture of 12 parts by weight of tartaric acid, 60 cod-liver oil, 4 charcoal-powder, 16 bone-black, 20 beef-suet, 10 yellow prussiate, and 6 burnt hart's horn. The red-hot steel is dipped into the pasty mass and then quenched in water.

7. Relation between the Physical Properties of Steel and its amount of Carbon.—An examination by W. Langly (*Amer. Chemist*, vii. 175) of twelve samples of steel which had previously been remelted, showed that with varying proportions of carbon, from $\frac{1}{10}$ per cent. upwards, the appearance of the fracture exhibited differences easily recognisable by a practised eye. The density was also found to diminish proportionally to the increase in the amount of carbon. Steel which has been very strongly heated and quickly cooled—so-called *burnt steel*—is well known to exhibit a very coarse granular texture on the fracture-surface. The specific gravity of the steel is also diminished by this process, the decrease being greater in proportion as the hardened specimen has been more strongly heated.

The decrease of specific gravity with increasing amount of carbon has also been observed in Bessemer steel by Koppermayer (*Dingl. pol. J.* ccxi. 22), as shown in the following table:—

Percentage of carbon	Specific gravity of the steel at 13°
0.14	7.9219
0.19	7.8784
0.30	7.8754
0.46	7.8711
0.55	7.8632
0.57	7.8569
0.66	7.8530
0.80	7.8434
0.87	7.8378
0.96	7.8291

On the Influence of an Electric Current on the Electric Conductivity of Iron and Steel, see ELECTRICITY (p. 718).

On the Magnetisability of Iron and Steel, see MAGNETISM.

On the Occlusion of Gases by Steel, see p. 1113.

According to S. Kern (*Chem. News*, xxvi. 19; *Chem. Soc. J.* xxxii. 815), the steel in the metallic bath of the Bessemer converter contains oxygen in the occluded state, and perhaps in the form of a definite chemical compound analogous to hydrogen-palladium. Five specimens analysed gave 0.054, 0.037, 0.025, 0.040, and 0.031 per cent. oxygen.

Classification and Nomenclature of Iron and Steel.—An International Commission formed in connection with the Philadelphia Exhibition in 1876, recommended the adoption of the following terms (English, German, French, Swedish):—

(1.) Weld-iron (*Schweiss-eisen, fer soudé, wäljern*) for all malleable compounds of iron with the ordinary ingredients, which have been prepared from softened masses

or faggots, or in any form other than the liquid state, and cannot be hardened or tempered, and are similar to the substance commonly called wrought-iron.

(2.) Weld-steel (*Schweiss-stahl*, *acier soudé*, *wälkstål*), for compounds of the previously described quality which from any cause are capable of being hardened and tempered, and are therefore similar to the product hitherto called 'puddled steel.'

(3.) Ingot-iron (*Fluss-eisen*, *fer fondu*, *götiern*), for all compounds of iron with the ordinary ingredients which have been cast in the liquid state to malleable masses and cannot be appreciably hardened when placed in water whilst red-hot.

(4.) Ingot-steel (*Fluss-stahl*, *acier fondu*, *göfstål*), for compounds of the last described quality which from any cause are capable of being tempered (*Dingl. pol. J.* cxxiii. 325; *Chem. Soc. J.* xxxii. 239). See also Greiner (*Chem. Centr.* 1873, p. 759; *Chem. Soc. J.* xxvii. 830).

ISATIN,

The formation of this compound by oxidation of amidoxindole (p. 1087) may be represented by the equation—

Now oxindole, $\text{C}^6\text{H}^4 \begin{array}{c} \text{CH}^2.\text{CO} \\ \text{NH} \end{array}$, is identical with the anhydride of orthamidophenylacetic acid, and isatin is converted into indigo-blue by heating it with a mixture of PCl^3 and PCl^5 , and subjecting the product to the action of reducing agents: hence this series of reactions affords the means of preparing indigo-blue from a compound belonging to the coal-tar group (p. 1086).

Acetyl-derivatives of Isatin (W. Suida, *Berl. Ber.* xi. 584). *Acetyl-isatin*, $\text{C}^6\text{H}^4 \begin{array}{c} \text{CO} \quad \text{CO} \\ \text{N}(\text{C}^2\text{H}^3\text{O}) \end{array}$, prepared by heating isatin with twice its weight of acetic anhydride for three or four hours, crystallises in yellow prismatic needles which melt at 141° . It dissolves easily in benzene and in alcohol, and is resolved into isatin and acetic acid by boiling with water, or more readily with hydrochloric acid.

Acetylisatic Acid, $\text{C}^6\text{H}^4\text{NO}^4 = \text{C}^6\text{H}^4 \begin{array}{c} \text{CO.COOH} \\ \text{NH}(\text{C}^2\text{H}^3\text{O}) \end{array}$, obtained by dissolving acetyl-isatin in dilute potash-ley and precipitating with dilute sulphuric acid, is a white crystalline substance, melting at 160° , sparingly soluble in cold water, more easily in alcohol, ether, and benzene; converted into isatin by boiling with hydrochloric acid. It dissolves in soda-ley, but the solution quickly undergoes alteration. The lead and silver salts are white precipitates.

Acetyl-hydrindic Acid, or *Acetyl-dioxindole*, $\text{C}^6\text{H}^4 \begin{array}{c} \text{CH}(\text{OH}).\text{COOH} \\ \text{NH}(\text{C}^2\text{H}^3\text{O}) \end{array}$, obtained by the action of sodium-amalgam on a solution of acetylisatic acid in acetic acid, forms colourless needle-shaped crystals, melting at 142° , easily soluble in water, alcohol, chloroform, and glacial acetic acid; insoluble in light petroleum. It does not yield isatin when boiled with hydrochloric acid. By reducing agents (hydriodic acid or sodium-amalgam) it is resolved into acetic acid and oxindole—

Amido-derivatives of Isatin (E. v. Sommaruga, *Liebig's Annalen*, xc. 367; *Berl. Ber.* xi. 1082). When an alcoholic solution of isatin saturated with dry ammonia-gas is heated to 100° in sealed tubes for 24 hours, two crystalline bodies are formed, one slightly soluble, the other easily soluble in water and in alcohol, together with a resinous substance and a very small quantity of a purplish-red colouring matter.

1. Amido-isatin, $\text{C}^6\text{H}^4\text{N}^2\text{O} = \text{C}^6\text{H}^4(\text{NH}^2)\text{NO}$, or Diamido-diisatin, $\text{C}^6\text{H}^{12}\text{N}^4\text{O}^2 = \text{C}^6\text{H}^4(\text{NH}^2)^2\text{N}^2\text{O}^2$, the less soluble of the two crystalline bodies, is produced in the manner shown by the equation—

It forms pale yellow crystals, sparingly soluble in alcohol and in water, melts with decomposition at 111° , and forms salts with acids. The *hydrochloride*, $\text{C}^6\text{H}^{12}\text{N}^4\text{O}^2\text{HCl}$, and the *nitrate*, $\text{C}^6\text{H}^{12}\text{N}^4\text{O}^2.\text{NO}^3\text{H}$, are yellow crystalline powders slightly soluble in

water. The *sulphate*, $C^{16}H^{12}N^4O^2 \cdot SO^4H^2$, crystallises in light yellow needles; the *chromate*, $C^{16}H^{12}N^4O^2 \cdot CrO^4H^2$, is an orange-coloured powder.

Diamido-diisatin is converted by sodium-amalgam into the compound $C^{16}H^{11}N^3O^3$, which is insoluble in water, but crystallises from alcohol in small colourless needles. Its sodium-derivative, $C^{16}H^{10}N^3O^3 \cdot NaN^3O^3$, crystallises in long colourless needles, very soluble in water; the potassium-derivative, $C^{16}H^{12}KN^3O^3$, in broad needles, having a silky lustre.

Oxydiimido-diamido-diisatin, $C^{16}H^{11}N^3O^3 = C^{16}H^8(NH)^2(NH^2)^2N^3O^3$, the easily soluble crystalline body, and *Deoxyimido-diisatin*, $C^{16}H^{11}N^3O^2 = C^{16}H^{10}(NH)N^2O^2$, the resinous compound above mentioned, are formed simultaneously in the manner shown by the following equation:

Oxydiimido-diamido-diisatin forms large colourless needle-shaped crystals, which melt between 295° and 300° , and dissolve readily in acids. When treated with potassium nitrate and sulphuric acid, it yields a nitroso-product, which is decomposed by water, and has not been obtained pure. By sodium-amalgam, the oxydiimido-compound is reduced in the manner shown by the equation—

The product, which is possibly the amide of hydrindic acid or dioxindole, $C^8H^8(NH^2)O^2$ (or the diamide of dihydrindic acid), is converted by oxidation with chromic acid mixture into an acid, $C^{16}H^{12}N^4O^4$, which may be called *diimido-hydrincarbonic acid*: $C^{16}H^{16}N^4O^2 + O^4 = 2H^2O + C^{16}H^{12}N^4O^4$.

Deoxy-imido-diisatin, $C^{16}H^{11}N^3O^2$, when purified by solution in potash, and reprecipitation by an acid, forms a yellowish powder resembling tannin. It melts, with decomposition, at 209° – 210° , and dissolves in alcohol and in water. Sodium-amalgam converts it into an amorphous isomeride of monamidodihydro-diisatin—

The same product is formed by the action of water or strong potash-ley under pressure on deoxy-imido-diisatin.

The existence of the compounds above described is regarded by v. Sommaruga as showing that the molecule of isatin—and therefore also that of indigo-blue—contains 16 atoms of carbon. This conclusion is in accordance with a recent determination, by Sommaruga, of the vapour-density of indigo-blue which was found, as the mean of nine experiments, to be 9.45, the formula $C^{16}H^{10}N^2O^2$ requiring 9.06. Isatin decomposes when vaporised, so that its vapour-density cannot be directly determined.

ISENITE. Sandberger described under the name of *Nosean-andesite* a volcanic rock which occurs at several localities in Nassau, especially on the Sengelberg near Sala in the Wisterwald, also on the Kriegershecke near Wölferlingen, and near Maxhayn (*Jahrb. f. Min.* 1874, 318). This same rock has been subjected to a very careful mineralogical, microscopical, and chemical investigation by G. A. Bertels (*ibid.* 873), who calls it *Iseinite*, from the name of a small river in Nassau, the Eis (formerly *Iseña*). The main results of this investigation are as follows:—

Amongst the macroscopically distinguishable constituents of the rock, the felspars, which are mostly unaltered, exhibit under a magnifier, distinct twin-marking. Hornblende appears in fine twin-crystals of known form, often however converted on the edges into a radiate mineral. Octohedrons of magnetic iron-ore and hexagonal titaniferous iron occur, as well as rhombic crystals of a red-brown mineral, recognised by Bertels as allied to fayalite. Lastly, needles of apatite are also found. The zeolitic mineral in the cavities is stilbite.

Microscopic examination showed, in the first place, a light-coloured ground-mass consisting of triclinic felspar, in which were imbedded tablets of ferruginous mica, granules of magnetic iron ore, and especially well-developed noseans regularly disseminated through the rock. Distorted hexagons of nephelin occur as subordinate constituents. The large crystals of felspar already mentioned frequently enclose granules of magnetic iron, laminae of iron-glance, glass-cells, vapour-pores, fine needles of apatite, and more rarely small noseans. The large hornblendes are often quite filled with granules of magnetic iron ore; needles of apatite and fayalite are also found in them, and even comparatively large crystals of fayalite, apatite, and felspar.

The powdered rock cautiously warmed with hydrochloric acid yields a distinct jelly. A chemical analysis of the entire rock, as well of the soluble part (35.74 per cent.) and of the insoluble part (64.26 per cent.), gave the following results. Sp. gr. = 2.78:

	Total analysis	Soluble	Insoluble
Silica	48.02	8.20	39.82
Alumina	16.92	2.41	14.51
Ferric oxide	11.63	10.74	0.89
Ferrous oxide	4.70	2.83	1.87
Manganous oxide	2.44	0.50	1.94
Magnesia	1.45	1.15	0.30
Lime	8.58	3.64	4.94
Soda	2.36	2.36	0.93
Water	1.78	1.78	—
Titanic acid	0.15	—	0.15
Phosphoric acid	1.55	1.55	—
Sulphuric acid	0.56	0.56	—
Chlorine	0.53	0.53	—
	100.67	36.25	65.35

A remarkable circumstance is the absence of potash, which could not be detected even spectroscopically.

Bertels has also analysed some of the separable constituents of the rock, viz., the felspar and the radiate transformation-product of hornblende. The felspar has a specific gravity of 2.648; melts easily before the blowpipe, imparting a strong yellow colour to the flame; is attacked, but not completely decomposed, by hydrochloric acid:

SiO ²	Al ² O ³	Fe ² O ³	CaO	MgO	Na ² O
53.51	29.37	trace	12.78	1.54	3.10 = 100.30

The radiate transformation-product of the hornblende has a chloritic aspect, and is sharply separated from the latter, its fibres standing perpendicularly on the hornblende faces. Hardness = 2. Specific gravity = 2.997–3.057. Before the blowpipe it melts easily (not exfoliating, like the easily fusible chlorites) to a black, strongly magnetic bead. Analysis gave:

SiO ²	Al ² O ³	Fe ² O ³	FeO	MnO	MgO	CaO	H ² O
32.78	15.60	29.90	2.98	1.15	4.90	6.74	7.52 = 101.57

whence may be deduced the formula—

By a comparison with other similar minerals, Bertels infers that this transformation-product of hornblende is a new species of the chlorite-group, for which he proposes the name *Phæactinite*, indicative of its grey-brown colour and radiate texture.

From a calculation of the total constituents of the rock, it is inferred that, whilst the porphyritically separated felspar is labradorite, the felspathic ground-mass consists of a more acid plagioclase. This remarkable association of a felspathic hornblende rock with nesean and nephelin, in which the felspar is exclusively triclinic without a trace of orthoclase, gives the rock a distinct character. The similarity of isenite to the Etna lavas, indicated by the comparatively large crystals of porphyritically intergrown labradorite which it contains, is still more plainly seen in the chemical constitution, as shown by comparison with the mean of 28 analyses of Etna lavas.

The rock most nearly allied to isenite, though still different from it, is the haüyn-tephrite from the Canaries, described by K. v. Fritsch and W. Reiss.

ISETHIONIC ACID. $\text{C}^2\text{H}^2\text{SO}^4 = \text{CH}^2\text{OH} \cdot \text{CH}^2\text{SO}^2\text{OH}$. The chloride of this acid, $\text{CH}^2\text{OH} \cdot \text{CH}^2\text{SO}^2\text{Cl}$, is formed, together with the same isomeric compounds, *chlorisethionic acid*, $\text{CH}^2\text{Cl} \cdot \text{CH}^2\text{SO}^2\text{OH}$, and *ethylsulphuric chloride*, $\text{C}^2\text{H}^5 \cdot \text{O} \cdot \text{SO}^2\text{Cl}$, by the action of sulphuric anhydride on ethyl chloride (p. 746).

On the conversion of isethionic into ethionic acid, $\text{C}^2\text{H}^2\text{SO}^2$, by the action of sulphuric acid, see page 742.

Action of Heat on Ammonium Isethionate.—This salt (m. p. 135°, or according to Strecker, 130°) remains unaltered when heated for several days on an oil bath at 210°–230°, but decomposes readily on raising the temperature of the saline mass to 230°–240°; and if, after the boiling has been continued for about eight hours, the resulting viscid syrup be dissolved in water, the solution boiled with animal charcoal and evaporated, the residue crystallised from alcohol, and the separated nodules, which are now almost insoluble in alcohol, constantly boiled with that liquid till they melt at 192°–193°, a compound is obtained which dissolves very easily in water, appearing indeed to be hygroscopic, gives off ammonia on addition of potash, and has the composition of taurine, $\text{C}^2\text{H}^2\text{NSO}^3$. Taurine, however, melts with decomposition at about 240°, and behaves in a different manner with potash (τ 700); hence the

compound formed by dehydration of ammonium isethionate is not identical, but isomeric with it, and appears indeed to be the true amide of isethionic acid (H. Seyberth, *Deut. Chem. Ges. Ber.* vii. 391).

ISOADIPIC ACID. The crystalline compound which Meyer a. Dulk obtained by the action of chloral on glacial acetic acid (*Ber.* iv. 963) is regarded by Hübner (*ibid.* vi. 109) as an isomeride of adipic acid, $C^6H^{10}O^4$.

ISOALLOXANIC ACID, $C^4H^4N^2O^5$. This modification of alloxanic acid—some of the salts of which were obtained by L. Hardy, by the action of bases on the red modification of alloxan produced by heating the latter to 260° (vi. 90)—has been further examined by Magnier de la Source (*Bull. Soc. Chim.* [2], xxii. 56), who obtains it by dropping bromine into water in which uric acid is suspended (1 part bromine to 40 or 50 parts water) till the liquid becomes clear. The whole is then transferred to a basin and heated over a water-bath in a stream of hydrogen, whereupon hydrobromic acid is abundantly evolved, the liquid becomes colourless, and a carmine-coloured precipitate is ultimately deposited on the sides of the vessel—apparently identical with the red modification of alloxan observed by Hardy. The solution above mentioned yields with baryta-water a splendid violet precipitate of barium isoalloxanate, which however cannot be obtained free from the colourless alloxanate, since it quickly passes into the latter on exposure to moist air. If ammonia be added in place of baryta-water, a fine purple colour is produced, and on subsequent addition of alcohol a red precipitate is formed, mixed with a large quantity of ammonium bromide; and on washing the precipitate with alcohol to remove the latter, and drying it in a vacuum, ammonium isoalloxanate is deposited in the form of a brick-red powder, very soluble in water, with which it forms a deep purple solution, very sparingly soluble in alcohol, insoluble in ether. Its solution gives with baryta-water a deep-red precipitate, with calcium chloride a rose-coloured precipitate, and with silver nitrate a precipitate of a fine indigo-blue colour; with carbonate of potassium or sodium a violet coloration, with cupric acetate a green coloration. The aqueous solution of the ammonium salt quickly loses its colour; the alcoholic solution, on the other hand, does not change colour perceptibly; the solid salt is permanent in dry air.

In accordance with these results it must be assumed that the so-called murexid reaction is due, on the one hand, to the formation of ammonium isoalloxanate, $C^4H^2(NH^4)^2N^2O^5$, and, on the other, to the formation of acid ammonium purpurate, $C^8H^4(NH^4)N^5O^6$. This latter compound is formed by treating alloxantin with ammonium carbonate, whereas the isoalloxanate is produced by similar treatment of alloxan, as shown by the following equations:

These two colouring matters are therefore formed simultaneously by the action of ammonium carbonate on a mixture of alloxan and alloxantin; the ammonium isoalloxanate may be partially removed by washing, but a portion of it is likely to remain mixed with purpurate, a circumstance which may account for the very different formulæ assigned by different chemists to murexid.

ISO-HEMIPINIC ACID. See NARCOTINE DERIVATIVES.

ISO-LEPIDENE. See LEPIDENE.

ISOBUTYL IODIDE. The conversion of this ether into tertiary butylamine, $(CH^3)^3C.NH^2$, by the action of dry silver cyanate—observed by Linnemann (vii. 223), but called in question by Hofmann (*Liebig's Annalen*, clxii. 19) who obtained chiefly isobutylamine—has recently been confirmed by Brauner (*ibid.* cxcii. 65), who operated with perfectly pure isobutyl iodide. On the properties of the butylamine thus obtained, see TRIMETHYLCARBINYLAMINE.

ISOBUTYLACETIC ACID. See PENTOLIC ACIDS.

ISOBUTYLACETO-ACETATE, ETHYLIC. Respecting this compound and its derivatives, heptic acid, oxyheptic acid, and ethylic methylisobutylglycerate, see **HEPTIC ACID** (p. 1020).

ISOBUTYLAMARIC ACID, $C^{50}H^{50}O^6$ (Zinin, *Deut. Chem. Ges. Ber.* x. 1735). This acid, homologous with amaric acid, $C^{48}H^{48}O^6$ (vii. 55)* is formed, similarly to the latter, by prolonged boiling of benzamarone with a solution of potash in isobutyl alcohol. It is nearly insoluble in water, but dissolves easily in ether and in alcohol, from which latter it crystallises in rhombic plates. It melts at 175° – 179° , and is thereby converted into an amorphous anhydride, $C^{50}H^{46}O^4$, which dissolves in ether,

* The formula there assigned to amaric acid is $C^{48}H^{48}O^6$, but subsequent experiments have shown that the true formula is that above given.

An *iodide*, $\text{C}_8\text{H}_{17}\text{I}$, is obtained, with even greater facility, by saturating the hydrocarbon at 0° with hydriodic acid gas. This iodide is attacked, even at 0° , by moist silver oxide. The product of the reaction, dried by anhydrous baryta, consists of regenerated isobutylene and an octylic alcohol, $\text{C}_8\text{H}_{18}\text{O}$, named *isodibutol*. This alcohol is a colourless thick liquid of characteristic odour, which boils at $146.5^\circ-147.5^\circ$, and solidifies at 20° . Sp. gr. at $0^\circ = 847$. Its alcoholic nature is proved by its

yielding, when treated with phosphorus pentachloride, the same chloride that is produced by the action of hydrochloric acid upon isodibutylene. It is a tertiary alcohol, its iodide, when treated with silver nitrite, giving neither a nitrolic nor a pseudonitrolic acid (Victor Meyer's test; see NITROPARAFFINS).

Isodibutyl submitted to the regulated action of oxidising agents, gave, besides unaltered alcohol and isobutylene, the same products that are furnished by oxidation of isodibutylene, but no ketone or aldehyde, a further proof that it is neither a primary nor a secondary alcohol. Its constitution may therefore be determined by studying the oxidation of isodibutylene. This body was accordingly treated in the cold for six days with a mixture of sulphuric acid and potassium dichromate, whereupon carbon dioxide was continuously evolved. The mixture was then distilled, that part of the distillate which contained oily drops being collected separately from the clear acid liquid which subsequently passed over. This clear liquid contained principally *acetic acid*. The first distillate was treated with potassium carbonate, whereby much of the oil was dissolved. The undissolved oil was removed, and the remaining alkaline liquid again distilled. From the first portions of liquid which then passed over *acetone* was easily separated by potassium carbonate in excess, not, however, in large quantity, probably because much of it had been oxidised to acetic acid. The alkaline solution, after removal of the acetone and oil, gave, on treatment with sulphuric acid, acetic and *trimethyl-acetic acids*. Since trimethyl-acetic acid does not give acetone on oxidation, it is thus evident that the primary oxidation-products of isobutylene are *acetone* and trimethyl-acetic acid, thus: $C^3H^{16} + O^3 = C^3H^{10}O^2 + C^3H^6O$. The acetone is partially oxidised to acetic acid.

This experiment establishes the constitution of isodibutylene. For of the two products one contains *three*, the other two, methyl groups; from which it must be inferred that the molecule of isodibutylene contains *five* such groups. Three of these must be united to one carbon-atom to form tertiary butyl, $(CH^3)^3C-$, which appears in the trimethyl-acetic acid, the remaining two methyls forming with another carbon-atom the group $(CH^3)^2C=$, which by oxidation yields acetone. From these considerations the formula of isodibutylene may be inferred to be $(CH^3)^3C-CHC(CH^3)^2$; and that of the corresponding tertiary alcohol, isodibutyl $(CH^3)^3C-CH_2-C(CH^3)^2OH$. The oxidation of the hydrocarbon follows the general rule for the series C^3H^{2n} , viz. that the carbon-atoms separate at the junction $C=C$.

This constitution of isodibutylene granted, the mode of its formation from trimethyl-carbinol is the following: (1) part of the alcohol splits up into water and isobutylene; (2) one molecule of isobutylene unites with one of unaltered trimethyl-carbinol, water being again eliminated. The course of the reaction is quite analogous to Collarits' and Merz's synthesis of aromatic ketones by the action of phosphoric anhydride upon a mixture of a hydrocarbon and an acid, or to Wischnegradsky's synthesis of diamylene (p. 635).

To account for the second phase of the reaction, it must be remembered that methyl groups and their derivatives are in general less prone to enter into reaction than the groups $-CH^2$ or $\equiv CH$, and their derivatives. The different degrees of stability are well observed in the alcohols of the three categories and the bodies allied to them, the radicles of the primary alcohols being least inclined to part with the hydroxyl or other simple radicles united to them, while in the tertiary alcohols and their allies such separations take place with the greatest ease. When, therefore, trimethyl-carbinol is partially resolved into water and isobutylene, the feebly-bound hydroxyl of the undecomposed alcohol combines more readily with the hydrogen in the group $\equiv CH^2$ of the hydrocarbon than with that belonging to the more stable methyl groups of its own molecule, thus—

On the other hand, when isobutyl alcohol, $CH^2(OH)-CH(CH^3)^2$, separates partially into water and this same (iso-) butylene, no such condensation takes place, because the alcoholic hydroxyl unites with the hydrogen of the group $\equiv CH$ in its own molecule, rather than with that of the $\equiv CH^2$ of isobutylene.

These considerations, somewhat modified, will also explain why secondary butyl alcohol, on treatment with sulphuric acid, gives, as a principal product, pseudo-butylene, but no dibutylene. Here the alcoholic hydroxyl tends to combine either with the hydrogen of the pseudo-butylene, $CH^3-CH=CH-CH^3$, first formed, or with that of the $\equiv CH^2$ in its own molecule. The proximity of the latter determines its union with it, and consequently the complete conversion of the alcohol into pseudo-butylene.

The higher-boiling portions of the oily acids from the oxidation of isodibutylene

were found to consist of trimethyl-acetic acid and a new octoic acid, $C^8H^{16}O^2$, the separation of which was ultimately effected by preparing the cadmium salts, and fractionally distilling the acids extracted from them. This octoic acid is a colourless oily liquid, smelling like trimethyl-acetic acid, and boiling with partial decomposition at 205° – 218° . Its constitution is best expressed by the formula, $C(CH^3)^3-CH^2-OH(CH^3)COOH$; since the carboxyl group must be formed at the expense of one of the five methyl groups of isodibutylene, and it is reasonable to assume that the group oxidised is one of those lying nearest to the point of attack of the oxidising agent, viz. the doubly united carbon-atoms $C=C$. The formation of this acid from isodibutylene appears strange at first sight, but is not without analogy, since oxidation of the hydrocarbons C^8H^{2n} appears in general to furnish the same products as that of the corresponding tertiary alcohols. Thus it is found that a certain quantity of isobutyric acid may be obtained by oxidation of trimethyl-carbinol. Now this octoic acid may be regarded as isobutyric acid in which hydrogen is displaced by tertiary butyl $(CH^3)_3C-$, isodibutol and isodibutylene being similarly derived from trimethyl-carbinol and isobutylene respectively. It may be assumed that, in both cases, by the successive removal and addition of water, an isomeric alcohol is first produced, which is then oxidised to the acid. Thus, when trimethyl-carbinol is oxidised—

which furnishes isobutyric acid, $(CH^3)_2CH-CO^2H$; and when isodibutylene is oxidised—

which yields the above octoic acid.

This explanation is supported by the fact that one of the oxidation-products of isodibutylene is a body derived from the octylene, $C(CH^3)^3-CH^2-C(CH^3)=CH^2$, whose existence is assumed in equations (2) and (3). This hydrocarbon would, upon oxidation, separate at the doubly-joined carbon-atoms, and give, as a first product, a ketone, $C(CH^3)^3-CH^2-CO-CH^3$; and, in fact, the oily products insoluble in potassium carbonate were found to consist of a mixture of isodibutylene, and a ketone of this composition boiling between 125° and 130° . The peculiar deportment of this body with metallic sodium is also exhibited by an undoubted ketone, namely, *ethylisopropyl ketone*, prepared by acting with zinc-ethyl on isobutyryl chloride; these bodies do not attack the sodium in the cold, but dissolve it rapidly when warm, giving solutions which, in contact with air, quickly assume a blood-red colour, finally passing into brown. On the other hand, the body in question is not oxidised by silver oxide; it does not combine with acid sodium sulphite; nor does it throw down ferric hydrate when boiled with ferric chloride, properties which distinguish it from the aldehydes and the oxides of the class to which ethylene oxide belongs. Finally, when oxidised with sulphuric acid and potassic bichromate, it yields acetic and trimethyl-acetic acids, as follows:—

This reaction is decisive with respect to its constitution.

The views above developed receive some support from Butlerow's observations on the action of sulphuric acid upon pentylene (trimethylated ethylene) from tertiary pentyl alcohol. Here the successive assimilation and separation of water take place without any change in position of the hydroxyl. In the cold sulphuric acid converts this pentylene into dipentylene. But when tertiary pentyl alcohol is heated to 100° in a tube with three times its volume of a mixture of equal weights of sulphuric acid and water, the principal product is uncondensed pentylene, which floats on the surface of the acid. If now the tube be laid on its side for some days, and occasionally shaken, the hydrocarbon again dissolves, i.e. assimilates water to reproduce the alcohol; and these operations may be repeated several times. Here, then, is an example of dissociation, and of gradual reunion of the dissociated bodies to form the original compound. In the case of isodibutol, on the other hand, the dissociated products (isodibutylene and water) would reunite to form, not the original alcohol, but an isomeride.

ISODULCITE, $C^8H^{16}O^6$. This crystalline sugar, isomeric with dulcete and mannite, which Hlasiwetz a. Pfandlner obtained by the action of dilute acids on quercitrin (v. 1091), is likewise produced by similar treatment of the glucoside of buckthorn berries (*Rhamnus infectoria*). Liebermann a. Hörmann, who obtained it

from this source (*Berl. Ber.* xi. 952), regarded it as a peculiar sugar, different from isodulcitol, and named it *rhamnodulcitol*, inasmuch as they found its melting point to be 92° – 93° , whereas isodulcitol from quercitrin was said by Hlasiwetz a. Pfaundler to melt at 105° . Berend, however (*ibid.* 1353), on re-examining the isodulcitol obtained from quercitrin, finds that it melts at 93° – 94° , and further that it agrees exactly with the sugar obtained by Liebermann a. Hörmann in crystalline form and in specific rotatory power; $[\alpha]_D = +8.04$ (Berend); $+8.07$ (L. and H.) The name *rhamnodulcitol* may therefore be dispensed with. 1 pt. isodulcitol dissolves, according to Hlasiwetz a. Pfaundler, in 2.09 pts. water at 18° ; according to Liebermann a. Hörmann, in 1.8 pts. (mean of three experiments; temperature not stated).

Isodulcitol heated with concentrated hydriodic acid is in great part converted into a tarry mass, and yields a heavy liquid distillate containing iodine and consisting of a mixture of bodies, none of which have yet been obtained in the pure state (Dale a. Schorlemmer, *Ber.* xi. 1197).

ISOMERISM. Compounds of the same elements in the same proportions, and of the same molecular weight, but having different properties, may be said to be *isomeric*, if from the manner in which they are formed and from their reactions, it may be concluded that they are bodies of the same type; if their behaviour indicates that they are bodies of different type, they may be said to be *metameric*.

A perusal of modern chemical literature shows that the term 'isomeric' is on the whole very loosely employed, some writers attaching a much more extended meaning to it than others; the foregoing definition is probably both the most restricted and the most extended that can well be given. The only difficulty which can arise in connection with it is that of determining whether two or more compounds more or less different in properties are bodies of the same type. If, however, a too formal construction of the phrase be avoided, this difficulty is a very slight one. For example, the hydrocarbons ethyl-benzene and the three dimethyl-benzenes or xylenes not only exhibit a very close general resemblance in behaviour, especially in the formation of substitution-compounds, but are also immediate derivatives of the same parent hydrocarbon, benzene: they may hence be regarded as bodies of the same type—*i.e.* as isomerides, although their behaviour with oxidising agents clearly indicates that ethyl-benzene differs to a much greater extent from the xylenes than these latter differ amongst themselves; a fact which finds an expression in the rational formulæ assigned to the several hydrocarbons. On the other hand, benzene and the hydrocarbon dipropargyl discovered by Henry differ so totally in properties that we without hesitation regard them as compounds of different type, *i.e.* as metamerides. Again, the four butylic alcohols or hydroxides of the formula $C^4H^9.OH$ are isomeric with each other, but metameric with methyl-propyl oxide, methyl-isopropyl oxide and diethyl oxide or ordinary ether, these last three oxides being isomeric with each other.

As the rational formulæ we employ are merely condensed symbolic expressions, affording more or less complete information as to the characteristic chemical properties of the compounds which they represent, especially with regard to the manner in which they are formed and in which they undergo change when submitted to the action of reagents, compounds which differ either in their mode of formation or in their behaviour under similar circumstances are necessarily represented by different rational formulæ. Recent investigations have, however, conclusively shown that a by no means inconsiderable number of 'isomeric' compounds exist, many of them widely different in so-called physical properties, which exhibit so close a resemblance in general chemical properties that, following the canons of the present system of notation, they can only be represented by identical formulæ.

The hydrocarbons of the formula $C^{10}H^{16}$, which occur in various essential oils, are the only instance of this kind that we meet with among the hydrocarbons, but a more striking instance can scarcely be advanced. At least, two classes of these hydrocarbons may be distinguished: those boiling at about 156° , which are conveniently termed terpenes; and those boiling at about 176° , which may be termed citrenes, as they are the chief constituents of the oils derived from the various species of *Citrus*. Each of these classes includes a considerable number of species which appear to differ only in their behaviour towards polarised light; in fact, up to the present time no two oils have been proved to contain the same terpene or citrene. It is highly probable, however, that many which are now regarded as distinct substances will be found to be mixtures, and that the number of separate species is not nearly so great as has been supposed; but the existence of *lævo*- and *dextro*

rotatory members in both classes is sufficient proof that there are several of each. At present the experimental evidence is not sufficient to enable us to say whether the terpenes and citrenes have identical formulæ. Their behaviour with hydrochloric acid would appear to favour the conclusion that they have not, inasmuch as the former furnish monohydrochlorides, and the latter dihydrochlorides. But, on the other hand, they have the same combining power, as they form tetrabromides; they yield identical oxidation-products (Fittig); they yield nitrosochlorides and nitroso-substitution compounds differing only in physical properties; and they are convertible into the so-called terpin, from which, by the action of hydrochloric acid, the corresponding dihydrochloride is obtained: so that indirectly the terpenes, as well as the citrenes, may be converted into dihydrochlorides, and that too by reactions taking place at ordinary temperatures and involving no violent treatment.*

It is impossible at present to assign a rational formula to the terpenes and citrenes which is consistent with their general behaviour; all those hitherto proposed appear to be insufficient.

The camphenes or solid hydrocarbons of the formula $C^{10}H^{16}$, which also exist in several modifications, differing only in their behaviour in polarised light, are undoubtedly bodies of an altogether different type, as they have only half the combining power of the terpenes and citrenes, and are directly converted into camphor by oxidation. Both dextro- and lævo-rotatory and optically inactive modifications of this last-named body are also known.

Among the haloïd-derivatives of hydrocarbons, no instances of isomerism similar to those just discussed have been met with; a number of haloïd-nitro-derivatives of benzene, however, have been shown to exist in several modifications differing in crystalline form and melting point, but readily convertible into each other. Thus, according to Jungfleisch, *two* dinitrochlorobenzenes may be obtained by nitration of chlorobenzene, one of which is converted into the other by merely bringing the two kinds of crystals into contact, the reverse change being effected by suddenly cooling the fused substance (vii. 145). Two modifications of nitrotetrabromobenzene exhibiting a similar behaviour have been described by v. Richter (viii. 182). Laubenheimer (*Deut. Chem. Ges. Ber.* ix. 766) states that metachloronitrobenzene exists in two forms, differing about 20° in melting point; and that no fewer than three crystalline modifications, and probably a fourth liquid modification of nitrometachloronitrobenzene may be obtained (viii. 183). A number of similar instances have been observed among oxygenated compounds of other classes. Thus Zincke has described two modifications of diphenyl-ketone or benzophenone (vii. 176), two modifications of tolylphenyl-ketone, and also two modifications of the diacetate from isohydrobenzoin; and Tollens has shown that dibromopropionic acid, $CH^2Br.CHBr.CO^2OH$, may be obtained crystallised in two forms of different melting point. It appears probable, as Laubenheimer has suggested (*Ber.* ix. 766), that the existence of these modifications is due to the formation of aggregates of the ultimate molecules of different degrees of complexity, the crystals being regarded as built up of such aggregates; and if it be assumed that the stable modifications consist of aggregates of lesser, and the unstable modifications of aggregates of greater complexity, we have an explanation of the fact that the melting point of the stable modification is always higher than that of the unstable, and that the unstable modification is formed by heating the substance. If such be the nature of these modifications, however, it appears desirable that they should be spoken of as physical *modifications*, and not as physical isomerides.

It is chiefly among the alcohols and acids that we meet with well-marked instances of isomerism which cannot apparently be explained by our present theory. The instances alluded to are, in the case of the alcohols, the diphenylglycols, hydrobenzoin and isohydrobenzoin, and the hexhydric alcohols, mannitol (mannite) and dulcitol (dulcite); the glucoses, which are closely related to the two latter alcohols, afford additional examples.

Hydroben-zoin and isohydrobenzoin are formed simultaneously by reduction of benzaldehyde, and therefore the most probable formula that can be assigned to them is that of a symmetrical diphenylglycol:

This formula is confirmed, and the possibility of isomeric change having taken place in the formation of either is precluded by the fact that both furnish benzaldehyde on oxidation, almost in the proportion required by the equation:

* Quite recently Tilden has shown that the terpenes may be directly converted into dihydrochlorides, by submitting them to the action of hydrochloric acid when dissolved in alcohol, ether, or acetic acid. Except sylvestrene, all the various terpenes and citrenes furnish the same dihydrochloride.

The only other possible formula which could account for this behaviour on oxidation, viz. $C^6H^2C(OH)^2.OH^2.C^6H^2$, cannot be assigned to either of them, on account of their comparative stability, all known compounds in which two hydroxyl groups are associated with the same carbon-atom being highly unstable bodies. Further evidence of the identity of the two alcohols from a chemical point of view is afforded by their behaviour with phosphoric pentachloride and with dilute sulphuric acid; the former reagent converts each into a chloride of the formula $C^{14}H^{12}Cl^2$, but the products from the two sources are identical; when boiled with the latter, both furnish diphenyl-acetaldehyde, $(C^6H^5)^2.HC.CO.H$, and a crystalline non-volatile body of the formula $C^{14}H^{12}O$, the body of this formula obtained from the one being however isomeric with that obtained from the other, and apparently in the same sense that the parent alcohols are isomeric (Forst a. Zincke, *Liebig's Annalen*, clxxxii. 241; Zincke and Breuer, *Deut. Chem. Ges. Ber.* ix. 1769).

The evidence that mannitol and dulcitol must have identical formulæ assigned to them is equally strong. By their conversion into secondary hexylic iodide (Hecht), $CH^3.(CH^2)^3.CH.I.CH^3$, both are proved to be derivatives of normal hexane; and as they are compounds of relatively very considerable stability, each of the hydroxyl groups must be regarded as associated with a distinct carbon-atom, so that their formula must be written

If this be the case, the only possible formula for the glucoses, dextrose, lævulose and galactose—supposing them to be bodies of identical molecular weight—is the following:

since they are penthydroxylated compounds, and are directly convertible into mannitol or dulcitol by the action of nascent hydrogen.

Passing now to the acids, we have to notice the examples afforded by the lactic acids, by malic and tartaric acids, by mucic and saccharic acids, by the hydromellitic acids, by the crotonic acids and a number of their homologues, by maleic and fumaric acids and their homologues, and by the camphoric acids.

The researches of Wislicenus have shown that a modification of ordinary lactic acid exists which differs from the latter only in that it is optically active: in their chemical reactions the two modifications are precisely similar, and both can be represented only by the formula

Several modifications of malic acid exist, apparently corresponding with the several modifications of tartaric acid, viz. a lævorotatory modification, which occurs naturally, a dextrorotatory modification, formed by partial reduction of tartaric acid (Dessaigues, Bræmer), and one at least optically inactive modification (Loyd, *Liebig's Annalen*, cxcii. 80). Theory admits only of the existence of a single acid of the formula

Tartaric acid, it is well known, exists in four distinct modifications. Racemic acid is no doubt a body of different molecular weight from either lævo- or dextro-tartaric acid, and it is not impossible, although improbable, that mesotartaric acid is also; but lævo- and dextrotartaric acid are undoubtedly isomeric. There is, however, only one formula which can be assigned to a body behaving like dextro- and lævo-tartaric acid, viz.

the alternative formulæ,

are entirely out of the question.

The camphoric acids obtained by oxidation of the various modifications of camphor, like the parent substances, appear to differ only in their optical characters.

Saccharic and mucic acids being derived from mannitol and dulcitol respectively, and being directly obtained therefrom by oxidation, must both be represented by the formula

which also is in accord with their general behaviour.

Hydro- and isohydromellitic acids, $C^6H^2(COOH)^4$, afford another instance of two compounds which apparently must be represented by identical formulæ. The former undergoes slow spontaneous conversion into the latter when kept, and the change is easily effected by heating with strong hydrochloric acid solution at 180° . The carboxyl groups in hydromellitic acid must be regarded as each associated with a different carbon-atom, and Baeyer assumes that the conversion into the iso-acid is the

result of the transposition of one of the carboxyl groups. But the fact that the iso-acid is an extremely stable body, and far more stable than mellitic acid, entirely negatives the assumption that more than a single COOH-group is associated with a single carbon-atom.

Crotonic acid being represented by the formula $\text{CH}^3\text{.CH=CH.COOH}$ —on account of its formation from acetaldehyde and of its behaviour on oxidation, and methacrylic acid by the formula $\text{CH}^2=\text{C}(\text{CH}^3)\text{.COOH}$ —because of the production of a mixture of formate and propionate on fusing it with potassium hydroxide, isocrotonic or quart-enylic acid (vii. 397; viii. 586), has been represented by the third of the three formulae possible for an acid of the composition $\text{C}^3\text{H}^5\text{.COOH}$, viz.

Recent investigations, however, throw considerable doubt on the correctness of this conclusion, and render it extremely probable that both crotonic and isocrotonic acids must be represented by the same formula. Thus the formation of acetate alone on fusing it with potassium hydroxide, instead of a mixture of formate and propionate, has been 'explained' by the assumption of a previous isomeric change similar to that which occurs on heating the acid; but, apart from the fact that the conversion of isocrotonic into crotonic acid is not complete even after prolonged heating at 170° – 180° (Alberti), it has been shown that similar products (formic, acetic and oxalic acids) are obtained when the oxidation is effected entirely without the aid of heat by permanganate (Hemilian, *Liebig's Annalen*, clxxiv. 380). It may be argued that the conversion of an acid of the formula $\text{CH}^2=\text{CH.CH}^2\text{.COOH}$ into that of the formula $\text{CH}^3\text{.CH=CH.COOH}$ is not without analogy, and is therefore probable, since allylic alcohol, $\text{CH}^2=\text{CH.CH}^2\text{.OH}$, yields solid crotonic acid, $\text{CH}^3\text{.CH=CH.COOH}$, when the cyanide prepared from allylic iodide by double decomposition with potassic cyanide is digested with alkali, &c.; the oxidation-products of allylic alcohol and iodide, and of the cyanide and crotonic acid which they furnish, are, however, very different, no acetic acid being obtained from either of the former (Kekulé and Rinne, *Deut. Chem. Ges. Ber.* vi. 386), and it appears improbable that an acid having the constitution $\text{CH}^2=\text{CH.CH}^2\text{.COOH}$ would furnish acetic acid on oxidation.

If crotonic and isocrotonic acids have identical formulae, the two chlorcrotonic acids obtained from ethyl acetoacetate must also be represented by identical formulae.

Cinnamic acid, $\text{C}^6\text{H}^5\text{.CH=CH.COOH}$, the analogue of crotonic acid in the aromatic series, affords another instance of isomerism requiring further elucidation. According to Glaser, the dibromide of this acid yields two isomeric (α and β) bromocinnamic acids; that of lower melting point (β) is converted into that of higher melting point by mere distillation or by heating with hydriodic acid, and Barisch has recently shown (*J. pr. Chem.* [2], xx. 173) that the ethyl salt prepared from the β -acid is identical with that obtained from the α -acid. The α -acid being represented by the formula $\text{C}^6\text{H}^5\text{.CBr=CH.COOH}$, the only other possible formula for an acid formed in such a manner, viz., $\text{C}^6\text{H}^5\text{.CH=CBr.COOH}$, is assigned to the β -acid, but it must be admitted that direct evidence of the correctness of this formula is wanting. The formation of cinnamic acid from both α - and β -bromocinnamene by the action of sodium and carbonic anhydride is also remarkable.

The isomerism of angelic and methylcrotonic acids, $\text{C}^4\text{H}^7\text{.COOH}$, is also highly remarkable. The former is converted into the latter by mere distillation. Both furnish the same products on fusion with potassium hydroxide, when combined with hydrobromic acid, or when combined with bromine, but dissimilar iodovaleric acids when united with hydriodic acid (compare Demarçay, *Compt. rend.* lxxx. 1400; lxxxiii. 906; Fittig, Kopp and Pagenstecher, *Liebig's Annalen*, xcxc. 81–128; Schmidt, *Deut. Chem. Ges. Ber.* xii. 252). The dibromide prepared from angelic acid is deprived of its bromine by distillation or by the action of nascent hydrogen: the parent acid is not regenerated, however, but methylcrotonic acid is produced instead. This behaviour can be represented in accordance with our present symbolic system of notation only by assigning the same formula to the two acids.

Lastly, it appears probable that the difference between oleic and elaidic acid is of the same order as that which obtains between the crotonic acids and between angelic and methylcrotonic acid, as they furnish the same products on fusion with potassium hydroxide, and are both converted into stearic acid by the withdrawal of 2 atoms of hydrogen.

Passing to the bibasic acids, fumaric and maleic acid and their homologues, citraconic and mesaconic acids, are apparently also to be included in the category of exceptions. As fumaric and maleic acid do not lose carbon dioxide when heated, and both yield ordinary succinic acid when treated with nascent hydrogen, we must assume that in both the carboxyl groups are associated with different carbon-atoms; but there is only one formula possible satisfying this condition, viz., COOH.CH=CH.COOH .

unless indeed we assume as Kekulé and more recently Fittig have suggested (*Liebig's Annalen*, cxxxviii. 95) that in the so-called unsaturated compounds the affinities of the carbon-atoms which are not engaged with other elements need not necessarily mutually satisfy each other: in this case the following formula is also possible,

Again, there are only two formulæ by which the pyrocitric acids, itaconic, citraconic and mesaconic acid can be represented, since each is converted into methylsuccinic (pyrotartaric) acid when submitted to the action of nascent hydrogen, thus:

Itaconic acid is most probably represented by the first of these formulæ, as it yields allene, $\text{CH}^2 = \text{C} = \text{CH}^2$, on electrolysis; only one formula therefore remains for both citraconic and mesaconic acid, but this accords entirely with their general behaviour and especially with the fact that both furnish methylacetylene (allylene) on electrolysis. If, however, we admit the 'unsatisfied affinity' hypothesis, we may, as Fittig suggests, represent the one acid by the formula

the other by the formula

But although this hypothesis appears to be applicable in the case of these acids, and also in the case of the acids of the acrylic series before alluded to, it does not enable us to explain the isomerism of mannitol and dulcitol, of the two hydrobenzoins, of the hydromellitic acids, or of the two tartaric acids of opposite rotatory power, which are all saturated compounds: this being so, it appears desirable to seek further for an explanation which shall include the whole of the exceptions we have referred to, and not to accept one which is only of very limited application.

Two other remarkable instances of isomerism yet remain to be noticed: that afforded by the methylethylsulphine-compounds, and that afforded by certain hydroxylamine derivatives.

Thus, according to Krüger (*J. pr. Chem.* [2], xiv. 193), the sulphur methiodiethiodide, $\text{CH}^3 \cdot \text{S}(\text{C}^2\text{H}^3)^2\text{I}$, obtained by combining methyl iodide with ethyl sulphide, not identical with the body of the same composition produced by combining ethyl iodide with methyl-ethyl sulphide: the former compound and all the simple salts prepared from it by displacing the iodine by other negative radicles being so extremely soluble and deliquescent as to be uncrystallisable, whereas the latter crystallises readily in long needles, and furnishes a series of double salts which are all deeper in colour, of different crystalline form, and have lower melting points than those of the same composition derived from the body prepared in the manner first described; moreover, the chloride obtained from the former furnishes with mercuric chloride a double chloride of the formula $\text{S}(\text{C}^2\text{H}^3)^2(\text{CH}^3)\text{Cl} \cdot 6\text{HgCl}^2$, while that from the latter yields only a double chloride of the formula $\text{S}(\text{C}^2\text{H}^3)^2(\text{CH}^3)\text{Cl} \cdot 2\text{HgCl}^2$.

If the formula generally assigned to hydroxylamine be correct, viz. $\text{N}'''\text{H}^2 \cdot \text{OH}$, at most two isomeric derivatives should be obtainable from it, and the only alternative formula by which its relation to ammonia can be expressed, N^0OH^3 , does not admit of the existence of any isomerides. Lossen, however, has shown that by varying the order in which benzoyl and anisyl are introduced in place of the three hydrogen-atoms no fewer than *three* isomeric dibenzoylanisyl and *three* isomeric dianisylbenzoyl derivatives may be obtained, all but one of which moreover are dimorphic, one being even trimorphic (comp. pp. 1075-1079).

The formulæ of our present system are all constructed on the hypothesis that the several units of affinity of a polyad atom such as that of carbon, sulphur, or nitrogen, are of the same value and have identical functions. If it be assumed that this is not the case, the anomalies above noticed would appear at once to meet with an explanation. But such an explanation cannot be regarded as satisfactory, or even probable, when it is remembered that none of the simpler derivatives of methane, ammonia, &c., exist in a greater number of modifications than our theory requires, the anomalous bodies being all of comparatively complex composition; and that, according to this view, the number of possible isomerides would be very greatly in excess of that required by the present hypothesis: this latter argument being almost without doubt perfectly valid, as our knowledge of the simpler compounds, though necessarily

far from complete, is sufficiently advanced to warrant the conclusion that if such are really capable of existing, they would long ere this have been discovered. In fact, all things considered, the agreement between theory and practice is wonderfully complete, and this alone suggests that our present system must be a very close approximation to the true system.

Again, if it be assumed that our present formulæ are not merely symbols indicating the chief chemical characteristics of the compounds to which they refer, but that they are really representative of the relative mode of arrangement of the atoms in the compounds, it may be supposed that, even if the hydrogen-atoms in a compound such as methane are of equal value, isomeric derivatives are still possible, since the radicles introduced in place of the hydrogen-atoms may occupy relatively different positions in the molecules; thus two di-derivatives of the form CRRR_1R_1 (figs. 8 and 9), two of the form CRRR_1R_2 (figs. 10 and 11), and no fewer than three of the form $\text{CRR}_1\text{R}_2\text{R}_3$ (figs. 12, 13, and 14) would appear to be possible, R , R_1 , R_2 and R_3 being different monad radicles. Moreover, the group R_a in the formula CRRRR_1 (fig. 15), has obviously on this hypothesis a different value from that of the group R_a , so that in a compound such as chloromethane, CH_3Cl , one of the hydrogen-atoms should have a special value. Conclusions of this kind are so entirely opposed to all experience, that they may be regarded as out of the question.

Van' t Hoff has proposed a system of formulæ based on the arrangement of the symbols in space, instead of in a single plane, which indicates a greater number of isomerides than our present system, and to which the objection above made does not apply (Van' t Hoff, *La Chimie dans l'Espace*, 1875; comp. *Die Lagerung der Atome im Raume*, a German adaptation of Van' t Hoff's pamphlet, by Herrmann, 1877). Similar views have also been advanced by Le Bel (*Bull. Soc. Chim.* xxii. 337, comp. *ibid.* xxiii. 295).

The fundamental hypothesis of the Van' t Hoff system consists in supposing that the carbon-atom occupies the centre of a tetrahedron, and that its four affinities are directed towards the four solid angles. The compounds of the forms CRRRR , CRRRR_1 , and CRRR_1R_2 , cannot exist in isomeric modifications, as in these cases a difference in the relative positions of the various radicles is not conceivable, but when all four radicles associated with the carbon-atom are different, two isomerides are possible, represented by figs. 16 and 17.

An observer lying along the edge R_2 , having his head at R , would in the one case (fig. 16) see R_1 on his right hand, and in the other on his left hand: the two

tetrahedrons bearing to each other precisely the relation of an object to its reflected image, and whatever the position in which they are placed, they cannot be superposed. A carbon-atom in this condition is termed *asymmetric*, and its presence in a formula may be indicated by an italicised *C*.

A combination of two carbon-atoms, associated by a single affinity of each, is represented by two tetrahedrons joined together, as in fig. 18.

FIG. 18.

Supposing the four corners R_1, R_2, R_4, R_6 of this figure to be in the same plane, and folding down the triangles $R_1R_2R_3, R_4R_5R_6$, in this plane, we have in fig. 19 a simpler symbol of such a combination.

FIG. 19.

FIG. 20.

FIG. 21.

FIG. 22.

FIG. 23.

FIG. 24.

FIG. 25.

If we regard the system as rotating round an axis joining the two carbon-atoms, figs. 19 and 20 obviously do not represent isomerides, but merely the same combination at two phases of the rotation; this is not the case, however, with figs. 20 and 21, which differ in that the rotation of the groups $R_1R_2R_3$ is in one (or +) direction in the one case and in an opposite (or -) direction in the other. Denoting the order of rotation $R_1R_2R_3$ by the symbol +A, and rotation in the opposite direction by the symbol -A, and the rotation of the groups $R_4R_5R_6$ in like manner by +B and -B, the following different forms are, in fact, possible:

$$\begin{array}{cc} +A & -A \\ +B & +B \end{array} \quad \begin{array}{cc} +A & -A \\ -B & -B \end{array}$$

These are represented by figs. 20, 21, 22, and 23. If, however, only one of the carbon-atoms be asymmetric, the number of possible isomerides is reduced to two (figs. 24 and 25), since the order of succession of the radicles associated with the one carbon-atom cannot be varied, and therefore $+B = -B$: so that, in short, a compound of whatsoever kind in which the carbon-atoms are united by single affinities may be expected to exist in two isomeric modifications if it contain a single asymmetric atom of carbon; and if it contain two such atoms of carbon, four modifications would appear to be possible. By similar reasoning it may be shown that a compound containing three asymmetric atoms of carbon may exist in eight modifications, viz.:

$$\begin{array}{cccccccc} +A & +A & +A & +A & -A & -A & -A & -A \\ +B & -B & +B & -B & +B & -B & +B & -B \\ +C & +C & -C & -C & +C & +C & -C & -C \end{array}$$

one containing four in sixteen modifications; one containing five in thirty-two; and generally, that a combination containing n asymmetric atoms of carbon may exist in $(2)^n$ modifications, or

$$N_i = 2^n.$$

If the compound be represented by a symmetrical formula, however, the number of possible isomerides is somewhat less. The simplest case of this kind is represented by the formula

Here $A = B$, and the following different groupings at first sight appear possible,

$$\begin{array}{cc} +A & +A \\ +A & -A \end{array} \quad \begin{array}{cc} -A & -A \\ +A & -A \end{array}$$

but it is easy to see, especially if the figs. 26, 27, 28, 29, representing these groupings, are inspected, that

$$\begin{array}{c} +A \\ -A \end{array} = \begin{array}{c} -A \\ +A \end{array}$$

the one being merely the reversal of the other in space, and therefore the number of possible isomerides in such a case is reduced to three.

A less simple case is the following:

If the formula were not symmetrical, a compound such as this should exist in $2^4=16$ isomeric modifications, thus:

+	+	+	+	+	+	+	+	-	-	-	-	-	-	-	-	A
+	+	+	+	-	-	-	-	+	+	+	+	+	+	+	+	B
+	+	-	-	+	+	-	-	+	+	-	-	+	+	-	-	C
+	-	+	-	+	-	+	-	+	-	+	-	+	-	+	-	D
1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	

But since $A=D$ and $B=C$, replacing D by A and C by B , it is evident that the symbols 2, 3, 4, 6, 8, 12, are merely reversals of the symbols 9, 5, 13, 11, 15, 14, so that only the 10 following isomeric modifications appear possible:

+	+	-	-	A	+	+	+	+	+	-	A
+	-	+	-	B	+	+	+	+	-	+	B
+	-	+	-	B	-	+	-	-	-	-	B
+	+	-	-	A	-	+	-	-	-	-	A
1	2	3	4		5	6	7	8	9	10	

The number (N_2) of isomerides possible of a compound represented by a symmetrical formula containing n asymmetric atoms of carbon is therefore:

$$N_2 = (2)^{\frac{n}{2}} + \frac{(2)^n - (2)^{\frac{n}{2}}}{2}$$

or, since there must always be an even number of asymmetric carbon-atoms in a compound of symmetrical formula, we may substitute $2p$ for n ; hence

$$N_2 = (2)^p + \frac{(2)^{2p} - (2)^p}{2} = (2)^{p-1}(1 + 2^p).$$

The hypothesis also indicates a greater number of isomerides than our present theory in the case of compounds in which the carbon-atoms are associated by two affinities of each, represented by the general formula

where R_1, R_2, R_3, R_4 are identical or different monad radicles. Such a combination is represented by two tetrahedrons having one edge in common. If the four radicles

FIG. 30.

FIG. 31.

are identical, only one figure of this kind can be constructed, and this is also the case when only R_1 differs from R_2 , or R_3 from R_4 ; but if R_1 be different from R_2 , or R_3 from R_4 , although R_1 and R_3 and R_2 and R_4 are identical, two such figures may be constructed (30 and 31), in which the radicles R_3, R_4 occupy different positions relatively to the radicles R_1, R_2 . The number of possible combinations of the form in question

which may be produced being represented by the following arrangements of the symbols R_1 , &c.:

only those numbered 4, 6, and 7 may be expected to exist in two isomeric modifications.

The hypothesis does not indicate a greater number of isomerides than our present theory in the case of compounds in which the carbon-atoms are united by three affinities of each, or in the case of the benzene derivatives.

Van'tHoff has pointed out (*op. cit.*) that the isomerism of hydrobenzoin and isdrobenzoin, of the two lactic acids, of the two dibromosuccinic acids, of fumaric and maleic acids, of citraconic and mesaconic acids, of crotonic and isocrotonic acids and the corresponding chlorocrotonic acids, and of oleic and elaidic acids may be explained on the above hypothesis; and the additional instances that have been cited above, including the sulphine compounds, but not the hydroxylamine derivatives, would also appear to meet with an explanation, if such a hypothesis be admitted.*

There is, however, an objection of considerable force to any such hypothesis, that it does not satisfactorily account for the very considerable difference in properties between many of the bodies instanced, such as the hydrobenzoins, mannitol and dulcitol, the glucoses, angelic and methylcrotonic acids, &c. As van'tHoff himself admits, isomerides differing in 'constitution' only in the manner described might be expected to differ in a comparatively slight degree and chiefly in certain physical properties; but there is a most distinct and often very considerable difference in so-called chemical properties between many of the bodies in question, dextrose and lævulose, for example, the latter undergoing fermentation less readily than the former, and yielding when digested with dilute sulphuric acid, acetopropionic acid, which is not produced from dextrose. If, as appears probable, the influence which a given substance exercises on the polarised ray is due to the molecules themselves, and is to a great extent independent of intermolecular action, it is conceivable that between bodies differing only in such a manner in constitution, there should be a difference such as that observed between dextro- and lævo-tartaric acid; but it is almost impossible to admit that there should be so substantial a difference in physical properties, such as melting and boiling point, which are chiefly dependent on intermolecular action, or on so-called chemical properties, as exist between many of the isomerides we have mentioned.†

In fine, whatever the imperfections of the present system of notation, it does not appear that any modification yet suggested is better adapted to the end in view; and it may be doubted, whether a more perfect system can be devised which does not take into account the dynamics of the molecules, and especially the loss or gain of energy involved in the passage of one system into another in similar reactions of isomerides.

H. E. A.

ISONITROBUTANE. See NITROPARAFFINS.

ISO-OXYCUMIC ACID, $C^{10}H^{12}O^3 = C^6H^2(CO^2H.OH.C^4H^7)$ (Jacobsen, *Deut. Chem. Ges. Ber.* xi. 1058). This acid is formed by prolonged fusion of carvacrol with potash; it may be purified by acidifying the crude product and distilling it in a current of steam; and separates out in flat needle-shaped crystals on adding hydrochloric acid to a solution of one of its salts. It melts at 93° , is only slightly soluble in cold water, but dissolves freely in hot water, also in alcohol, ether, and chloroform. The cold aqueous solution gives a deep red-violet colour with ferric chloride. The *barium salt* crystallises in anhydrous rhombic tablets, slightly soluble in water. The *calcium salt*, also anhydrous, crystallises in very soluble silky needles. The *potassium salt* is very soluble in water, but crystallises well; its concentrated solution gives with ferric chloride a dirty violet precipitate which dissolves in a large quantity of water with a fine red-violet colour; no precipitate or coloration with ferrous salts; no precipitate with magnesium salts. With zinc, manganese, cadmium, and silver salts, it forms precipitates which dissolve in boiling water and crystallise out on cooling. The cupric and mercuric salts are likewise soluble in hot water.

* Van'tHoff has pointed out that all compounds capable of rotating the plane of polarisation of a ray of light have one or more asymmetric atoms of carbon in their formulae; the converse does not hold good, however, that all compounds containing asymmetric carbon-atoms are optically active, but he has discussed a possible explanation of this (see art. LIGHT, section Circular Polarisation, *Theory of the Constitution of optically active bodies*).

† It may be questioned whether any two compounds different in physical characters are precisely alike in so-called chemical properties; the two tartaric acids, which probably resemble each other more closely than any other two compounds with which we are acquainted, undergo fermentation, it is said, with different degrees of readiness, the dextro-rotatory acid disappearing first.

Iso-oxyeumic acid heated alone to 235°–238° or with hydrochloric acid to 190°, is for the most part resolved, with ebullition, into carbon dioxide and the corresponding phenol, viz. *metapropylhydroxyl-benzene*, $C^6H^{11}(OH) = C^6H^4(C^2H^7)(OH)$. See PHENOLS and PROPYL-BENZENE.

ISOPENTYLMETHYL KETONE. See KETONES.

ISOPIANIC ACID. See NARCOTINE-DERIVATIVES.

ISOPIC ACID, syn. with *Methylnorhemipinic acid*. See NARCOTINE-DERIVATIVES.

ISOPICRIC ACID. See PICRIC ACID.

ISORCIN. See ORCIN.

ITACONIC ACID. See PYROCITRIC ACID (p. 517).

ITADIEROMOPYROTARTARIC ACID. See PYROTARTARIC ACID.

ITAMALIC ACID and **ITATARTARIC ACID.** See PYROCITRIC ACIDS (p. 518).

IXOLYTE. A fossil resin, occurring in the lignite of Gloggnitz, in the form of fluid drops which darken in colour and harden on exposure to the air. When fused with potash, it yields pyrocatechin (Weidel, *Wien. Akad. Ber.* [2], lxxiv. 387).

J

JABORANDI. This is the native name for several drugs of a sudorific and salivating character, consisting of the leaves and twigs of various species of *Pilocarpus* and other trees growing in Brazil, Paraguay, and Pernambuco. Some varieties are said to be obtained from *P. pinnatifolius* growing in northern Brazil. According to E. M. Holmes (*Pharm. J. Trans.* [3], v. 581, 641) the jaborandi of Pernambuco is most probably obtained from *P. Selloanus*; according to Schelenz (*Arch. Pharm.* [3], vii. 414) and Baillon (*ibid.* 327) the drugs included under the name of Jaborandi are obtained from a whole series of plants belonging to different families.

Byasson (*Pharm. J. Trans.* [3], v. 826) has obtained from Jaborandi leaves an alkaloid which he calls jaborandine, and regards as the active principle of the plant. It is viscid; tastes sharp and bitter; volatilises like nicotine with vapour of water in presence of ammonia; dissolves in chloroform, ether, absolute alcohol, ammoniacal water and dilute acids.

A. W. Gerrard (*ibid.* 865, 965) prepares from jaborandi bark an alkaloid which he calls pilocarpine. The bark is exhausted with alcohol; the soft extract remaining after evaporation of the solvent is washed on a filter with water; the watery filtrate is evaporated at a gentle heat to the consistence of a fluid extract; ammonia is added in slight excess; and the liquid is shaken up with chloroform. The chloroform solution when evaporated yields impure pilocarpine. The hydrochloride, nitrate, and sulphate of this base are crystalline salts which dissolve in water and produce the characteristic physiological effects of jaborandi. Gerrard also found in jaborandi an acrid resin, tannic acid, chlorophyll and a volatile oil.

E. Hardy (*Bull. Soc. Chim.* [2], xxiv. 497) prepares pilocarpine by exhausting jaborandi leaves with water; evaporating the liquid to a syrup; mixing the residue with excess of magnesia and drying it; exhausting the dried residue with chloroform; evaporating the extract, dissolving the residue in water; and evaporating the filtered solution in a vacuum. Pilocarpine thus obtained is a syrupy mass, forming crystalline salts with hydrochloric, nitric and sulphuric acids.

By distilling jaborandi leaves with water, Hardy obtained a volatile oil consisting mainly of a hydrocarbon, $C^{10}H^{16}$, called pilocarpene, having a fragrant odour, a specific gravity of 0.852 at 18°, vapour-density = 4.0, and boiling at 178°.

Kingzett (*Chem. Soc. J.* xxxii. 367) finds that the alkaloid obtained from the stalks and branches of jaborandi is amorphous, and yields an uncrystallisable hydrochloride. The gummy base dried in a vacuum gave by analysis numbers agreeing with the formula $C^{23}H^{35}N^4O^4 \cdot 4H^2O$, and that of the platino-chloride dried at 80° led to the formula $C^{23}H^{35}N^4O^4 \cdot 2HCl, PtCl^4$. This salt crystallises in reddish-yellow octohedrons slightly soluble in cold, easily in hot water.

On the physiological action of jaborandi, see Continho a. Gubler (*N. Rep. Pharm.*

xxiv, 231, 233; Robin, *ibid.* 236; *Jahresb. f. Chem.* 1875, 888; M. Stumpf, *N. Rep. Pharm.* xxv. 703).

JACOBSITE. A mineral from Långban belonging to the spinel group; it is strongly magnetic and has the following composition:

Fe ² O ³	Mn ² O ³	MnO	MgO	CaO	P ² O ⁵	Pb	Insol. residue
58.39	6.96	29.93	1.68	0.40	0.06	1.22	2.17 = 100.81

leading to the formula MnO(Fe²O³, Mn²O³) (A. E. Nordenskiöld, *Jahresb. f. Min.* 1878, 206).

JAMESONITE. *Sulphantimonite of Lead* (iii. 442).—This mineral occurs, together with arsenical pyrites, iron pyrites and copper pyrites, in a vein of crystalline calcite implanted on clay-slate in the Sierra de los Angeles, the northern continuation of the Sierra de Famatina in the Argentine Republic (p. 733). It forms fibrous to cauline aggregates or crude masses; has a specific gravity of 4.25; melts without decrepitation when heated; and gives by analysis the following numbers:

S	Sb	As	Pb	Ag	Cu	Zn	Fe &c
21.75	32.00	0.20	39.05	1.34	3.45	0.62	2.00 = 100.41

(A. Stelzner, *Jahrb. f. Min.* 1874, 537).

JAROSITE. This native potassio-ferrous sulphate originally found in yellowish rhombohedrons at Baranco Jaroso, near the Sierra Amugnera in Spain (iii. 443), occurs also at Beresowsk, in blackish-brown crystals exhibiting the combination R. 0R. Angle R: R = 89.8° (N. v. Kokscharow, *Jahrb. f. Min.* 1875, 872).

JAVANINE. An alkaloïd not yet fully examined, occurring in the bark of *Cinchona Calisaya*, var. *Javanica* (Hesse, *Berl. Ber.* x. 2152).

JEFFERISITE. This name was given by Brush to a chloritic mineral from the serpentine of West Chester, Pennsylvania (vi. 763). The same mineral occurs accompanying corundum in the Culsagee mine near Franklin, Macon County, N. Carolina. *Analysis:* 1. Broadly laminar variety from the Culsagee mine, analysed by König. 2. The same by Chatard. 3. A greenish-brown-yellow microlaminar variety from the same locality analysed by Chatard. 4. Broadly laminar variety from West Chester, by König. 5. The same by Chatard:

	SiO ²	Al ² O ³	Fe ² O ³	FeO	MgO	Loss by ignition
1.	33.93	17.33	5.42	0.50	23.43	10.17 = 99.83
2.	33.77	17.56	5.61	0.50	22.48	20.30 = 100.22
3.	34.00	20.36	4.91	0.42	21.71	18.50 = 99.90
4.	33.35	17.78	7.32	2.11	19.26	19.87 = 99.69
5.	34.40	16.63	8.00	2.11	19.30	19.03 = 99.47

Small quantities of potash and soda were also present but not determined (F. A. Gent, *Contributions from the Laboratory of the University of Pennsylvania*, No. 1. *J. pr. Chem.* [2], ix. 49).

JERVINE. See VERATRUM ALKALOÏDS.

JEYPOORITE. This, according to W. A. Ross (*Proc. Roy. Soc.* xxi. 292), is the correct name of the native cobalt sulphide, hitherto called *Syrcpoorite* (1.1050), occurring in the copper mines of *Khetree* in the principality of Jeypoor in Rajpootana, India. A blow-pipe analysis made with a very small quantity of material gave 82 per cent. cobalt, 7 antimony, 6 arsenic, and at most 5 sulphur, whereas the older analysis by Middleton gave 64.64 Co and 35.36 S, agreeing nearly with the formula CoS. The mineral occurs in very small monometric crystals ∞O∞.O.O.∞O, in an intimate sandy mixture of magnetic pyrites, copper pyrites and quartz.

JOGYNAITE. This name was given by the late N. v. Nordenskiöld to a mineral species (commonly regarded as an earthy scorodite) formed by decomposition of arsenical pyrites in the mountain-range of Adan-Tschilon, in the Government of Nertschinsk (N. v. Kokscharow, *N. Petersb. Acad. Bull.* xix. 564).

JORDANITE. This sulphur-compound, originally found in the Binnenthal (vi. 763), occurs also at Nagjag (Tschermak, *Jahrb. f. Min.* 1874, 188). *Analyses:* (1 and 2). From the Binnenthal (Sipöcz, *Jahrb. f. Min.* 1873, 644). (3). From Nagjag (E. Ludwig, *ibid.* 1874, 188):

	S	As	Sb	Pb
(1).	18.18	12.78	—	68.99 = 99.95
(2).	18.13	12.86	0.11	68.95 = 100.05
(3).	17.06	9.90	1.87	70.80 = 99.63

Sipöcz deduces from his analyses the formula PbAs²S⁷.

JUGLONE. See NUCEN.

JUNIPER. The following analysis of juniper-berries, differing considerably from that by Donath (vii. 710), is given by Ritthausen (*Landw. Versuchs-St.* xx. 409):

Water	10.77 per cent.	Other substances soluble	
Fat, resin and essential oil	12.24 "	in water	11.70 per cent.
Albuminoids	5.41 "	Non-nitrogenous matter	
Woody Fibre	31.60 "	sol. in H ² SO ⁴ , and in	
Grape-sugar	14.36 "	caustic alkalis, but not	
		in water	10.55 "
		Ash	3.37 "

JUTE. The fibre of certain tiliaceous plants cultivated in Bengal, chiefly the annuals, *Corchorus capsularis* and *C. olitorius*. The sowing takes place in March or April, and the crop is reaped in August before the seeds are ripe. The plants, which grow to the height of about 12 feet, are tied up in bundles and retted in water for five or six days, and then swung in the air to separate the long fibres from the brittle woody matter. In this state the jute is imported into Europe. Successful attempts have also been made to cultivate jute in China and in America, where it is used for the packing of cotton.

The crude jute, about 12 feet long, is usually somewhat woody at the lower end. It is nearly colourless at first, but becomes dark-coloured after some time. It is bleached by passing it, first through an alkaline bath and then through a bath of magnesium or sodium hypochlorite.

Jute is easily distinguished by the microscope from flax, cotton and hemp by the very irregular thickness of its cell-walls, so that the central space does not conform to the external outline, whereas flax fibre consists of bundles of cells having thick walls and a circular outline. Jute fibre, like all woody fibres, is coloured yellowish-red by aniline sulphate, and the presence of a considerable amount of woody matter in jute is shown by the great depth of colour which it acquires when thus treated, whereas hemp is scarcely affected by the same reagent, and flax not at all.

Retted jute fibre dried at 100° C. contains 15.540 per cent. water, 83.131 organic matter and 1.329 ash. A more detailed analysis gave the following results.

Wax and fatty matters, soluble in ether	=	0.235
Tannic acid and colouring matters soluble in alcohol	=	1.135
Sugar, Pectin	=	2.427
Soluble Nitrogenised matters	=	0.512
Insoluble Nitrogenised matters	=	2.433
Inorganic matters united with fibre	=	1.010
Cellular fibre	=	92.248
		<hr/> 100.000
Nitrogen in original fibre	=	10.291
Nitrogen in the fibre after treatment with solvents	=	10.210

The fibre in its crude state contains 0.291 per cent. nitrogen, and after exhaustion with the reagents above mentioned, it still retains 0.210 per cent.

The quantity of jute imported through Dundee alone amounts yearly to 100,000 tons, and in addition large quantities are imported by way of London, Liverpool and Glasgow.

Jute is used for the manufacture of all kinds of coarse spun and woven fabrics, such as sacking, mats, stair-carpetts, &c. It also forms an excellent material for the making of false hair, and for the substance of silk hats,

K

KAINITE. H. Schwarz (*Dingl. pol. J.* ccxix. 345) has analysed two samples of crude kainite from Kalusz in Galicia (vii. 710), with the following results:

K ² SO ⁴	MgSO ⁴	NaCl	MgCl ²	Clay	Water and Loss
21.55	18.21	29.02	12.79	2.38	16.05 = 100
22.77	17.20	23.92	14.60	5.65	15.86 = 100

These numbers represent a mixture of about 51 per cent. schönite, (K^2SO_4 , $MgSO_4$, $6H^2O$), 24–29 sodium chloride, 17–19 magnesium chloride (with $2H^2O$), and 2 to 3 clay.

To obtain the potassium sulphate from this salt, Schwarz recommends the use of finely ground gypsum, which separates a double sulphate of potassium and magnesium. This double salt may be decomposed by boiling water, which dissolves out the potassium sulphate; and the residual gypsum, perhaps containing a little potash, may be utilised for the decomposition of fresh quantities of kainite.

Use of Kainite as Manure.—Experiments on the manurial effect of Stassfurt kainite (24·97 K^2SO_4 , 12·01 $MgSO_4$, 14·70 $MgCl^2$, 32·40 $NaCl$, 1·46 $CaSO_4$, 12·00 water, and 1·56 insoluble matter) have been made by P. Wagner (*Landw. Versuchs-St. Darmstadt*, 1874), leading to the following results. The potash introduced into the soil in the form of kainite, distributes itself more uniformly and more widely than pure potassium salts: consequently manuring with kainite is especially beneficial to deep-rooting plants. The chlorine-compounds in the kainite must be washed out of the soil, as they act injuriously on vegetation; and for this reason kainite must be laid upon the land in autumn, winter, or the beginning of spring. There is no fear of washing out the potassium salts at the same time. If an abundant enrichment of the soil with potash is desired, pure potassium salts are preferable to kainite.

KAISER OIL. See PETROLEUM.

KAOLIN. Analyses of several kaolins used in Austria for the manufacture of bricks are given by F. Fischer (*Dingl. pol. J.* cccxvii. 65; *Chem. Soc. J.* xxxiv. 691). The composition and properties of kaolin from the Middle Variegated Sandstone of Thuringia are described by H. Herold (*Jahrb. f. Min.* 1875, 877; *Chem. Soc. J.* xxix. 530) and by E. Schmid (*Jahrb. f. Min.* 1876, 669; *Chem. Soc. J.* xxxii. 119). A silicate having the composition of kaolin, $Si^2Al^2H^4O^9$, but differing from it in specific gravity, and other physical properties, occurs imbedded in the porphyry of Stein in Carniola. Sp. gr. = 2·209. Analysis:

SiO^2	Al^2O^3	CaO	MgO	H^2O
45·97	38·96	1·17	0·12	14·24 = 100·46

(F. Ullik, *Min. Mitth.* 1873, 197).

Kaolin from Göppersdorff, in the circle of Strehlen, Silesia, contains, according to C. Bischof (*Dingl. pol. J.* cccxiii. 60).

SiO^2 (¹)	SiO^2 (²)	Al^2O^3	MgO	CaO	Fe^2O^3	K^2O	Na^2O	Loss by ignition
21·44	49·00	21·35	trace	0·23	0·61	0·84	0·68	7·08 = 100·23.

A kaolin from Langenstriegis near Freiberg contains, according to A. Frenzel (*Jahrb. f. Min.* 1874, 675), 48·82 per cent. SiO^2 , 38·51 Al^2O^3 , and 13·20 H^2O (=100·53). Under the microscope this kaolin appears to consist of crystalline granules.

A plastic material from Collonges, near Fort l'Ecluse in the Department of Ain, differing from kaolin by its smaller amount of silica and larger amount of water, has been analysed by Ador a. Rilliet (*N. Arch. ph. nat.* xlix. 242). By decomposition with sodium carbonate it was found to contain 38·22 per cent. SiO^2 , and 35·40 Al^2O^3 ; with strong hydrochloric acid it yielded 39·60 SiO^2 and 34·01 Al^2O^3 .

On the separation of kaolins by levigation, see Schlesing, p. 552 of this volume; also *Jahresb. f. Chem.* 1874, p. 1261.

KAPOK. The kapok-tree (*Eriodendron anfructuosum*) of Java and the Indian Archipelago, bears a seed resembling, in many respects, that of the cotton-plant. Like cotton-seed, it is covered with a wool, which, though less suited for spinning than cotton, has long been used in India and the Netherlands for filling bolsters, &c.

The following analyses show the composition of a trial-cake made from this seed, as compared with that made from seed of the cotton-plant:—

	Kapok cake	Cotton cake
Water	13·28	12·60
Nitrogenous (albuminous) compounds	26·34	20·62
Fat	5·82	6·36
Non-nitrogenous extractive matter	19·92	35·42
Woody fibre	28·12	20·36
Ash	6·52	5·64

The ash of the seed contains 28·5 per cent phosphoric acid and 24·6 per cent. potash; it would, consequently, have about the same manurial value as linseed (Reinders, *Landw. Versuchs-St.* xix. 161).

KARARFVEITE. A mineral containing fluorine, from Kararfvet, near Fahlun in Sweden, formerly mistaken for gadolinite. It occurs in light yellow to brown imperfect crystals and crystalline masses, sometimes weighing more than a kilogram, and associated with gadolinite and hjelmite. Sp. gr. 4.93. Analyses made with very impure material gave, as a mean result:

Oxides of Ce, La, Di	CaO	MgO	Fe ² O ³	P ² O ⁵	F	H ² O
67.40	1.24	trace	0.32	27.38	4.35	trace = 100.69

(F. Radominski, *Compt. rend.* lxxviii. 764).

KAURI GUM. Syn. with DAMMARA RESIN (p. 625).

KAIVA-ROOT. The root of *Piper methysticum* (iii. 455). E. Nölting a. A. Kopp (*Monit. scient.* [3], iv. 9, 20) have found, in the alcoholic extract of this root, besides kawain—which is not a glucoside—a body, likewise neutral and free from nitrogen, crystallising in prismatic needles, and like kawain yielding benzoic acid by oxidation. Kawain agrees in many of its properties with cubebin, but differs from it in the composition of its nitro-derivatives.

According to Czuzent (*Analyst*, i. 150; *Jahresb. f. Chem.* 1876, 894), kawain, karakin, or methysticin is insoluble in water, and is coloured red by hydrochloric acid, the colour changing to a splendid yellow on exposure to the air. Strong sulphuric acid colours kawain purple-violet, changing to green.

KEATINGIN. A mineral resembling Fowlerite (v. 107), occurring in a mass of yellow garnet at Franklin, New Jersey. The angles of its cleavage-prism measure 64° and 116°. Sp. gr. = 3.33. Composition:

SiO ²	MnO	ZnO	CaO	H ² O
47.8	27.7	5.6	18.0	0.8 = 99.9

(C. U. Shephard, *Sill. Am. J.* [3], xii. 231).

KENNGOTTITE. See MIARGYRITE.

KERAMOHALITE. This hydrated aluminium sulphate, Al²(SO⁴)₃.18H²O, originally found near Königsberg in Hungary (iii. 446), occurs also as a granular, crystalline, ochre-yellow efflorescence, on the clay-substance interposed between the lignite beds of the Bauersberg near Bischoffsheim, Rhön. The mineral from this latter locality gave by analysis 16.7 per cent. Al²O³, 4.2 Fe²O³, 2.9 FeO, 2.3 MgO, 39.3 SO₃, and 33.3 H²O (= 98.7) (A. Hilger, *Jahrb. f. Min.* 1877, 420).

KEROSIN. See PETROLEUM.

KERRITE. A mineral accompanying corundum in the Culsagee Mine, North Carolina. See CORUNDUM (p. 570).

KERSANTITE and **KERSANTON.** These names are applied to certain dioritic rocks occurring in granite and in the oldest sedimentary formations, in the Vosges and in the roadstead of Brest. 1. *Kersantite* from Visembach in the Vosges, where it forms an irregular vein in a gneiss-granite, consists for the most part of 70 per cent. oligoclase and 30 per cent. mica, sometimes together with hornblende, and is almost wholly crystalline. It lost by ignition 1.93 per cent., consisting essentially of water, carbon dioxide, and organic matter. 2. *Kersantite* from Sainte-Marie aux Mines, forming a vein in a syenite-granite, differs from the preceding by its less decided crystalline structure. Loss by ignition 1.70 per cent. 3. *Kersantite* (also called *Kersanton*) from Brest, is very much like the two preceding. It often has a granitic structure, and contains triclinic felspar exhibiting the usual twin-striation; mica of a pinchbeck-brown, brown-black or black colour, and a magnesium-iron mica; dark-green iron-spar, somewhat resembling hornblende; white or red calcite, filling up the interstices between the felspar, and occurring also in veins. Kersanton includes in its mass iron pyrites and a large quantity of magnetic pyrites, microscopic grains of magnetic iron oxide, very rarely quartz, sometimes epidote in thin irregular veins. A green hydrated silicate of iron and magnesium (*Chlorite ferrugineux*) is likewise found, especially in the cavities. The loss by ignition (chiefly CO²) was found in three specimens to be 4.49, 6.75, and 7.41 per cent. The analysis of a Kersanton from Daoulas, commonly used for building in Brest, and effervescing strongly with acids, gave:

SiO ²	Al ² O ³ , FeO, MgO, K ² O, Na ² O	Cr ² O ³	CaO	CO ² , H ² O
52.80	35.05	traces	5.40	6.75 = 100

(Delesse, *Bull. Géol.* [2], vii. 704; *Jahresb. f. Chem.* 1850, 802).

4. *Kersantite* from Langenschwalbach, Nassau, has been analysed by E. Zicken-drath (*Jahrb. f. Min.* 1875, 753). Like the rocks above described, it is a mixture of

oligoclase and mica in varying proportions. Where the mica predominates, the rock appears compact, with the dark brownish-black colour of tridinic felspar; the mass is coarse-grained and lighter in colour. The oligoclase has a reddish-white to pure white colour, and with a lens the twin-striation is perfectly distinct. The mica crystallises in the rhombic system, and has a brownish-black colour, which, however, appears brownish-yellow in thin laminae. Augite occurs nearly always in this rock, but generally partially decomposed, with the original form still recognisable. Magnetite occurs in grains, apatite in colourless needles. Iron-pyrites is distributed in small crystals throughout the whole mass, which is also strongly impregnated with carbonates. Quartz is also observed, but is difficult to recognise. Oligoclase, quartz, iron-pyrites, and carbonates occur, sometimes in isolated crystals; also a green mineral resembling melanolite.

Analyses.—1. Compact from Adolfseck, specific gravity = 2.75. 2. Coarse-grained from Heimbach, specific gravity = 2.86. 3. Oligoclase from the Heimbach rock, specific gravity = 2.66. 4. Mica from the Adolfseck rock, specific gravity = 2.92.

	SiO ²	Al ² O ³	Fe ² O ³	FeO	MnO	MgO	CaO	K ² O	Na ² O	H ² O	F	CO ²	P ² O ⁵
1.	54.94	7.69	9.58	4.37	1.53	3.03	5.11	4.03	2.47	1.49	0.22	4.32	0.91 = 99.79
2.	53.16	7.96	9.24	4.77	1.23	3.05	6.64	3.06	2.37	1.77	0.04	4.08	1.20 = 99.17
3.	63.40	20.87	trace	—	—	trace	2.87	3.48	7.55	0.85	—	—	— = 99.02
4.	40.80	11.89	18.97	—	—	11.94	3.68	10.63	—	0.55	1.05	—	— = 99.51

From these data Zickendrath calculates the mineral constitution of the rock as follows:

	Adolfseck	Heimbach
Oligoclase	32.17	37.61
Mica	27.10	15.88
Iron-pyrites	0.167	0.32
Augitic pseudomorphs	10.09	14.19
Apatite	1.98	2.62
Magnetite	2.74	4.5
Carbonates	9.82	9.52
Quartz	18.74	14.67
	<hr/> 102.807	<hr/> 99.31

KETONES. 1. FATTY KETONES. *Bye-products formed in the Preparation.*—In the preparation of ketones by the action of acid chlorides on organo-zinc compounds according to the general equation, $2(R.CO.Cl) + ZnR^2 = ZnCl^2 + 2(R.CO.R)$, condensation-products are also formed by the further action of the organo-zinc compounds on the ketones. Thus, for instance, mesityl oxide, $C^6H^{10}O = 2C^3H^5O - H^2O$, is formed by the action of zinc-methyl on acetone:

In like manner propionyl chloride and zinc-methyl yield, besides methyl-ethyl ketone, C^4H^8O , a body having the composition $C^6H^{10}O = 2C^3H^5O - H^2O$. This compound is a colourless liquid, insoluble in water, having a density of 0.877 at 0°, 0.862 at 18°, and boiling at 167°–168°. Similarly the compound, $C^{10}H^{18}O = 2C^5H^{10}O - H^2O$, is formed by the action of zinc-methyl on isobutyryl chloride. It is a colourless liquid of peculiar odour, insoluble in water, boiling at 189°–191°. Sp. gr. 0.87 at 0°; 0.855 at 20°. It combines with hydrogen chloride to form a yellowish oily body ($C^{10}H^{18}ClO$) having the odour of turpentine; and with hydrogen iodide to form a dark coloured crystalline body. Lastly, a bye-product having the formula $C^{12}H^{22}O$ is formed in the preparation of dimethyl-isobutyl carbinol by the action of zinc methyl on valeryl chloride. It is a colourless liquid, insoluble in water, boiling at 217°–219°. Sp. gr. 0.864 at 0°; 0.849 at 20°. Like the two preceding bodies, it combines with hydrogen chloride and iodide.

All these compounds combine with bromine, and may, therefore, be regarded as non-saturated ketones. Their chemical structure has not yet been made out (Pawloff, *Liebig's Annalen*, clxxxvii. 104).

Oxidation.—An investigation by M. Herz (*Liebig's Annalen*, clxxxvi. 257) of the action of various oxidising agents (potassium dichromate and sulphuric acid, chromic acid, potassium permanganate in neutral, acid, and alkaline solution, silver oxide and bromine, lead dioxide and nitric acid), on certain ketones of the fatty group (dimethyl-ketone, methyl-propyl-ketone, butyrene, caprone, and palmitone) has led to the following conclusions:

(1). Popoff's law (vi. 765; vii. 711), according to which the lower of the two alcohol-radicles in the ketone remains united with the carbonyl, and by taking up

an OH-group, is converted into a fatty acid, while the higher radicle is oxidised and forms a second fatty acid,—holds good for the ketones of normal fatty acids. (2). Whatever may be the oxidising agent used, and in whatever proportion to the ketone, a further oxidation of the primary products invariably takes place, resulting in the formation of less highly carbonised fatty acids, and ultimately of carbonic acid. (3). The oxidation is more difficult and less complete in proportion as the ketone is more highly carbonised. Palmitone, for example, is very difficult to oxidise, and yields but a small amount of normal products.

Dimethyl Ketone, Acetone, $\text{CO}(\text{CH}_3)_2$. *Action of Potash* (Heintz, *Liebig's Annalen*, clxix. 114).—When pure acetone is treated with potash-ley of sp. gr. 1.25–1.30, and then freed from the adhering alkaline liquid by a few drops of sulphuric acid, it is found to be altered in such a manner that it no longer distills completely at the heat of the water-bath, but leaves a considerable residue, which partly passes over at about 130° , as a very mobile liquid insoluble in water, partly at a temperature above 200° . The latter and thicker portion is probably phorone; the former, which after repeated fractionation boils between 130° and 132° , is probably a mixture of mesityl oxide with a more highly oxygenised body of similar boiling point. An impure commercial acetone, after treatment with potash as above, yielded, at about 170° , a distillate which after purification boiled at 166° – 168° , and had the percentage composition of acetone. This substance, which may be called *Polyacetone*, is probably analogous in constitution to the 'duplosulphacetone' described by Wislicenus (vii. 12). It is a colourless thin syrup, wholly soluble in water. Heintz supposes that it did not exist ready formed in the commercial acetone, but was formed by the action of the potash on some impurity contained therein.

Bromacetones.—On Monobromacetone, see p. 22 of this volume. On Pentabromacetone, the so-called Bromoxaform, see p. 351.

Chloracetones.—According to Theegarten (*Berl. Ber.* vi. 897) unsymmetrical dichloracetone, $\text{CH}_3\text{CO}.\text{CHCl}_2$, prepared according to Mulder's directions (vii. 14), has a density of 1.326 at 0° , and forms crystalline compounds, with acid sulphites of alkali-metal.

On the Polymerides of Dichloracetone, see p. 24.

Chlorobromacetone, $\text{C}^6\text{H}^4\text{ClBrO}$ (probably $\text{CH}_2\text{Cl}.\text{CO}.\text{CH}_2\text{Br}$), is obtained by the action of hydrobromic acid on epichlorhydrin, and oxidation of the resulting chlorobromhydrin. On cooling the portion of the product which boils between 176° and 188° with ice, the chlorobromacetone separates in crystals which may be purified by recrystallisation from ether. Chlorobromacetone forms well-defined crystals melting at 34° – 35.5° , boiling at 177° – 180° , sparingly soluble in water, easily in alcohol and in ether. It has an extremely pungent odour. With sodium-hydrogen sulphite it forms a compound which resembles the corresponding compound of symmetrical dichloracetone in all respects except its crystalline form (Theegarten, *Deut. Chem. Ges. Ber.* vi. 1276).

Allyl-acetone or Methyl-crotonyl Ketone, $\text{C}^6\text{H}^{10}\text{O} = \text{CH}^3.\text{CO}.\text{C}^4\text{H}^7$ (p. 14), treated with sodium in an ethereal solution floating on water, is converted into the alcohol $\text{C}^6\text{H}^{12}\text{O}$, which has a density of 1.842 at 16.2° , boils at 138° – 139° , and yields with bromine an uncrystallisable mass having the composition $\text{C}^6\text{H}^{12}\text{Br}^2\text{O}$. The *acetic ether* boils at 143° – 149° (J. K. Crow, *Chem. News*, xxxvi. 264).

Methyl-ethyl Ketone, $\text{C}^4\text{H}^8\text{O} = \text{CH}^3.\text{CO}.\text{C}^2\text{H}^5$, formed by the action of zinc-ethyl on acetyl chloride, is converted by the action of sodium in presence of strong potash-ley, into the 8-carbon pinacone or octylene glycol, $\text{C}^8\text{H}^{18}\text{O}^2$.

(Lawrenowitsch, *Ber.* vii. 767).

Methyl-propyl Ketone, $\text{C}^5\text{H}^{10}\text{O} = \text{CH}^3.\text{CO}.\text{CH}^2\text{CH}^2\text{CH}^3$ (b. p. 99° – 105°), is converted by sodium-amalgam and water into methyl-propyl-carbinol, $\text{C}^5\text{H}^{12}\text{O} = \text{CH}^3.\text{CHOH}.\text{CH}^2\text{CH}^2\text{CH}^3$, boiling at 118.5° – 119.5° (corr.) (Belohoubek, *Wien. Akad. Ber.* [2 Abth.], lxxiv. 80).

Methyl-isopropyl Ketone, $\text{CH}^3.\text{CO}.\text{CH}(\text{CH}^3)_2$, (b. p. 93.5°), obtained by dry distillation of a mixture of equivalent quantities of isobutyrate and acetate of calcium, is a colourless liquid, of not unpleasant odour. Sp. gr. 0.811 at 15° . It forms a crystalline compound with sodium-hydrogen sulphite, but does not reduce an ammoniacal silver solution. By oxidising agents it is converted into acetic and carbonic acids; by nascent hydrogen into a secondary pentyl alcohol (R. Münch, *Ber.* vii. 1370). Frankland and Duppa obtained the same ketone by the action of boiling

potash-ley on ethylic acetodimethylacetate (Wanklyn's isobutyrate of acetylated ethyl, vi. 768).

Chlormethyl-isopropyl Ketone, $C^3H^3ClO = CH^2Cl.CO.CH(CH^3)^2$, (inappropriately called *Chlorinated Methylisobutyl Ketone*).—This compound, formed by the action of chromyl chloride, CrO^2Cl^2 , on petroleum pentane and on inactive amyl chloride, is a colourless liquid having a pungent aromatic odour and boiling without decomposition at about 120° . It is insoluble in water and in aqueous potash; reduces ammoniacal silver solution; does not unite with bisulphites (Etard, *Compt. rend.* lxxxiv. 127).

A compound, $C^6H^{11}ClO$, probably homologous with the preceding, is formed in like manner from hexane. It easily reduces an ammoniacal silver solution, does not unite with $NaHSO^3$, and is not attacked by potash. A similar body is also formed from heptane (Etard).

Methyl-butyl Ketone, $C^6H^{12}O = CH^3.CO.(CH^2)^3CH^3$, is formed by oxidation of the secondary hexyl alcohol, $(CH^3.CHOH.C^4H^9)$, obtained from petroleum hexane (p. 1030). It has a specific gravity of 0.829 at 0° , boils at 127° , and is converted by oxidation into acetic and normal butyric acids (Schorlemmer, *Liebigs Annalen*, clxi. 263).

Methyl-isobutyl Ketone, $CH^3.CO.CH^2CH(CH^3)^2$, formed by the action of zinc-methyl on valeryl chloride, has a sp. gr. of 0.819 at 0° , boils at 114° , and is converted by oxidation into acetic and isobutyric acids.

Methyl-katabutyl Ketone or Pinacolin, $CH^3.CO.C(CH^3)^3$, is formed by the action of zinc-methyl on trimethyl-acetyl chloride. As thus prepared it has the same peppermint odour as pinacolin prepared by dehydration of acetone (iv. 617) and agrees very closely with the latter in boiling point and density, as shown by the following numbers.

	Synthetical Pinacolin	Pinacolin from Acetone
Boiling point	$105.5-106.5^\circ$	105°
Sp. gr. at 0°	0.830	0.823
" " 50°	0.791	0.787
Expansion for 1° between 0° and 50°	0.00122	0.00117

Both unite with sodium-hydrogen sulphite, and are converted by oxidation into trimethylacetic acid (Butlerow, *Liebigs Annalen*, clxxiv. 125).

Homologues of Pinacolin.—Three of these bodies have been prepared synthetically by Wischnegradsky (*Liebigs Annalen*, clxxviii. 103) by processes similar to that just mentioned for the preparation of pinacolin itself, viz. by the action of trimethyl-acetyl chloride on zinc-ethyl, and of ethyl-dimethyl-acetyl chloride, $C(CH^3)^2(C^2H^5).CO.Cl$, on zinc-methyl and zinc-ethyl respectively. The composition and principal properties of the three products are given in the following table:

	Ethyl-butyl Pinacolin $(CH^3)^3C.CO.C^2H^5$	Methyl-amyl Pinacolin $(CH^3)^2(C^2H^5).C.CO.CH^3$	Ethyl-amyl Pinacolin $(C^2H^5)^2(C^2H^5).C.CO.C^2H^5$
Boiling point	125.5° to 126°	131.5° to 132.5°	150.5° to 151.5°
Sp. gr. at 0°	0.831	0.842	0.845
" " 21°	0.810	0.825	0.829
Expansion coefficient from 0° to 21°	0.00109	0.00102	0.00098
Product of Oxidation	Trimethyl- acetic acid.	Ethyl-dimethyl-acetic acid.	

Hence it appears that in the oxidation of these bodies the carbonyl remains attached to the tertiary radicle, which therefore behaves in these reactions like a radicle of the aromatic group.

Dipropyl Ketone or Butyrone, $C^7H^{14}O = C^3H^7.CO.C^3H^7$, is almost the sole product of the dry distillation of normal calcium butyrate. It boils at $143^\circ-145^\circ$, yields with phosphorus pentachloride the bodies $C^7H^{14}Cl^2$ (b. p. 181°) and $C^7H^{13}Cl$ (b. p. 141°), and is converted by phosphoric anhydride into a liquid of variable boiling point. The portion which distils between 200° and 250° has the composition C^7H^{12} , and probably consists of polymerides (Tawildarow, *Deut. Chem. Ges. Ber.* ix. 1442).

Di-isopropyl Ketone, $CH(CH^3)^2.CO.CH(CH^3)^2$, prepared by dry distillation of calcium isobutyrate, and purified by repeated fractional distillation, is a colourless mobile liquid, having a strong ethereal camphorous odour, nearly insoluble in water, but dissolving in all proportions in alcohol and ether. Sp. gr. = 0.8254 at 17° . Boiling point $124^\circ-125^\circ$. It does not unite with acid sulphites of alkali-metal, but reduces an ammoniacal silver solution. By oxidation it yields isobutyric, acetic and carbonic acids, and by reduction (with sodium in a benzene solution of the ketone

floating on water), a secondary heptyl alcohol, together with oily products of high boiling point (Popoff, *Deut. Chem. Ges. Ber.* vi. 1255; R. Münch, *ibid.* vii. 1370).

Palmitone or **Dipentadecyl Ketone**, $C^{31}H^{62}O = C^{15}H^{31}.CO.C^{15}H^{31}$. This ketone, subjected in the fused state to the action of bromine, is converted into a yellowish oil, which after purification solidifies in a freezing mixture and melts at 5.5° . Its analysis gave results which might be represented either by the formula $C^{31}H^{60}Br^2O$ (tribromopalmitone hydrobromide), or by $C^{31}H^{61}Br^2O$ (dibromopalmitone hydrobromide). The latter is perhaps the more probable, as, under similar conditions, a body was once obtained which crystallised from ether in white laminae containing an amount of bromine which agreed with the formula of dibromopalmitone (Hercz, *Liebig's Annalen*, clxxxvi. 257).

On the Oxidation of Palmitone, see p. 1147.

Suberone, $C^7H^{14}O$. The constitution of this body, hitherto somewhat doubtful (v. 450), has been determined by Schorlemmer and R. S. Dale (*Chem. Soc. J.* xxvii. 985). The crude product of the distillation of suberic acid with lime yields on fractionation, first a small quantity of hexane, and then a distillate from which pure suberone is easily separated by fractional distillation, a tarry mass remaining behind.

Suberone is a colourless liquid having a pungent odour, like that of peppermint, and boiling at 179° – 181° (mercury-column wholly in the vapour). By strong nitric acid it is oxidised to α -pinelic acid (*q. v.*) Regarding suberic acid as a normal compound, *i.e.* as having all its carbon-atoms in a single chain, the formation and constitution of suberone and α -pinelic acid may be represented by the following equations:

II. AROMATIC KETONES. *Formation*.—1. By heating aromatic hydrocarbons with mixtures of benzoic acid and its homologues, or the corresponding anhydrides, and phosphoric anhydride, *e.g.*

(Kollarits a. Merz, *Deut. Chem. Ges. Ber.* vi. 446, 536).

2. By heating aromatic hydrocarbons with acid chlorides, in presence of finely divided zinc (Grucaevic a. Merz, *ibid.* 60, 966, 1238), *e.g.*

3. By the action of aluminium chloride on a mixture of an acid chloride and a hydrocarbon (Friedel, Crafts a. Ador, *Compt. rend.* lxxxv. 672), *e.g.*

also by the action of carbonyl chloride on a hydrocarbon in presence of aluminium chloride, an acid chloride being first formed (*e.g.* $C^6H^6 + COCl^2 = HCl + C^6H^5.CO.Cl$), which then reacts with the hydrocarbon and the aluminium chloride as above.

Phenyl-methyl Ketone or **Acetophenone**, $C^8H^8O = C^6H^5.CO.CH^3$. This compound, treated with sodium-amalgam, yields: (1). The pinacone of acetophenone, $C^6H^5.C(OH).CH^3$, or phenyl-methyl glycol, $C^6H^5.C(OH).CH^3$, which separates from dilute ethyl alcohol

in spicular crystals, and from the secondary alcohol formed at the same time, in crystals belonging to the quadratic system. (2). Phenyl-methyl Carbinol, Secondary Ethyl-benzene Alcohol, or Secondary Acetophenonic Alcohol, $C^6H^5.CHOH.CH^3$, contained in the portion of the crude product which passes over between 190° and 210° . This last compound is a colourless, strongly refracting, fetid liquid, having a density of 1.013, and boiling at 202° – 203° (Emmerling and Engler, *Ber.* vi. 1005). See PHENYL ALCOHOLS.

On the action of dry ammonia and phosphoric anhydride on acetophenone, whereby triphenyl-benzene, $C^6H^3(C^6H^5)^3$, and the so-called acetophenonine, $C^{24}H^{18}N$ or $C^{16}H^{10}N^2$, are produced, see vii. 940.

When acetophenone (20 grams) is heated to 130° – 150° with hydriodic acid

(10–15 grams) and phosphorus (1.8 grams), for eight to ten hours, part of the phosphorus remains unattacked, and the chief product of the reaction is an oxygenised body, $C^6H^{16}O$, which may be obtained pure by recrystallising the portion of the product which distils over at 300° – 340° , after freeing it from iodine and phosphorus. This compound crystallises in white laminae or transparent colourless plates, melts at 70° , and boils at 340° – 345° (mercury column wholly in the vapour); it is insoluble in water, but dissolves very easily in ether, carbon sulphide, benzene, and hot alcohol, less easily in cold alcohol. Its formation is represented by the equation:

It is related to acetophenone in the same manner as pinacolin to acetone, but its constitution is probably not analogous to that of pinacolin, but rather that which is represented by the formula $C^6H^5.CO.CH^2.CH \begin{smallmatrix} C^6H^5 \\ \diagup \\ CH^3 \end{smallmatrix}$, according to which it may be supposed to be produced by hydrogenation of a previously formed condensation product, $C^6H^5.CO.CH=C \begin{smallmatrix} C^6H^5 \\ \diagup \\ CH^3 \end{smallmatrix}$. By further hydrogenation it is converted into

diphenyl-dimethylethane, $C^6H^5.CH.CH^3$, which is also produced directly by heating acetophenone with hydriodic acid and phosphorus; and by the action of sodium on phenylmethyl-carbinyl bromide, $C^6H^5.CHBr.CH^3$, or the corresponding chloride (Graebe, *Deut. Chem. Ges. Ber.* vii. 1623).

Substitution-derivatives of Acetophenone.

Acetophenone can yield two series of substitution-derivatives, according as the substituted radicle enters into the phenyl or the methyl group. There is great confusion in the nomenclature of these derivatives, but they are best designated by names which indicate directly the positions of the substituted radicles, *e.g.*

Brominated Acetophenones (Emmerling a. Engler, *Ber.* iv. 148; Hunnius, *ibid.* x. 2006).—According to Emmerling a. Engler, two modifications of this compound are formed simultaneously by the action of 2 atoms of bromine on 1 mol. acetophenone at ordinary temperatures; and, on treating the product with dilute alcohol, acetobromophenone, $C^6H^4Br.CO.CH^3$, is dissolved, while bromacetophenone, $C^6H^5.CO.CH^2Br$, remains in the form of a syrupy mass, which solidifies only after a considerable time. Acetobromophenone separates from solution in dilute alcohol by slow evaporation in colourless laminar crystals melting at 50° . It has a pungent odour, and exerts a violent irritating action on the eyes. It dissolves easily in alcohol and ether, but is insoluble in water, which moreover does not attack it sensibly even at the boiling heat. By oxidation with chromic acid mixture it is converted into bromobenzoic acid, whereas bromacetophenone, $C^6H^5.CO.CH^2Br$, yields, by oxidation with the same reagent, bromine and benzoic acid.

Hunnius, on the other hand, by dropping 1 mol. bromine into a solution of 1 mol. acetophenone in carbon sulphide, obtained nothing but bromacetophenone (which he designates as *acetophenone bromide*), exhibiting the crystalline form, melting point, and solubility ascribed by Emmerling and Engler to acetobromophenone, but converted by oxidation with permanganate into benzoic acid.

Bromacetanitrophenone or *Nitrophenyl-bromomethyl Ketone*, $C^6H^4NO^2.CO.CH^2Br$, is obtained by slowly adding bromacetophenone to fuming nitric acid in a cooled vessel; when separated by water, washed with sodium carbonate, and crystallised from dilute alcohol, it forms small needles melting at 96° , soluble in alcohol, chloroform, and carbon sulphide, very slightly soluble in ether, insoluble in water. By oxidation it yields metanitrobenzoic acid; by reduction with tin and hydrochloric acid it is converted into acetamidophenone or amidophenyl-methyl ketone, the hydrochloride of which, $C^6H^4NH^2.CO.CH^2.HCl$, forms easily soluble colourless needles, turning brown on exposure to air and light.

Bromacetophenone treated with potassium acetate and ethyl alcohol, or with silver benzoate and toluene, yields the compounds $C^6H^5.CO.CH^2(OC^2H^5O)$ and $C^6H^5.CO.CH^2(OC^7H^5O)$, which are respectively the acetic and benzoic ethers of benzoyl carbinol, or primary acetophenonic alcohol, $C^6H^5.CO.CH^2OH$ (Hunnius). See PHENYL ALCOHOLS.

Dibromacetophenone or *Phenyl-dibromomethyl Ketone*, $\text{C}^6\text{H}^5\cdot\text{CO}\cdot\text{CHBr}_2$, obtained similarly to the monobrominated compound, with 2 mols. bromine to 1 mol. acetophenone, melts at 36° , is insoluble in water, but dissolves in almost all other solvents, and crystallises with great facility. By potassium permanganate it is converted into benzoic acid; by solution of sodium carbonate, apparently into benzoyl-formic acid, $\text{C}^6\text{H}^5\cdot\text{CO}\cdot\text{COOH}$. With alcohol and potassium acetate it yields an oil which solidifies in a vacuum, and probably consists of the ether, $\text{C}^6\text{H}^5\cdot\text{CO}\cdot\text{CH}(\text{C}^2\text{H}_5\text{O})_2$.

Phenyl-chloroacetyl Ketone, *Chloracetophenone*, or *Chloroacetylbenzene*, $\text{C}^6\text{H}^5\cdot\text{CO}\cdot\text{CH}_2\text{Cl}$.—To prepare this compound, chlorine is passed into the vapour of boiling acetophenone in quantity equal to that which can be evolved by the use of a quantity of manganese dioxide equal in weight to the acetophenone; the product is then distilled, and the liquid which passes over below 200° is again subjected to the same treatment. The crude product is best purified by crystallising it in a freezing mixture and drawing away the portion which liquefies at ordinary temperatures.

Pure chloracetophenone is colourless, permanent in the air, very soluble in alcohol, ether, and benzene, insoluble in water. It melts at 58° – 59° , and boils without decomposition at 244° – 245° (uncorr.) It has a pleasant aromatic taste, but its vapour excites a flow of tears. From the fused state as well as from its alcoholic solution, it separates in large well-defined crystals. The crystals separated from alcoholic solution were found by Friedlander to belong to the orthorhombic system. Axes $a : b : c = 0.9957 : 1 : 0.2135$. Observed forms $\infty\text{P}\infty$, ∞P , $\text{P}\infty$, $2\text{P}\infty$. Tabular development parallel to a . Angle $\infty\text{P} : \infty\text{P} = 89^\circ 46'$; $\text{P}\infty : \text{P}\infty = 24^\circ 12'$. Plane of optic axes the brachypinacoid $\infty\text{P}\infty$. Axis a the first median line. Angle of optic axes in oil about 74° (Staedel).

Action of Ammonia.—When chloracetophenone is boiled with aqueous ammonia for about an hour, or heated with it in a sealed tube to 140° – 150° , it is converted into a deep-red liquid which solidifies on cooling, while the whole of the chlorine remains as sal-ammoniac in the aqueous solution. From this red product two compounds may be isolated by means of ether, one remaining undissolved when the crude product is heated with ether for a short time, the other separating slowly from the red ethereal solution. The former, which is produced in small quantity only, is an isomeride of indole, $\text{C}^8\text{H}^7\text{N}$ (Staedel a. Rugheimer, *Ber.* ix. 563, 798, 1758). For the properties of this iso-indole, see p. 1089. Staedel (*ibid.* x. 1830) points out that of the three following formulæ by which it might be represented, supposing its molecular weight to be the same as that of indole, viz.

the last seems to be the most probable, on account of the stability of iso-indole towards acetic acid at 150° , acetic anhydride at 130° – 140° , acetyl chloride at 120° , and ethyl iodide at 100° , also (which affords an argument against the double carbon-linking) towards fuming hydrobromic acid at 130° – 140° , fused potash, and faintly-glowing quicklime.

The second product of the action of ammonia on chloroacetylbenzene is formed most abundantly when alcoholic ammonia is used. It is free from nitrogen; crystallises in long prisms or needles; is insoluble in water, alcohol, ether, benzene, carbon sulphide and acetone; and melts at 89° . It dissolves in strong hydrochloric acid, and is reprecipitated by water.

When dry ammonia gas is passed at intervals of ten to twelve hours through a cooled ethereal solution of chloracetophenone till the liquid is saturated, crystals of sal-ammoniac separate abundantly after five or six days, and the product contains, besides these and a trace of red resinous substance, two isomeric bodies having the formula $\text{C}^{10}\text{H}^{10}\text{O}\cdot\text{Cl}$. One of those bodies is moderately soluble in alcohol and ether, and crystallises therefrom in stellate or moss-like groups of needles; it melts at 117° , sublimes undecomposed and is easily oxidised to benzoic acid. The other isomeride is less soluble in alcohol and ether, crystallises in isolated prisms, melts at 155° , sublimes undecomposed, and is less easily oxidised than the preceding. The formation of the two bodies is represented by the equation:

(Staedel a. Rugheimer).

Phenethenyl-methyl Ketone or **Acetocinnamone**, $\text{C}^{10}\text{H}^{10}\text{O} = \text{C}^6\text{H}^5\cdot\text{CH}=\text{CH}\cdot\text{CO}\cdot\text{CH}_3$ (Engler a. Leist, *Berl. Ber.* vi. 254). This ketone is prepared by the dry distillation of a mixture of the calcium cinnamate and acetate. On fractionating the first portions of the oily distillate (35 per cent. of the calcium cinnamate) the acetocinnamone passes over between 220° and 270° . It is a fragrant

liquid having a density of 1.008 and boiling at 240° – 241° ; unites with bisulphites, forming crystalline compounds, from which it is separated in the pure state by sulphuric acid; gives by nitration and subsequent oxidation, para- and meta-nitrobenzoic acids, and is converted by nascent hydrogen into phenethyl-methyl carbinol, $C^{10}H^{14}O = C^6H^5.CH^2.CH^2.CH(OH).CH^3$ (also called *pseudobutyl-benzene alcohol*), which melts at 68° , and is metameric with thymol, cymphenol and cymyl alcohol.

The portions of the distillate obtained by heating the mixture of calcium acetate and cinnamate, which boil below 220° , contain benzene, toluene, a hydrocarbon having the composition C^8H^8 or $C^{10}H^{12}$, and cinnamene; the portions collected between 290° and 330° contain a hydrocarbon C^8H^8 melting at 117° (probably a polycinnamene) which gradually separates from the distillate in plates. The portion which goes over above 330° contains a body, $C^{20}H^{18}O$ (perhaps the acetocinnamic analogue of mesityl oxide). The true ketone of cinnamic acid was not found in either of these distillates; neither was it obtained by distilling calcium cinnamate alone—a process which yields a large quantity of a compound apparently consisting of a polycinnamene.

The following methods of preparing acetocinnamone were also tested by Engler a. Leist (*Deut. Chem. Ges. Ber.* vi. 257). The sodium-derivative of cinnamic aldehyde was heated with methyl iodide to 120° – 130° for twenty-four hours and then distilled. The portion which passed over between 240° and 245° contained acetocinnamone, but only to the amount of 5 per cent. of the cinnamic aldehyde. Cinnamic aldehyde and methyl alcohol in equal numbers of molecules, boiled for a day with excess of zinc chloride, yielded a product containing acetocinnamone, but again only in very small quantity. The use of phosphoric anhydride also did not yield a favourable result.

Phenyl-ethyl Ketone or Propiophenone, $C^9H^{10}O = C^6H^5.CO.C^2H^5$ (Th. D. Barry, *Ber.* vi. 1006; *Inaugural Dissertation*, Halle, 1874). This compound, prepared by distilling a mixture of calcium benzoate and propionate, boils at 210° and has a density of 1.01 at 22.5° . It does not unite with sodium bisulphite. Sodium-amalgam converts it into phenyl-ethyl carbinol, $C^6H^5.CH(OH).C^2H^5$, boiling at 210° – 211° ; the pinacone of propiophenone is probably formed at the same time.

Nitropropiophenone, $C^6H^4(NO_2).CO.C^2H^5$, is formed in two modifications, crystalline and syrupy, according to the manner in which the nitration is effected. The crystallised modification is but slightly soluble in ether, alcohol, and benzene, nearly insoluble in water, melts at 100° and solidifies at 95° . By reduction it is converted into amidopropiophenone, which is syrupy in the free state, but yields a crystallisable hydrochloride, and a platino-chloride which forms granular crystals having the composition $[C^6H^4(NH_2).CO.C^2H^5.HCl]^2PtCl_4$.

Phenyl-propyl Ketone or Butyrophenone, $C^{10}H^{12}O = C^6H^5.CO.C^3H^7$ (Popoff, *Ber.* vi. 560; Schmidt a. Fieberg, *ibid.* 498). This ketone, prepared by distilling a mixture of calcium benzoate and butyrate, is an aromatic liquid having a density of 0.992 at 15° , and boiling at 218° – 221° (Popoff); density 0.990 at 15° ; b. p. 220° – 222° (S. and F.). It does not unite with sodium bisulphite; yields by oxidation benzoic and propionic acids (Popoff; S. and F.). When subjected to the regulated action of nitric acid, it yields nitro-derivatives; when the action is more violent, the product consists almost wholly of benzoic and nitrobenzoic acids. The ketone treated in alcoholic solution with sodium-amalgam is converted into the pinacone, $(C^6H^5.CH.C^3H^7)^2O^2$ —which is a solid body melting at 64° —and a liquid probably containing phenyl-pseudobutyl carbinol. With bromine a liquid bromo-compound is obtained which distils with vapour of water (Schmidt a. Fieberg).

Phenyl-isopropyl Ketone, $C^8H^8.CO.CH(CH^3)^2$, obtained in like manner with calcium isobutyrate and benzoate, boils at 209° – 217° , and yields by oxidation, benzoic, acetic, and carbonic acids (Popoff, *ibid.* 1255).

Diphenyl Ketone or Benzophenone, $C^{13}H^{10}O = C^6H^5.CO.C^6H^5$, is produced in abundance by heating a mixture of benzoic anhydride and benzene with phosphoric anhydride to 200° :

Pyrophosphoric acid may also be used as the dehydrating agent, but not boric anhydride, or dry hydrogen chloride (Kollarits a. Merz, *Ber.* vi. 446). The quantity obtained by heating benzene with benzoyl chloride in contact with zinc is but small (Grucařevic a. Merz, *ibid.* 60).

Diphenyl ketone heated with *hydriodic acid and amorphous phosphorus* is converted into diphenyl-methane, $CH_2(C^6H_5)^2$, and with zinc-dust into diphenyl-methane, tetraphenyl-ethane and tetraphenyl-ethylene (pp. 682, 683). By fusion with *potassium hydroxide* it is almost wholly converted into benzoic acid (Städel, *Ber.* vi. 178); by heating with *alcoholic potash* into diphenyl carbinol (Zagumieny, p. 682). Heated

with *fuming sulphuric acid*, it yields benzophenone-sulphonic acid, $\text{CO}(\text{C}^6\text{H}^4\text{SO}^3\text{H})^2$, and a body having the composition $\text{C}^{13}\text{H}^5\text{SO}^3$ (p. 682).

Chlordiphenyl Ketone or *Chlorobenzophenone*, $\text{C}^6\text{H}^4\text{Cl.CO.C}^6\text{H}^5$, is obtained, by heating chlorobenzene with benzoic anhydride and phosphoric anhydride, as an oily liquid which boils above 300° , solidifies quickly on cooling, and when recrystallised forms broad shining needles, which melt at 75.5 to 76° , dissolve with moderate facility in cold alcohol, sparingly in cold ligroin, easily in hot alcohol and ether (Grucarevic a. Merz).

Bromodiphenyl Ketone, $\text{C}^6\text{H}^4\text{Br.CO.C}^6\text{H}^5$, obtained in like manner from bromobenzene, is crystalline, melts at 81.5° and distils without decomposition (Grucarevic a. Merz).

Attempts to prepare *cyanodiphenyl ketone* by similar means led only to the production of a polymeric cyanobenzene, agreeing in its properties with the so-called *cyaphenine* (iii. 449), which may also be obtained, without the aid of benzoic acid, by heating cyanobenzene to 200° with phosphoric anhydride.

Dinitrobenzophenone, $\text{C}^{13}\text{H}^5(\text{NO}^2)^2\text{O}$.—Benzophenone is not attacked by nitric acid of sp. gr. 1.4, and only imperfectly nitrated by fuming nitric acid at ordinary temperatures; but on heating it to 60° for $\frac{1}{2}$ to $1\frac{1}{2}$ hours with acid of sp. gr. 1.5 to 1.54, it is almost wholly converted into dinitro-compounds. By precipitating the product with water, washing, and crystallising it from glacial acetic acid, needles were first obtained melting at 189° – 190° ; afterwards (in larger quantity) laminae, which when recrystallised from benzene or toluene yielded large plates melting at 148° – 149° . Both these products had the composition of dinitrobenzophenone. The toluene mother-liquor moreover deposited small prisms melting at 118° – 120° which were not analysed (? Doer's isodinitrobenzophenone, vii. 639). Both the above products (m. p. 189° – 190° and 148° – 149°) were likewise obtained when a substance melting at 127° – 129° , which was obtained by nitration of benzophenone and crystallised from alcohol, was recrystallised from glacial acetic acid; they are also readily produced by nitration of diphenyl carbinol or benzhydrol (iv. 478). The needles melting at 189° – 190° were likewise obtained from diphenylmethane (Prätorius, *Ber.* x. 1855).

Diamidobenzophenone, $\text{C}^8\text{H}^8(\text{NH}^2)^2\text{O}$, is the compound, formerly called *Flavine*, which Chancel a. Laurent obtained by reducing dinitrobenzophenone with ammonium sulphide (ii. 656); it is more readily obtained by treating the dinitro-compound with tin and hydrochloric acid. It crystallises from hot water in slender yellow needles, melting at 165° . The *hydrochloride* forms small tablets; the *stannoschloride*, $\text{C}^{13}\text{H}^8(\text{NH}^2)^2\text{O} \cdot 2\text{HCl} \cdot 2\text{SnCl}^2$, crystallises in plates; the *acetyl-derivative* $\text{C}^{13}\text{H}^8(\text{NH} \cdot \text{C}^2\text{H}^3\text{O})^2\text{O}$, in colourless needles melting at 226.5° (Staedel, *Ber.* xi. 744).

Tetramethyl-diamidobenzophenone, $\text{C}^{12}\text{H}^8[\text{N}(\text{CH}^3)^2]^2\text{O}$ or $\text{CO}[\text{C}^6\text{H}^4\text{N}(\text{CH}^3)^2]^2$, is the chief product of the action of carbonyl chloride on dimethylaniline in sealed tubes at about 120° ; its formation is represented by the equation:

The crude product is a dark grey crystal-pulp saturated with a blue colouring matter which produces a dark blue stain on wool and on the skin. The excess of dimethylaniline is removed by boiling with water, and the undissolved residue is washed on a filter and then treated with hydrochloric acid, which leaves a portion still undissolved. The hydrochloric acid solution gives with soda-ley a precipitate of tetramethyldiamidobenzophenone. This compound possesses basic properties, dissolves readily in alcohol and ether, and crystallises from alcohol in yellow laminae melting at 179° (uncor.) Its solution in hydrochloric acid gives with alcoholic platinochloride small gold-yellow laminae of the platinochloride, $\text{CO}[\text{C}^6\text{H}^4\text{N}(\text{CH}^3)^2]^2 \cdot 2\text{HCl} \cdot \text{PtCl}^4$ (W. Michler, *Ber.* ix. 716).

The portion of the crude product of the above reaction which is insoluble in hydrochloric acid, consists of hexmethyl-diamidobenzoyl-benzene, $\text{C}^9\text{H}^8\text{N}(\text{CH}^3)^2[\text{CO.C}^6\text{H}^4\text{N}(\text{CH}^3)^2]^2$, which is neither acid nor basic, and forms lemon-yellow monoclinic crystals melting at 122° (p. 1032).

The conditions under which one or the other of these bodies is more especially produced have been examined by Michler a. Dupertuis (*Ber.* ix. 1879). For the preparation of tetramethyldiamidobenzophenone, carbonyl chloride is passed into dimethylaniline at ordinary temperatures till the increase of weight equals the amount required by calculation; to obtain hexmethyltriamidobenzoylbenzene, on the other hand, the gas is passed into boiling dimethylaniline as long as it continues to be absorbed. When an alcoholic solution of tetramethyldiamidobenzophenone is boiled for a few hours with sodium-amalgam, the liquid evaporated to dryness, and the

residue washed with water and crystallised from ether, small colourless crystals are obtained melting at 96° , and possessing basic properties (probably the corresponding benzhydrol). They dissolve readily in ether and alcohol, and in the latter, as well as in glacial acetic acid, with a deep blue colour, which disappears on addition of an alkali.

When dimethylaniline and benzoyl chloride are heated together in a sealed tube to 150° – 180° , or boiled for several hours in a flask with reversed condenser, a thick crystalline mass is obtained; and on washing this mass with water, dissolving the oily layer in ether, drying it over calcium chloride; distilling—whereupon the greater portion passes over above 300° —and leaving it for a few days over sulphuric acid, the whole solidifies to a beautiful crystalline mass consisting of dimethyl-amido-dibenzoylbenzene, $C^6H^2N(CH^3)^2(CO.C^6H^5)^2$. This compound melts at 55° , and dissolves readily in alcohol and ether (Michler a. Dupertuis).

Tetraphenyl-diamidobenzophenone, $CO[C^6H^4N(C^6H^5)^2]^2$, is obtained, together with hexethyl-triamidobenzoylbenzene (p. 1031), by saturating diethylaniline with carbonyl chloride, then adding half the original volume of diethylaniline, and heating the mixture in a sealed tube to 120° . The two bodies are separated in the same manner as the corresponding methyl-compounds.

Tetraphenyl-diamidobenzophenone forms small laminae melting at 95° – 96° . Its hydrochloride forms with platinic chloride a double salt, $CO[C^6H^4N(C^6H^5)^2]^2 \cdot 2HCl \cdot PtCl_4$, of a fine yellow colour (Michler a. Gradman, *Ber.* ix. 1912).

Action of Ammonia and Amines on Benzophenonic Chloride (Pauly, *Liebig's Annalen*, clxxvii. 198).—Benzophenone itself is not attacked by ammonia, or by aniline or its methylated derivatives, but these bodies act readily on the chloride $C^6H^5.CCl_2.C^6H^5$.

1. Alcoholic ammonia does not act on benzophenone even at 180° – 200° , but it acts energetically on the chloride (as formerly observed by Behr, *Ber.* iii. 791), producing benzophenone, sal-ammoniac, and perhaps also ethylamine hydrochloride, but not any ammonia-derivative of benzophenone. The chloride is not attacked by ammonia in ethereal solution, or (contrary to Behr's statement) by dry ammonia-gas.

2. *Action of Aniline*.—When 1 mol. benzophenonic chloride is added to 4 mols. aniline in a cooled vessel, the mixture solidifies to a crystalline mass; and on treating this mass with water and ether, aniline hydrochloride dissolves in the water, while the ether takes up diphenylmethyleno-aniline, $C^6H^5N=(C^6H^5)^2C=N.C^6H^5$ (see PHENYLAMINES).

Dimethylaniline acts on benzophenonic chloride only with the aid of heat, yielding as final product a dark-red syrupy liquid which yields to ether a base having the composition $C^{12}H^{14}N$. Diphenyl-methyleno-toluidine, $(C^6H^5)^2C=N.C^6H^7$, and diphenyl-methyleno-naphthylamine, $(C^6H^5)^2C=N.C^{10}H^7$, are produced similarly to diphenyl-methyleno-aniline, by treating benzophenonic chloride with paratoluidine and naphthylamine respectively. See PHENYLAMINES.

Tolyl-phenyl Ketones, $C^6H^4(CH^3).CO.C^6H^5$. Two of these compounds are known, one solid and the other liquid. The solid modification is *paratolyl-phenyl* ketone, having the methyl of the group $C^6H^4(CH^3)$ in the para-position with respect to the CO-group, inasmuch as it is resolved by heating with soda-lime into benzene and para-toluic acid:

The liquid ketone appears to be a mixture of the *o*- and *m*- modifications (see BENZOYL-BENZOIC ACID, p. 309).

Zincke, by oxidising benzyl-toluene, $C^6H^4(CH^3).CH^2(C^6H^5)$, with chromic acid, obtained a mixture of tolyl-phenyl ketone and benzoyl-benzoic acid (resulting from further oxidation); and on dissolving out this acid with caustic soda, and purifying the residue by solution in hydrochloric acid, agitation with ether, fractional distillation, &c., tolyl-phenyl ketone was obtained in the form of an oily liquid, which became viscid at low temperatures, but did not solidify (vii. 177).

Kollarits a. Merz (*Ber.* vi. 446), by heating benzoic acid with toluene and phosphoric anhydride (p. 149), obtained the ketone in the form of a liquid which solidified after standing for some months, or more quickly on the introduction of a crystal. According to Thörner (*Liebig's Annalen*, clxxxix. 83) the best proportions for the preparation of the solid ketone are 3 parts benzoic acid, 4 toluene, 4 phosphorus pentoxide, and 4 sand, the mixture being heated in sealed tubes for eight or ten hours to 200° – 220° . On subjecting the product to fractional distillation, the fraction 300° – 305° solidified immediately in the crystalline form, and was easily obtained pure by recrystallisation from ether-alcohol. By this process 1000

grams of benzoic acid yielded 330 of pure paratolyl-phenyl ketone and 402 of the liquid compound still containing some of the solid.

Paratolyl-phenyl ketone crystallises in thick colourless prisms, melts at 56.5° – 57° , dissolves sparingly in cold ligroin, with moderate facility in cold alcohol, easily in ether and in benzene. After fusion it often remains fluid for a long time and easily forms supersaturated solutions (Kollarits a. Merz).

Chlorinated Derivatives.—Paratolyl-phenyl ketone heated with phosphorus pentachloride appears to be converted into the corresponding ketonic chloride, $C^6H^4.CCl_2.C^6H^5$; but this compound decomposes on distillation and has therefore not been isolated. When the ketone is heated in dry chlorine gas, the hydrogen in the methyl-group is more or less replaced by chlorine, and by regulating the temperature and the proportion of chlorine, the three following chlorides may be obtained.

Parabenzoyl-benzyl Chloride, $C^6H^5.CO.C^6H^4.CH_2Cl$, is formed at 100° – 110° , and purified by crystallisation from alcohol and washing with ether, which removes some dichloride. It forms long white prisms melting at 97° – 98° . On adding a little water to its solution in absolute alcohol it crystallises in long, slender, silky needles. It is readily soluble in chloroform, carbon sulphide, benzene, toluene, hot alcohol, and glacial acetic acid, more sparingly in cold alcohol and ether. It can be sublimed, and easily undergoes double decomposition.

Parabenzoylbenzylene dichloride, $C^6H^5.CO.C^6H^4.CHCl_2$, is produced by the continued action of chlorine at 130° – 140° , and crystallises from alcohol and acetic acid in silky plates, melting at 94° – 95° . It dissolves easily in the same solvents as the monochloride, and also in ether. It can be sublimed, and boiling alkalis convert it slowly into parabenzoylbenzoic acid. When it is heated with alcohol and silver nitrate, or with water and silver oxide or lead oxide, the same acid is formed, and not the aldehyde.

Parabenzoylbenzenyl trichloride, $C^6H^5.CO.C^6H^4.CCl_3$, is formed at 150° – 160° ; like the preceding compound it is best purified by the fractional precipitation of its boiling solution in glacial acetic acid with water. It crystallises in small glistening plates or larger thin square plates, melting at 111° – 111.5° . It does not dissolve very freely in cold alcohol and acetic acid, but readily in the hot liquids and in the solvents mentioned above. It can be sublimed, and on heating it with water or silver nitrate to 170° – 180° , or boiling it with alkalis, it is converted into parabenzoylbenzoic acid. On heating it with phosphorus pentachloride, it is converted into $C^6H^5.CCl_2.C^6H^4.CCl_3$, which is readily soluble in acetic acid, carbon sulphide, benzene, &c. It crystallises in square striated thin plates, melting at 78° – 80° ; it cannot be sublimed, and is converted into parabenzoylbenzoic acid by concentrated nitric acid, and by boiling it with alkalis.

Paratolyl-phenyl Pinacolins, $C^{10}H^{14}O$.—Two of these bodies, α and β , are formed by the action of zinc and hydrochloric acid on the ketone.

The α -pinacolin, which is the first product, is easily converted into the β -compound, and therefore obtained pure only by working under certain conditions. A good yield is obtained by dissolving 10 grams of the ketone in 500 c.c. of alcohol of 75 per cent., and adding it to a mixture of zinc and so much hydrochloric acid that a brisk evolution of hydrogen goes on in the cold. The liquid is then boiled for two or three hours, and the pinacolin which has separated out is purified by crystallising it from alcohol. It forms microscopic glistening needles, melting at 214° – 215° , and dissolves freely in chloroform, carbon sulphide, toluene, and boiling acetic acid, less readily in boiling alcohol and ether, very sparingly in cold alcohol.

The β -pinacolin is much more easily obtained by using a stronger alcoholic solution of the ketone, and allowing the reaction to go on for four or five days. It crystallises from hot absolute alcohol in strongly refractive, small square plates, which become opaque on drying, and turn yellow on exposure to light. It dissolves readily in the same liquids as the α -compound, also in boiling alcohol. When the α -pinacolin is heated with benzoyl chloride or with concentrated hydrochloric acid to 150° – 160° , or with glacial acetic acid to 170° – 180° , it is converted into the β -compound. The α -compound is scarcely acted upon by boiling with nitric acid, an aqueous solution of chromic acid, or potassium permanganate, but a boiling solution of chromic trioxide in acetic acid oxidises it again to paratolylphenyl ketone.

The β -pinacolin cannot be converted into the α -compound; on heating it or the latter with concentrated hydriodic acid and amorphous phosphorus to 210° – 220° , the hydrocarbon, $C^{10}H^{16}$, is formed, which is readily soluble in chloroform, carbon sulphide, and toluene, but very sparingly in cold alcohol and ether. It separates from boiling alcohol or acetic acid in microscopic, probably triclinic crystals, melting at 213° – 213.5° .

On boiling the β -pinacolin with glacial acetic acid and chromic trioxide, a large

portion is completely burnt to carbon dioxide, and only a small quantity of an acid is obtained having the formula $C^{21}H^{18}O^2$, or more probably $C^{22}H^{20}O^2$, some benzoic acid being formed at the same time. This acid separates from ether as an amorphous transparent mass, and is precipitated from an ammoniacal solution by hydrochloric acid, as a bulky amorphous white powder. It dissolves freely in ether, benzene, alcohol, glacial acetic acid, &c., melts at 78° – 83° , and cannot be sublimed. Its alkaline solution is precipitated by carbon dioxide; the salts which it forms with the alkali-metals are amorphous and deliquescent; the other salts are gelatinous precipitates.

From these results it appears most probable that, by the action of nascent hydrogen on the ketone, first the corresponding pinacone is produced, which, however, at once loses the elements of water and is converted into the α -pinacolin. As this compound can be easily reconverted into the ketone, it must have a similar constitution, while the β -compound, which by oxidation loses carbon and yields a monobasic acid, is produced by an intramolecular change, and its constitution is therefore probably similar to that of ordinary pinacolin from acetone, which by oxidation yields trimethyl-acetic acid.

Cymyl-phenyl Ketone, $C^{10}H^{18}.CO.C^6H^5$, is formed in small quantity by heating a mixture of cymene and benzoic acid, or benzoyl chloride, with phosphoric anhydride. It is a slightly yellow, very fragrant oil, which boils at 140° , and does not solidify in a freezing mixture (Kollarits a. Merz, *Deut. Chem. Ges. Ber.* vi. 546; Grucarevic a. Merz, *ibid.* 1244).

Dibenzyl Ketone, $(C^6H^5)CH^2.CO.CH^2(C^6H^5)$. This compound, heated to about 180° with hydriodic acid and amorphous phosphorus, yields a viscid product, solidifying on addition of soda to a crystalline pulp, from which ether extracts dibenzyl-methane, $C^{15}H^{16} = CH^2(CH^2.C^6H^5)^2$, forming about a third of the entire product (p. 640). The remainder consists of a phosphorised acid, $C^{15}H^{17}PO^3 = C^{15}H^{15}.PO.(OH)^2$, related to dibenzyl-methane in the same manner as phosphenylic acid, $C^6H^5.PO.(OH)^2$, to benzene (Graebe, *Ber.* vii. 1623). See p. 640.

Naphthyl Ketones (Kollarits a. Merz, *Ber.* vi. 541; Grucarevic a. Merz, *ibid.* 966, 1238).

Naphthyl-phenyl Ketone, $C^{10}H^7.CO.C^6H^5$.—Two isomeric forms of this compound, α and β , are produced by heating a mixture of naphthalene and benzoic acid with phosphoric anhydride, to 200° – 220° for ten or twelve hours. The viscid product is exhausted with benzene, and the solution submitted to fractional distillation, whereupon it yields above 300° , a thick reddish-yellow oil, which when rectified yields a mixture of the two naphthyl-phenyl ketones. This liquid first deposited slender needles, which, when purified by washing with alcohol and crystallisation from ether-alcohol, melted at 82° ; afterwards mixtures from which, by solution in ether-alcohol, short prisms and needles were obtained, and these were further separated by sifting through a fine sieve which allowed only the needles to pass. The short prisms which melted at 75.5° were likewise obtained by heating a mixture of α -naphthoic acid and benzene with phosphoric anhydride, and may, therefore, be designated as α -naphthyl-phenyl ketone. The needles, melting at 82° , and identical with those above mentioned, were obtained in like manner from β -naphthoic acid and benzene, and may, therefore, be called β -naphthyl-phenyl ketone: from the resulting oil they are most easily separated by solution in ether, addition of alcohol, and recrystallisation of the powder which separates as the ether evaporates. The β -modification is somewhat less soluble than the α in cold alcohol (α in 41, β in 49 pts.); they are both more readily soluble in hot alcohol, also in ether and in benzene; both are nearly inodorous, and volatilise without decomposition.

Dinaphthyl Ketones, $C^{10}H^7.CO.C^{10}H^7$.—Two of these ketones are known, and may be distinguished by the letters *a* and *b*. The *a*-modification is obtained by

heating a mixture of α -naphthoic acid and naphthalene with phosphoric anhydride, as an oil which solidifies after a while to a vitreous mass. By dissolving this product in ether, adding alcohol, and recrystallising the precipitate from ether-alcohol, it is obtained in crystals melting at 130° . It dissolves at 14° in 77 parts of absolute alcohol; more easily in hot alcohol, ether, and benzene; crystallises from boiling alcohol in colourless pointed needles; from ether-alcohol in thick prisms and tablets (Kollarits a. Merz). Grucarevic a. Merz (*Ber.* vi. 1238) prepare the same compound by boiling α -naphthoyl chloride with excess of naphthalene, and introducing into the liquid a thin strip of zinc; an excess of zinc must be avoided. The product yields by distillation a brown oil which soon solidifies; and by dissolving the mass in warm chloroform and adding ether-alcohol, prisms of the α -ketone are first obtained, melting at 135° ; afterwards mixtures of this compound with another which crystallises in reddish scales. The quantity of α -naphthyl ketone obtained by this process amounts to between $\frac{1}{3}$ and $\frac{1}{4}$ of the naphthoyl chloride used, and is larger than that produced from an equal weight of naphthoic acid.

b-Dinaphthyl Ketone.—Kollarits a. Merz prepared this modification from β -naphthoic acid and naphthalene, and after repeated crystallisation from various solvents, obtained it in needles which sintered together at 123° , melted at 135° , and were altogether less soluble than the α -ketone. Grucarevic a. Merz prepared it from naphthalene and β -naphthoyl chloride in quantity amounting to about $\frac{2}{3}$ of the latter; and by repeatedly crystallising the crude product from chloroform and ether, white shining laminae were obtained melting at 164.5° , together with white needles having the same composition but melting at 125.5° . The former dissolved at 19° in 1256 parts, the latter in 267 parts of alcohol.

Naphthalene, as already explained (vi. 212), may be represented by the following constitutional formula:

in which the positions 1, 4, 5, 8 are similar to one another, but different from the positions 2, 3, 6, 7, which are also similar among themselves. Naphthalene monoderivatives (chloro-, nitro-naphthalenes, &c.) in which the substituted radicle occupies one of the positions 1, 4, 5, 8, are called α -derivatives; those in which it occupies either of the other four positions are called β -derivatives. This being understood, it is easy to see that dinaphthyl ketone, $C^{10}H^7.CO.C^{10}H^7$, is susceptible of three modifications, $\alpha\alpha$, $\alpha\beta$, $\beta\beta$; thus:—

Now, according to Grucarevic a. Merz (*Ber.* vi. 1246), α -dinaphthyl ketone, finely triturated with soda-lime and heated for eight hours in a sealed tube to about 350° , is resolved into naphthalene and a mixture of α - and β -naphthoic acids: hence it must be the $\alpha\beta$ -modification. β -dinaphthyl ketone (both modifications, m. p. 125.5° and 164.5°) is resolved by heating with soda-lime into naphthalene and β -naphthoic acid; and since this latter can be formed only from a dinaphthyl ketone having the CO-group attached to one of its β -positions, and moreover the $\alpha\beta$ -modification has been shown to be that which is designated as α -dinaphthyl ketone, it follows that both the $\beta\beta$ -modifications must have the $\beta\beta$ structure, and can therefore be only physical isomerides.

In α -naphthyl-phenyl ketone, the CO-group is attached on the one side to either of the α -carbon-atoms of the naphthalene-molecule, and on the other to either of the carbon-atoms of the benzene-molecule; similarly with regard to β -naphthyl-phenyl ketone.

KINOIN, $C^{14}H^{12}O^6$ (Etti, *Berl. Ber.* xi. 1879). When Malabar Kino is boiled with twice its weight of dilute hydrochloric acid (1 : 5), and the solution decanted

from the deposit of kino-red is shaken up with ether, a solution is obtained which, on evaporation, leaves kinoïn in the form of a reddish crystalline substance; and by repeatedly crystallising this substance from a small quantity of water, pure colourless crystals of kinoïn are obtained, to the amount of about 15 grams from a kilogram of kino.

Kinoïn is anhydrous; it dissolves sparingly in cold water, easily in hot water and in alcohol. The solutions may be evaporated without alteration, but decompose on exposure to the air. Kinoïn heated to 120° – 130° till its weight becomes constant yields the anhydride, $C^{28}H^{22}O^{11} = 2C^{14}H^{11}O^6 - H^2O$, which appears to be identical with kino-red; and this anhydride heated to 160° – 170° loses another molecule of water and is converted into $C^{28}H^{20}O^{10}$. Both these anhydrides are precipitated by gelatin; kinoïn itself is not.

When kinoïn is heated to 120° – 130° in a sealed tube with strong hydrochloric acid, methyl chloride escapes on opening the tube, and a solution is formed containing pyrocatechin and gallic acid: hence it may be inferred that kinoïn has the constitution of *methyl-pyrocatechyl gallate*, $C^7H^4(CH^3)(C^6H^3O)O^5$.

Kino-red yields by dry distillation a small quantity of watery and oily distillate, the greater part of the substance however becoming carbonised. The oily distillate yields by fractional distillation pyrocatechin and phenol, mixed with small quantities of an ethereal compound, probably anisole or guaiacol.

KJERULFIN. A mineral from Bamle in Norway, occurring massive, with imperfect cleavage in two directions at right angles to one another. Fracture uneven and splintery. Lustre, fatty. Colour, pale red. Translucent in thin fragments. Sp. gr. = 3.15. Hardness = 4.5. Exhibits faint white phosphorescence when heated. Fusibility about 3; melts with some intumescence to a blistered enamel. Easily soluble in hot concentrated hydrochloric acid; somewhat less easily in nitric acid. With sulphuric acid it evolves hydrofluoric acid, while calcium sulphate separates. Analysis gave:

P ₂ O ₅	MgO	CaO	Na ₂ O	Fl	SiO ₂	Al ₂ O ₃
42.22	37.00	7.56	1.56	4.78	1.50	5.40 = 100.02

with traces of potassium, iron, and sulphuric acid.

When the non-essential constituents are deducted, this composition corresponds with the formula $2Mg_3(PO_4)^2 + CaF_2$, a small portion of the calcium being replaced by sodium.

Kjerulfin differs from wagnerite, which it resembles in many respects, by containing less fluorine and sodium, and more calcium, so that its solution in hydrochloric acid gives a precipitate with sulphuric acid, which is not the case with wagnerite.

KLINOHUMITE or **CLINOHUMITE.** See HUMITE (p. 1044).

RÖNIGINN. A mineral from Russia belonging to the Brochantite group (p. 349).

KOPPITE. This name is given by A. Knop (*Jahrb. f. Min.* 1875, 67) to a variety of pyrochlore from the limestones of the Kaiserstuhl, which he regards as a distinct mineral species, on account of the smallness of its amount of fluorine (1.28 to 1.82 per cent.), and the absence of titanate and thorina.

KOSIN, $C^{21}H^{38}O^{10}$ (Flückiger a. Buri, *Arch. Pharm.* [3], v. 193; *Pharm. J. Trans.* [3], v. 562). A substance obtained from the flowers of the koso tree of Abyssinia (*Hugeria abyssinica* Lamarck), and supposed to be the principle to which the anthelmintic properties of these flowers are due. It has a sulphur-yellow colour; crystallises in rhombic forms; dissolves at 15° in strong sulphuric acid, and crystallises unaltered on cooling; melts but does not give off water at 142° ; and at higher temperatures emits an odour of butyric acid and yields a brown tar. It is nearly insoluble in water, but easily soluble in ether, benzene, carbon sulphide, chloroform, glacial acetic acid and alcohol; dissolves also in aqueous alkalis and alkaline carbonates, and is precipitated therefrom by acids. Ferric chloride added to the alcoholic solution produces, after a while, a permanent red coloration.

Kosin dissolves in strong sulphuric acid, forming isobutyric acid and a red amorphous body, which has the composition $C^{22}H^{21}O^{10}$ [$C^{22}H^{20}O^{10}$], or $C^{23}H^{22}O^{10}$, accordingly as it is prepared with cold or with warm sulphuric acid.

Kosin fused with potash produces formic, butyric and oxalic acids, together with a brown unctuous substance. With sodium-amalgam it yields a volatile oil, $C^{22}H^{16}O^2$, and an amorphous substance having the colour of stannic sulphide, and the empirical formula $C^3H^3O^2$. Acetic anhydride converts kosin into acetyl-kosin, $C^{31}H^{32}(C^2H^3O)^6O^{10}$. From these results Flückiger a. Buri regard kosin as an ether of isobutyric acid.

The substance called *Koussin* or *Tenin*, which Pavese and Bedall obtained from

the flowers of *Brayera anthelmintica* (v. 654), is, according to Flückiger a. Buri, a mixture containing variable quantities of pure kosin.

KOUMISS. Observations on the preparation of this beverage have been published by J. T. George (*Pharm. J. Trans.* [3], iii. 544; *Jahresb. f. Chem.* 1873, 1080), and a continuation of former observations (vii. 715), by Jagielski (*American Chemist*, v. 448).

KRYOCONITE. See CRYOCONITE (p. 589).

KUNKUR. An argillaceous sedimentary limestone occurring in India, and used for the preparation of mortar. Recently burnt kunkur-stone was found to contain 40·0 per cent. silicates, 8·8 calcium carbonate, and 51·2 quicklime. This lime possesses considerable hydraulic properties. When slaked it increases greatly in bulk, its density diminishing from 1 to 0·67. To form the mortar, slaked kunkur lime is mixed with sand in such proportion as to form a mixture having the following composition reckoned on the dry mass:

1 vol. lime, weighing 0·67	{ 0·33 Silicates
2 vols. sand „ 3·00	{ 0·34 Lime
	<hr/>
	3·67

This mortar therefore contains scarcely 10 per cent. of its dry weight of lime. Nevertheless it hardens under water to such a degree, that after a month it is able to bear a weight of 15 pounds on the square inch (E. Nicholson, *Chem. News*, xxxii. 82).

L

LABRADORITE. See FELSPAR (p. 774).

LAC. Japanese lac is described by Wagner (*Dingl. pol. J.* cccviii. 361, 452). It is obtained from the juice of a species of Sumach (*Rhus vernioifera*), growing chiefly in the district of Yoshino, by making incisions in the bark. The viscid juice, which, on exposure to the air, quickly becomes dark-coloured and covered with a crust, is known by the name of *Urushi*. The value of the lac varies according to the season in which it is collected, the best being obtained towards the end of August. A well-grown tree yields about 375 grams of juice, and then dies. The juice is filtered through a peculiar kind of paper made in Yoshino. It is only the red lac (coloured by cinna-bar) that retains its colour; all other shades become deteriorated by the darkening of the lac on exposure to the air. Black lac is produced by stirring the juice for a day in contact with the air, after adding to it a certain quantity of water which has stood over iron filings. Lacs which are to be polished after hardening have only a small quantity of oil added to them; others are mixed with one-fifth of an oil obtained from the Ye plant (*Perilla ocimeoides*). The working of this lac is a somewhat unhealthy occupation, the vapours emitted from the juice producing painful cutaneous eruptions.

In articles to be coated with this lac, all cracks and holes must be stopped with linen or cotton soaked in a quickly hardening lac (Seschime lac from the twigs of *Rhus vernioifera*). A thin cloth or a layer of the long-fibred Yoshino paper is then immediately attached to the surface with Seschime lac; on this is laid a coating of the same lac mixed with powder of burnt clay; and the articles are left for twenty-four to forty-eight hours in a dark moist place for the lac to harden. The hardened coating is next rubbed with a soft stone, after which a second layer of fine tripoli and lac is laid on, and this, when hardened, is rubbed with charcoal and water. The surface thus prepared is ready to receive the true lac. At first a few layers of a cheaper lac are laid on and finally the best coloured lac, each layer, after hardening, being rubbed with a smooth piece of charcoal and water. Lastly, to produce the lustre, a very thin coating of Seschime lac is laid on the object by means of a cotton pad, and polished, when dry, with very fine powder of stag's horn or burnt bones, rubbed on with the finger or the palm of the hand.

On Japanese lac, see further Robertson (*Pharm. J. Trans.* [3], vi. 487). On Chinese lac, see *American Chemist*, v. 453.

LACTIC ACID, $C^3H^5O^3$. The isomeric modifications of this acid have been further examined by Wislicenus (*Liebig's Annalen*, clxvi. 3; clxvii. 302, 346).

1. **Hydracrylic Acid**, produced by the action of silver oxide on β -iodopropionic acid, $CH^1I.CH^2.CO^3OH$, is not identical with ethylene-lactic acid, as might be supposed from its mode of formation, but a modification distinct from both ethylene-lactic and ethylidene-lactic acids, and represented by the formula $CH^2O.H.C \begin{smallmatrix} \diagup \\ \diagdown \end{smallmatrix} CHO^3H$ (vii. 718).

2. **Sarcolactic Acid**. The more recent experiments of Wislicenus confirm the view formerly suggested (*loc. cit.*) that sarcolactic acid is a mixture of two distinct acids, the more abundant of which, called paralactic acid, turns the plane of polarisation to the right and forms well-crystallised salts, whereas the other, which is present in much smaller quantity, and is probably the true ethylene-lactic acid, exhibits but very little crystallising power.

To separate the two acids, sarcolactic acid, prepared from extract of meat, was saturated with zinc carbonate, and the concentrated solution was precipitated with four or five times its volume of alcohol of 90 per cent. The paralactate was thereby precipitated as a bulky mass of very small colourless crystals, which afterwards became denser; these were washed with alcohol and pressed, then several times dissolved in water and precipitated by alcohol, and finally recrystallised from boiling water. The quantity of pure zinc salt thus obtained amounted on the average to 2 per cent. of the meat-extract used. The alcoholic mother-liquors contained chiefly the zinc salt of the second constituent of sarcolactic acid. Of the properties formerly attributed to zinc paralactate (iii. 459, 460), chiefly according to the experiments of Engelhardt (*Liebig's Annalen*, lxx. 359), two only have been confirmed by Wislicenus, viz. the amount of crystallisation-water, which agrees with the formula $C^3H^{10}ZnO^6.2H^2O$, and the tendency of the salt to form distinct crystals, whereas the fermentation lactate tends rather to form groups or crusts of crystals. On the other hand, all the earlier determinations of solubility of this salt appear to have been made with supersaturated solutions; and Wislicenus finds that the amount of water in a solution prepared with the aid of heat, and left to cool in contact with the crystals which separate, decreases continually, and does not attain a constant value till after about a month, this value agreeing with a solubility of 1 pt. of the crystallised salt in about 17.5 pts. water at 14° – 15° (1 pt. fermentation lactate requires for solution 58 to 63 pts. water). In boiling alcohol, zinc paralactate dissolves in the proportion of about 1 : 1000, and in much smaller proportion in cold alcohol. *Calcium paralactate* has the composition $2C^3H^{10}CaO^6.9H^2O$.

The conversion of sarcolactic acid into the anhydride of fermentation lactic acid [dilactic acid, $C^3H^{10}O^5 = 2C^3H^5O^3 - H^2O$] was observed by Strecker in 1858 (iii. 457). Wislicenus finds that when pure paralactic acid is heated for some time in a retort at 135° , a small quantity of it distils unaltered, together with the water, and the residue contains dilactic acid, the quantity of which increases as the heating is continued, so that after a few days the residue consists almost exclusively of it. The same acid, heated to 150° in a current of air, was, for the most part, converted into ordinary lactide, $C^3H^4O^2$, melting at 124.5° . Optically active lactic acid, therefore, when heated to 135° – 150° , is gradually but completely converted into the anhydrides of optically inactive fermentation-lactic acid. Paralactic acid left in a perfectly dry atmosphere at ordinary temperatures, is dehydrated exactly in the same manner as ordinary lactic acid, that is to say, it is converted first into dilactic acid and then into lactide (vii. 720). The mixture of the anhydrides of dextrogyrate paralactic acid possesses a high degree of levogyrate power. A preparation which had been kept over sulphuric acid for 21 months, and then consisted of 84.19 per cent. dilactic acid and 16.04 lactide, exhibited in alcoholic solution, for the line D, a specific rotatory power of -85.80° to -85.93° . This residue, boiled for a long time with zinc carbonate, was converted into a mixture of salts, in which the paralactate greatly predominated.

The optical rotatory power of paralactic acid, in a specimen which had been prepared by dehydration at ordinary temperatures, and contained 0.0738 gram of acid in a cubic centimeter, was found to be $[\alpha]_D = 2.78$. It did not, however, remain constant, but decreased suddenly and considerably after every further addition of water, and the more considerably in proportion as the original solution was more concentrated; after some time it gradually increased again, without, however, regaining its original value. The rotatory power of the metallic paralactates is of opposite sign to that of the free acid; that of the zinc salt being smaller in supersaturated than in normal solutions, in which latter $[\alpha]_D = -7.6^\circ$ to -7.7° for the crystallised salt. For the crystallised calcium salt, $[\alpha]_D = -3.87^\circ$.

Paralactic acid heated alone to 140° – 150° is resolved, like the fermentation acid.

into formic acid and acetaldehyde. By oxidation with a slight excess of potassium dichromate and sulphuric acid (1 at. disposable oxygen to 1 mol. lactic acid) it yields acetaldehyde, together with formic, acetic, and carbonic acid, but neither malonic nor oxalic acids.

The production of formic and acetic acids by the oxidation of paralactic acid is easily explained if the latter be represented by the formula, $\text{CH}^3-\underset{\text{O}}{\text{C}}(\text{OH})-\text{CH}(\text{OH})$, thus:

On this view, paralactic acid would be related to ethylidene-lactic acid in the same manner as hydracrylic to ethylene-lactic acid. As, however, hydracrylic acid—the formula of which is better established than that of paralactic acid—does not exhibit circular polarization, Wislicenus thinks it preferable to assign to paralactic acid the same constitutional formula as to ethylidene-lactic acid, regarding these two acids as physical isomerides (vii. 720).

Ethylene-lactic Acid, $\text{CH}^3\text{OH}.\text{CH}^2.\text{COOH}$. This acid, whether prepared from sarcosolactic acid, or synthetically by combining ethylene with carbonyl chloride, and decomposing the resulting chloride, $\text{CH}^3\text{Cl}.\text{CH}^2.\text{COCl}$, with an alkali, or by either of the other processes already given (vi. 770), is very difficult to purify, being mixed in the first case with paralactic acid, and in the case of the synthetical preparation, with ethylidene-lactic acid, formed at the same time by intramolecular transposition. It may, however, be obtained quite pure by digesting its zinc salt—previously freed as far as possible from ethylidene-lactate or paralactate respectively by the difference of solubility of these salts in water (vii. 719)—with quantities of nearly absolute alcohol not sufficient to dissolve the whole of it, or by fractionally precipitating its alcoholic solution with ether. The zinc salt, either of the synthetically formed acid or of that prepared from different animal fluids, is thus obtained in the form of a brittle transparent gum which deliquesces in contact with the air.

Pure ethylene-lactic acid is not converted by hydriodic acid into β -iodopropionic acid, and does not yield a sparingly soluble zinc-calcium salt. By oxidation with chromic acid, it yields large quantities of carbon dioxide and oxalic acid, and a small quantity of malonic acid, but no formic acid (Wislicenus, *Annalen*, clxvii. 346; *Ber.* vi. 1395).

Ethylidene-lactic acid is produced by prolonged boiling of isotrichloroglyceric acid with tin and hydrochloric acid (Schroeder, *Annalen*, clxxvii. 282):

Iodo-lactic acid, $\text{C}^3\text{H}^3\text{IO}^3$, is prepared by heating chlorolactic acid to 50° with potassium iodide. It melts at 84° – 85° , and forms a zinc-salt crystallising in tablets (Glinsky, *Ber. Ber.* vi. 1257).

LACTIC ETHERS, CHLOR- and BROMINATED (L. Henry, *Ber.* vii. 762). Ethyl lactate unites with *chloral* gradually and with slight elevation of temperature, forming a viscid liquid which, when treated with phosphorus pentachloride, yields ethylic tetrachlorethyl-lactate, $\text{CH}^3-\text{CHO}(\text{CHCl}.\text{CCl}^3)-\text{COOC}^2\text{H}^5$, a thick, colourless, non-distillable liquid, having a peculiar odour, sweetish taste, and sp. gr. = 1.42 at 11° .

Trichlorethylidenic Lactate, $\text{C}^3\text{H}^3\text{Cl}^3\text{O}^3 = \text{CH}^3.\text{CH} \begin{array}{c} \text{CO.O} \\ \diagup \quad \diagdown \\ \text{O} \end{array} \text{CH}.\text{CCl}^3$, is formed by heating lactic acid with chloral in a sealed tube to 150° – 160° , and passes over on distilling the product with steam, as an oil which has a peculiar odour, is nearly insoluble in water, and, after drying with calcium chloride, solidifies in splendid crystals. It melts at 45° , boils without decomposition at 222° – 224° , dissolves easily in alcohol, ether, and carbon sulphide (Wallach & Heymer, *Ber.* ix. 545).

Trichlorethylidenic Trichlorolactate, $\text{CCl}^3.\text{CH} \begin{array}{c} \text{CO.O} \\ \diagup \quad \diagdown \\ \text{O} \end{array} \text{CH}.\text{CCl}^3$, or *Chloralide*, is formed in like manner by heating chloral with trichlorolactic acid (p. 445 of this volume).

Chloralide crystallises in splendid monoclinic crystals, often more than an inch long. Axes $a : b : c = 1.2038 : 1.03620$. Angle $ac = 84^\circ 52'$. Observed forms, $\infty P \infty$, $\infty R \infty$, ∞P , $\infty P2$, $0P$, $R \infty$. Angle $\infty P : \infty P = 100^\circ 33'$; $R \infty : R \infty = 39^\circ 40'$; $R \infty : \infty P \infty = 85^\circ 10'$. Cleavage perfect, parallel to $\infty R \infty$. Plane of optic axes perpendicular to the clinopinacoid. The median line situated in the plane of symmetry forms with the vertical in the acute angle of the axes a and c , for Li-red

11° 34', for Na-yellow 11° 44'. The median line parallel to the axis *b* exhibits negative double refraction and crossed dispersion; the axial angle in oil is for Li 99° 27', for Na 99° 51' (Bodewig, *Zeitschr. f. Krystallographie*, i. 594).

Tribromomethylidene Tribromolactate, or *Bromalide*, $C^6H^2Br^6O^3 = CBr^3.CH \begin{smallmatrix} CO.O \\ \diagdown \quad \diagup \\ O \end{smallmatrix} CH.CBr^3$, is obtained in like manner from tribromolactic acid and bromal, and by heating bromal with fuming sulphuric acid (Reincke, *Berl. Ber.* ix. 1215). It melts at 158° (Wallach a. Reincke, *ibid.* x. 2128).

Trichlorethylidene Tribromolactate.

from tribromolactic acid and chloral, melts at 132°–135°. *Tribromomethylidene Trichlorolactate*, $CCl^3.CH \begin{smallmatrix} CO.O \\ \diagdown \quad \diagup \\ O \end{smallmatrix} CH.CBr^3$, from trichlorolactic acid and bromal, melts at 149°–150°. *Tribromomethylidene Lactate*, $C^6H^5Br^3O^3 = CH^3.CH \begin{smallmatrix} CO.O \\ \diagdown \quad \diagup \\ O \end{smallmatrix} CH.CBr^3$, from lactic acid and bromal, melts at 95°–97° (Wallach a. Reincke). This last compound, called by Klimentko *lactide bromal*, is also formed by dropping bromine into a solution of lactic acid in twice its volume of ether. A brisk action then takes place, which must be moderated by cooling; and after 2 mols. bromine have been added, the liquid is heated on the water-bath in a vessel with reversed condenser, till that which runs back exhibits a yellowish colour. A large quantity of hydrogen bromide is then given off, and considerable quantities of ethyl bromide pass over in the subsequent distillation. Crystals form in the residue on standing, and on adding water, a thick oil separates, which after a while solidifies to a crystalline mass. The crystals, which have a strong pungent odour, may be purified by washing with water, pressing, and recrystallisation from hot alcohol. They have then a neutral reaction, an agreeable though pungent odour, and agree in composition with the formula of tribromomethylidene lactate, $C^6H^5Br^3O^3$.

The formation of this compound by the action of bromine on lactic acid in presence of ether, may be represented by the following equations:

Tribromomethylidene lactate is insoluble in water, very slightly soluble in cold, much more readily in hot alcohol, and separates therefrom on cooling in small concentrically grouped needles, melting at 95°–97°, and solidifying again at 90°. From ether, which dissolves it freely, it crystallises in large rhombic prisms, acuminate at the summits. Caustic potash slowly decomposes the crystals, even at ordinary temperatures, with formation of bromoform. Sodium abstracts all the bromine from the aqueous solution, part only from the ethereal solution (Klimentko, *J. pr. Chem.* [2], xiii. 98).

LACTIDE, $C^6H^8O^4$. The formation of this compound from paralactic acid, as well as from ordinary lactic acid, has been already mentioned (p. 1160). L. Henry (*Ber. vii. 753*) finds that its vapour-density is 4.81; consequently its molecular formula must be, not $C^6H^4O^2$ as hitherto supposed, but $C^6H^8O^4$, the vapour-density calculated from the latter formula being 4.96.

By absorption of dry ammonia, lactide is converted into lactamide, $CH^3.CH(OH).CO.NH^2$, identical with that (m. p. 74°) which is produced by the action of ammonia on ethyl lactate (iii. 453). Hence it must be regarded as an

ethereal compound, $\begin{smallmatrix} O & O \\ | & | \\ CO.CH.CO \end{smallmatrix}$, and not as a body which would be at the same

time acid anhydride and alcoholic anhydride, viz. $\begin{smallmatrix} CH^3.CH.CO \\ O & O \end{smallmatrix}$, since it would then

be converted by ammonia into a diamide, $\begin{smallmatrix} CH^3.CH.CO.NH^2 \\ O \end{smallmatrix}$, or the correspond-

ing acid ammonium salt, $\begin{smallmatrix} CH^3.CH.CO.NH^2 \\ O \end{smallmatrix}$.

Lactide melts at 121° (according to Wislicenus at 124.5°; see p. 1160), and boils

under a pressure of 757 mm. at 255° (uncorr.) It is not attacked by acetyl chloride. The temperature at which lactic acid, when subjected to dry distillation, passes into dilactic acid, $C^6H^{10}O^8$, is between 140° and 150°, and that at which this latter compound when heated alone is converted into lactide, is between 200° and 250° (Henry).

LACTIDE BROMAL, syn. with TRIBROMETHYLIDENIC LACTATE (p. 1162).

LACTOGLUCOSE. A constituent of milk-sugar, according to Fudakowski (see SUGARS).

LACTOPHOSPHATES. A pharmaceutical name for mixtures of lactic acid with calcium phosphate. R. Rother (*Pharm. J. Trans.* [3], iii. 570) found that lactic acid saturated with tricalcic phosphate contained 4 mols. of the former to 1 mol. of the latter. The solution, when boiled or left at rest for some time, deposited a precipitate of PO^4CaH :

The formation of this precipitate may be prevented by adding a quantity of lactic acid equal to half that originally present. Directions for the preparation of syrups of calcium lactophosphate are given by Rother (*loc. cit.*), also by Menières a. Langellé (*Pharm. J. Trans.* [3], iv. 142), and for the preparation of cod-liver oil containing calcium lactophosphate by E. Chiles (*ibid.* iii. 785).

LACTUCA. The leaves of the common lettuce (*Lactuca sativa*) fresh and well-developed were found by Church (*Journal of Botany*, March 1876) to contain water, 95·98 per cent.; albuminous matter, 0·71; starch, sugar, gum, 1·68; cellulose and lignose, 0·52; chlorophyll and fat, 0·22; ash, 0·89. This ash was very rich in nitrates.

LACTURAMIC ACID, $C^4H^8N^2O^3 = CH^3.CH(NH.CONH^2).COOH$ (see vol. vii. p. 723).

LACTYL-CARBAMIDE or **LACTYL-UREA**, $C^4H^8N^2O^2 = \begin{array}{c} CH^3.CH.NH.CO \\ | \\ CO-NH \end{array}$ (*ibid.*)

LANTHANUM. Atomic weight, $La''' = 138·75$ (Marignac); 139·15 (Cleve); 139·2 (Frerichs a. Smith); 139 (Hillebrand).

On the preparation of Lanthanum and its separation from Cerium and Didymium, see CERITE METALS (pp. 421, 422); also DIDYMIUM (p. 642).

A large number of lanthanum salts prepared and examined by Cleve are described under CERITE METALS (pp. 422, 423). The following have been examined by Frerichs a. Smith (*Liebigs Annalen*, xcvi. 355–366); they were prepared in the same manner as the corresponding didymium compounds (p. 642), which, for the most part, they closely resemble.

Platinochloride, $2LaCl^3.3PtCl^4.24H^2O$.—Large orange-coloured very soluble 4-sided plates.

Aurochloride, $2LaCl^3.3AuCl^3.21H^2O$.—Shining plates, very soluble and absorbing moisture from the air, but not deliquescent.

Oxychloride, $LaOCl$.—White, nearly insoluble in water even at the boiling heat. By boiling with an excess of didymium oxychloride suspended in water, it is gradually converted into the soluble chloride, the didymium oxychloride being first resolved into insoluble oxide and soluble chloride, which then gives up its chlorine to the lanthanum and is itself converted into didymium oxide:

Lanthanum and Zinc Bromide, $2LaBr^3.3ZnBr^2.39H^2O$ (or perhaps $36H^2O$).—Resembles the corresponding didymium salt.

Lanthanum and Nickel Bromide, $2LaBr^3.3NiBr^2.18H^2O$.—Exactly resembles the didymium salt.

Lanthanum and Zinc Iodide, $2LaI^3.3ZnI^2.27H^2O$.—Small white very soluble needles; absorbs moisture from the air much more quickly than the corresponding didymium salt.

Lanthanum and Hydrogen Fluoride, $2LaF^3.3HF^*$.—Thrown down by hydrofluoric or silicofluoric acid from a solution of lanthanum sulphate, as a bulky precipitate, which dries up to a thick white crust.

* Frerichs a. Smith suggest that the precipitate obtained by Cleve on adding hydrofluoric acid to lanthanum acetate, and regarded by him as $2LaF^3.H^2O$ (p. 422), may possibly have been the acid fluoride above described, the hydrogen fluoride of which, given off on heating, may have been mistaken for water of crystallisation.

Lanthanum-zinc Nitrate, $2\text{La}(\text{NO}_3)_3 \cdot 3\text{Zn}(\text{NO}_3)_2 \cdot 69\text{H}_2\text{O}$.—Agrees in properties with the salt prepared by Damour a. Deville (*Instit.* 1858, 111), who, however, assigned to it the formula $\text{La}''(\text{NO}_3)_2 \cdot \text{Zn}(\text{NO}_3)_2 \cdot 8\text{H}_2\text{O}$ or $2\text{La}'''(\text{NO}_3)_3 \cdot 3\text{Zn}(\text{NO}_3)_2 + 24\text{H}_2\text{O}$.

Lanthanum-nickel Nitrate, $2\text{La}(\text{NO}_3)_3 \cdot 3\text{Ni}(\text{NO}_3)_2 \cdot 36\text{H}_2\text{O}$.—Light green very soluble crystals, which do not absorb moisture from the air so quickly as the corresponding didymium salt.

Lanthanum Hypochlorite, $\text{La}(\text{OCl})_3$.—Chlorine passed into water in which lanthanum hydroxide is suspended, forms after a while a crystalline powder, which redissolves if the stream of chlorine be continued; and on evaporating the filtered solution over the water-bath, the hypochlorite is obtained in easily soluble lustrous plates.

Lanthanum Sulphide, La_2S_3 , obtained by heating the oxide in a current of CS_2 and CO_2 , is a brownish-grey powder which dissolves in acids with evolution of hydrogen sulphide. Cold water decomposes it into lanthanum hydroxide and hydrogen sulphide.

Sulphates.—The normal sulphate, $\text{La}_2(\text{SO}_4)_3$, crystallises from a neutral saturated solution with $6\text{H}_2\text{O}$. On mixing the saturated solution with an equal volume of sulphuric acid and evaporating over the water-bath, fine crystals of the bihydrated salt, $\text{La}_2(\text{SO}_4)_3 \cdot 2\text{H}_2\text{O}$, are obtained.

Basic Sulphate, $[\text{La}^2(\text{OH})_3]_2(\text{SO}_4)_3$.—Hermann obtained this salt by precipitating the normal sulphate with ammonia, as a white bulky precipitate containing water. Frerichs a. Smith have obtained it in the anhydrous state.

Selenate, $\text{La}_2(\text{SeO}_4)_3 \cdot 12\text{H}_2\text{O}$.—Colourless prisms, soluble in water. Cleve obtained it with $6\text{H}_2\text{O}$. *Selenite*, $\text{La}_2(\text{SeO}_3)_3 \cdot 9\text{H}_2\text{O}$. Precipitated by alcohol from a concentrated solution of the sulphate mixed with selenious acid. Decomposes as readily as the didymium salts. Cleve's acid selenite (p. 423) was not obtained by Frerichs a. Smith.

Phosphates.—The orthophosphate, LaPO_4 , is a colourless gelatinous precipitate formed from lanthanum sulphate and trisodic phosphate. The triphosphate, $(\text{La}^2)^3\text{H}^3(\text{PO}_4)_3$, is formed as a gelatinous precipitate on mixing the solutions of lanthanum sulphate and disodic phosphate. The pyrophosphate, $\text{La}_2\text{H}^6(\text{P}^2\text{O}_7)_3$, is obtained on adding sodium pyrophosphate to lanthanum sulphate, as a colourless precipitate soluble in excess of the sodium salt. Cleve assigns to it the composition $\text{LaHP}^2\text{O}_7 \cdot 3\text{H}_2\text{O}$. The metaphosphate, $\text{La}(\text{PO}_3)_3$, is precipitated by sodium metal phosphate from lanthanum sulphate.

Phosphite, $\text{La}_2\text{H}^3(\text{PO}_3)_3$.—Colourless precipitate.

Arsenate, $\text{La}_2\text{H}^3(\text{AsO}_4)_3$, is a colourless gelatinous precipitate; the *arsenite*, $\text{La}_2\text{H}^3(\text{AsO}_3)_3$, is obtained as a crystalline powder by boiling lanthanum hydrate for several hours with aqueous arsenious acid.

Chromate, $\text{La}_2(\text{CrO}_4)_3$.—Obtained, on mixing the solution of neutral potassium chromate and lanthanum sulphate, as a yellow granular precipitate, appearing crystalline under the microscope. Slightly soluble in cold, more readily in hot water, easily in acids.

Manganate, $\text{La}_2(\text{MnO}_4)_3$.—Obtained by heating manganese dioxide (1 pt.) with lanthanum nitrate (4 pts.) for half an hour, then washing the mass with water and drying, as a grey-black powder, insoluble in water, but dissolving with fine rose-red colour in sulphuric acid. The *permanganate*, $\text{La}(\text{MnO}_4)_3 \cdot 21\text{H}_2\text{O}$, is deposited as a brown powder on leaving a solution of potassium permanganate and lanthanum sulphate to itself for about a month.

Borate, $\text{La}_2(\text{B}^4\text{O}_7)_3$.—Gelatinous precipitate which dries up to a transparent brittle crust.

Tungstate, $\text{La}_2(\text{WO}_4)_3$.—Obtained on mixing sodium tungstate with a lanthanum salt as a colourless gelatinous precipitate which dries up over the water-bath to a thick white crust; it is soluble in acids. The *molybdate*, $\text{LaH}^3(\text{MoO}_4)_3$, is very much like the tungstate.

The *cyanide* is a gelatinous precipitate which dries up to a dense crust. It unites with other metallic cyanides, forming well-crystallised double cyanides. The *platinocyanide*, $2\text{La}(\text{CN})_3 \cdot 3\text{Pt}(\text{CN})_2 \cdot 18\text{H}_2\text{O}$, is obtained, according to Czudnowicz, on adding barium platinocyanide to an excess of lanthanum sulphate.

LANTANURIC ACID, $\text{C}^9\text{H}^4\text{N}^2\text{O}^3$. See GLYOXYL-CARRAMIDE (p. 890).

LARCH FUNGUS. This fungus, treated with alcohol of 95 per cent., yields a mixture of at least four different resins. The yellowish-white portion, which dissolves with difficulty in cold alcohol, may be separated by digestion with chloroform into two different constituents. (a). The part which is insoluble in chloroform has

the composition $C^{41}H^{77}O^8$, melts at 125° , and dissolves at 14° in 303.8 pts. alcohol of 95 per cent. (8). The part which dissolves in chloroform has the composition $C^9H^{10}O$, melts at 90° , and dissolves in 130 pts. of alcohol.

The portion of the original resin which dissolves easily in alcohol of 95 per cent. has a red colour, and consists of 69.16 per cent. C., 9.44 H., and 21.40 O. It dissolves readily also in alcohol of 75 per cent., and is precipitated therefrom for the most part by water. The constituent which is soluble in water contains 61.91 per cent. C., 8.11 H., and 29.98 O.; it dissolves in 58.8 pts. of alcohol and in 590 pts. of distilled water.

A chemical change appears to be brought about in the resinous mixture by continued boiling with milk of lime, the precipitate thrown down by hydrochloric acid from the filtrate being separable by digestion with chloroform into two different substances. The part insoluble in chloroform has the formula $C^{39}H^{68}O^4$, and dissolves in 165 pts. of alcohol. The constituent which is soluble in chloroform has the composition $C^{36}H^{52}O^6$, and dissolves in 47.8 pts. of alcohol. Both of these bodies contain more carbon than the white resin. On the contrary, the red residue on the filter, which can be separated from the calcium hydrate by hydrochloric acid, and does not pass into the solution, contains a smaller amount of carbon than the red resin of the fungus.

The white resin of the fungus is tasteless. The red resin is, even after the most careful purification, intensely bitter, and is the chief cause of the bitter taste of the fungus. The resin of the Larch fungus contains no constituent which can be converted into sugar by treatment with dilute acid. Umbelliferone occurs among the products of dry distillation of the resin. The resin of the Larch fungus offers considerable resistance to the action of concentrated nitric acid. Among the products of the action of this acid, aided by heat, on the mixture of resins, are found picric acid and succinic acid (E. Masing, *Arch. Pharm.* [3]. vi. 111).

LARCH-RED. This substance, obtained by boiling the extract of larch-bark with very dilute sulphuric acid, yields protocatechuic acid when fused with 4 pts. of sodium hydroxide. The same acid may be obtained by similar means, though less advantageously, from the extract itself (Stenhouse, *Chem. Soc. Jour.* xxviii. 7).

LAUREL-WATER. Determinations of the proportion of hydrocyanic acid in laurel-water, prepared from leaves gathered at different seasons, have been made by M. Leger (*Pharm. J. Trans.* [3]. iii. 871). 1500 grams of distillate prepared in each of the twelve months of the same year from 1000 grams of leaves were found to contain the following quantities of hydrocyanic acid :

January	76 mgm.	June (old and young leaves)	84 mgm.
February	96 "	July	125 "
March	100 "	August	116 "
April {old leaves	76 "	September	110 "
{buds	100 "	October	116 "
May {old leaves	44 "	November	100 "
{young leaves	110 "	December	66 "

The loss of hydrocyanic acid which laurel-water suffers in keeping is particularly great when it is kept in corked bottles not quite filled.

On Artificial Laurel-water, see A. Ripping (*Arch. Pharm.* [3], ix. 526; *Chem. Soc. Jour.* xxxii. 241).

LAUROCERASIN. This name is given by E. Lehmann (*N. Rep. Pharm.* xxiii. 449) to a substance intermediate in composition between amygdalin and amygdalic acid (i. 201), obtained from the bark of the berry-bearing alder (*Rhamnus frangula*), and the leaves of the cherry-laurel (*Cerasus Laurocerasus*). Rhamnus bark or laurel leaves are exhausted with hot absolute alcohol; and the decoctions, mixed with recently precipitated lead hydroxide, are left to stand for a week, whereby chlorophyll and tannin are thrown down. On subsequently warming the liquid, filtering, and mixing the filtrate with ether, an amorphous precipitate is obtained which may be freed from sugar by boiling with alcohol. Of this substance rhamnus bark yields 0.7, laurel leaves 1.38, per cent. The amorphous product, when freshly precipitated, exhibits the appearance of microscopic granules; they deliquesce very quickly, appear light yellow with a glassy lustre when dried over sulphuric acid, and brownish when dried at 100° ; they are diffusible, optically dextrogyrate, and taste like salicin. Strong sulphuric acid colours them violet, afterwards brownish yellow. They are decomposed by almond-emulsion, but less easily than crystallised amygdalin. When boiled with baryta-water, they yield barium amygdalate and ammonia, of the latter, however, only half as much (reckoned on the dry substance) as is obtainable from the crystallised glucoside. To the product from rhamnus bark Masing assigns the

formula $C^{80}H^{156}N^{20}O^{71} = 2C^{40}H^{78}NO^{23} + 25H^2O$; to that from laurel leaves the formula $C^{80}H^{134}N^{20}O^{60} = 2C^{40}H^{78}NO^{23} + 14H^2O$,—the body, $C^{10}H^{32}NO^{23}$, common to them both, containing the elements of amygdalin, $C^{30}H^{27}NO^{11}$, and amygdalic acid, $C^{30}H^{26}O^{12}$. When the bark or the leaves were simply exhausted with hot alcohol, without the use of lead hydroxide, the same substance was obtained in union with a smaller quantity of water, $2C^{40}H^{78}NO^{23} + 2H^2O$.

LAUROSTEARIN. H. Schiff (*Berl. Ber.* vii. 781) points out that the correction of the older analyses of this substance according to the atomic weights now in use leads to the formula $C^{30}H^{74}O^6 = C^3H^2(O.C^{12}H^{23}O)^3$, instead of the older formula $C^{27}H^{50}O^4$ (iii. 475), so that the fat of the bay-tree, like all other natural glycerin fats, may be regarded as a normal (tri-acid) glycerin-ether—viz. tri-lauryl-glycerin. The mean of the analyses by Marsson and by Sthamer gives 73.36 per cent. carbon and 11.47 hydrogen, the formula requiring 73.35 C. and 11.60 H.

LAVA. See VOLCANIC PRODUCTS.

LEAD. *Occurrence.*—Native lead is found in the Kirghis Steppe, associated with heavy spar and cerussite in hornstone, and in the gold washings of Katharinenburg in grains, together with gold, magnetic iron ore, and specular iron ore (v. Kokscharow, *Jahrb. f. Min.* 1875, 873).

On the occurrence of lead as carbonate, sulphide, &c., see the several compounds.

Desilveration of Raw Lead.—The following method is described by Rozeau (*Dingl. pol. J.* ccxvi. 171). The lead is melted in a pot, skimmed, and then transferred to a second pot, through the bottom of which steam is passed in a fine spray. The steam is blown in with a pressure of 3 atmospheres, and to induce the crystallisation the surface of the bath is sprinkled with water. The oxides thereby formed are skimmed off, and the steam which has passed through the fused metal is condensed in chambers in which the portions of oxide carried with it are at the same time deposited. The melting pot is of course covered, and the lead thrown against the cover must from time to time be removed. As soon as two-thirds of the lead has crystallised out, the still fluid residue, which is rich in silver, is made to flow through heated tubes into moulds in which it is cast into blocks each weighing half a hundredweight. A fresh quantity of raw lead is then run in from the first pot upon the crystalline mass in the second, and the operation proceeds as before. Lastly the lead crystals are fused in the pot itself, then cast into ingots, and sent into the market.

At the St. Louis les Marseille works a jet of steam is used to stir the fused lead during the Pattinson process. By this the copper is oxidised to black oxide, and antimony is carried away with the stream of vapour; 16 tons of lead are thus worked up in a time in which only 8 to 10 tons could be desilverised by hand labour. The desilverised lead is very soft, and contains only 2 grams of silver in 100 kilograms, whereas the raw lead contains from 1600 to 2000 grams of silver in 100 kilograms (Luce a. Rozan, *Dingl. pol. J.* ccxiv. 238).

At the Clyde Lead-works in Glasgow, a method of desilveration, known as the Flach-Guillem process, is adopted. 18 tons of rich argentiferous lead are melted, 1 per cent. of zinc is added, the molten mass is left to cool, the crust of zinc containing the silver and other foreign metals is removed, and the lead sweated out in a small pot. The lead in the large pot is then treated with another $\frac{1}{2}$ per cent. of zinc in the same way. A third addition of $\frac{1}{4}$ per cent. of zinc suffices to remove the greater part of the remaining silver, 5 dwts. being left in the lead per ton. This lead is then run into the refining pan, and the last traces of zinc are oxidised out.

The zinc and silver alloy is heated in a plumbago crucible having a luted cover, and connected by a plumbago pipe with a cast-iron receiver. The zinc distils over, and is used again. The silver and lead alloy is then cupelled.

All the oxide of lead formed in the operation is reduced in a slag hearth, the fumes being condensed in Johnstone's patent condenser. The lead from the slag hearth, being very impure, has to be treated in a refining pan, by which the impurities are removed. The purified lead is then desilverised as before. Lead by this process can be desilverised in thirty hours with a loss of $1\frac{1}{2}$ per cent. The market lead contains only .0015 per cent. of antimony, and .0004 per cent. of silver (*Engineering*, 1876, September 15; *Dingl. pol. J.* ccxxv. 67).

See further, Roswag a. Geary (*Chem. Centr.* 1878, 367; *Chem. Soc. J.* xxxiv. 819); Kirchhoff (*Dingl. pol. J.* ccxxviii. 265; *Chem. Soc. J.* xxxv. 761). On Keith's method of desilveration by electrolysis, see *Dingl. pol. J.* ccxxx. 75, 328; *Chem. Soc. J.* xxxvi. 288, 410.

On the properties of pure lead, and the influence of foreign bodies on its properties and technical utility, see G. Brigel (*Deut. Chem. Ges. Ber.* vi. 191; *Dingl. pol. J.* ccvii. 490).

Hard lead may be prepared by fusing 5 parts of lead with 1 part antimony sulphide, or 2 parts of litharge with 1 part antimony sulphide. The reguli thus obtained consist of lead sulphide and lead antimonide (Brügel).

The presence of bismuth in lead is said to be advantageous in the preparation of white lead by the ordinary Dutch process, the bismuth when intimately mixed with the lead facilitating the oxidation. It often happens, however, that the bismuth accumulates at particular parts of the lead plate, and then withstands oxidation for a considerable time, the plates exhibiting certain unoxidised portions of regular shape, the fractured surface of which is covered with a black coating of metallic bismuth. This effect is probably due to overheating of the lead in melting, the interior of the metal in casting then remaining fluid long enough to allow of the formation of an alloy of lead and bismuth (H. Endemann, *Amer. Chemist*, vi. 457).

Specific Gravity.—The specific gravity of pure lead has been determined by P. Schweizer (*Amer. Chemist*, vii. 174) with the following results:

(1.)	11.352 at 23° = 11.345 at 4°
(2.)	11.366 „ 23° = 11.358 „
(3.)	11.366 „ 18° = 11.356 „

Specimen 1 was taken from the end, 2 and 3 from the middle of an ingot.

Reactions.—1. With Water and Saline Solutions. According to L. Besson (*Compt. rend.* lxxviii. 322), the deposit formed by the action of distilled water and of rain-water on lead and alloys of lead and tin, consists, not of lead carbonate as hitherto supposed, but of a compound containing ammonia, easily recognised on heating the deposit. This result is due to an electrochemical action, whereby ammonia is formed from the elements of air and water.

Mayençon a. Bergeret (*ibid.* 484) find that lead is attacked by all waters, hard as well as soft, a certain quantity of the lead dissolving in the water. According to their experiments, hydrogen sulphide will not detect extremely small quantities of lead in water, because lead sulphide, either precipitated or native, is soluble in soft water, and even in water saturated with hydrogen sulphide. If, however, an electric current be passed through a water containing lead, through which hydrogen sulphide has been passed, metallic lead will be deposited on the platinum wire forming the negative electrode. In this way it has been found that lead is dissolved even by highly calcareous waters, and that it is present in all waters which have passed through lead pipes. The quantity thus dissolved is however too small to exert any deleterious action.

G. Bischof (*Chem. Soc. J.* xxxi. 428) observed that a leaden pipe containing 1.7 per cent. antimony, which passed into a cistern where it was exposed to the alternate action of air and water, according to the variation of the level, became coated with a crust of lead carbonate containing about 4 per cent. of sulphate, whereas a pipe of pure lead exposed to similar influences remained uncorroded. This result shows the danger of using impure lead for the construction of water pipes.

According to Balard (*ibid.* 392), lead is oxidised in contact with water containing air; but if the water contains any salt capable of forming an insoluble compound with this oxide, such a salt will be formed, and the lead will become covered with a closely adhering crust which stops all further action. If, on the contrary, no such salt is present, the action will go on without interruption.

According to Bobierre and Belgrand (*Compt. rend.* lxxviii. 317), lead pipes constantly filled with drinking water are not attacked by it. Distilled water, holding in solution calcium sulphate or bicarbonate, or sodium phosphate, borate, carbonate, or bicarbonate, does not act on lead, whereas potassium nitrate, calcium chloride, barium chloride, sodium acetate, and sodium formate do not interfere with the action of distilled water on lead.

The following observations on the influence of various salts on the solvent action of water on lead, have been made by M. M. P. Muir (*Chem. News*, xxxiii. 102, 125, 145; xxxiv. 223, 234). *Nitrates* when alone, even when present in small quantity only, increase the solubility of lead in water to a very considerable extent. The presence of other salts, however, such as sulphates, carbonates, and chlorides, greatly diminishes this solvent influence of the nitrates, and sometimes destroys it altogether; the action of carbonates in this way is especially favourable. *Sulphates, carbonates, and chlorides*, added to distilled water, likewise diminish its solvent action on lead, a small quantity of either of these salts producing even a better effect than a larger quantity. In presence of those salts which exert a retarding action, the quantity of lead dissolved scarcely exhibits any further increase after the lapse of twenty-four hours, whereas in the case of salts which, like the nitrate, increase the solubility, the amount dissolved increases continuously with the duration of the action. Water

saturated with carbonic acid under ordinary pressure does not exert much solvent action on lead, but water saturated with carbonic acid under a pressure of 6 atmospheres dissolves lead in considerable quantity. The solubility is not increased by the presence of a small quantity of ammonium nitrate, and potassium carbonate exerts a retarding influence in this case also; but the quantity of lead dissolved is still so considerable as to render such water unfit for drinking.

The precipitate formed on the surface of exposed lead, or deposited at the bottom of the vessels, consists of hydrated basic lead carbonate, $2\text{PbCO}_3 \cdot \text{Pb}(\text{OH})_2$. The solubility of this salt in the saline solution is increased when access of air is prevented; addition of carbonic acid increases the solubility. A solution of potassium carbonate does not exert any solvent action on lead hydrocarbonate. The action of the air gives rise to a slow separation of the dissolved hydrocarbonate, which is slowest from the solution in ammonium nitrate. The order of solubility of lead hydrocarbonate in various saline solutions, agrees nearly with that of metallic lead in the same liquids. The following table shows the numerical results, which, however, must be regarded as only approximate.

Solubility of Lead Hydrocarbonate, $2\text{PbCO}_3 \cdot \text{Pb}(\text{OH})_2$, in various dilute Saline Solutions at ordinary temperatures.

Solution.	Grams of salt per litre.	Solubility of lead salt.	
		Experiments carried out in corked flasks.	Experiments in beakers.
Ammonium sulphate . . .	0.20	1 part in 32,000	1 part in 43,000
Potassium nitrate . . .	0.20	1 " 26,000	1 " 43,000
Calcium chloride . . .	0.20	1 " 23,000	1 " 26,000
Ammonium nitrate . . .	0.20	1 " 4,600	1 " 26,000
Water saturated with CO_2 .		1 " 4,300	1 " 4,300

(Muir, *Chem. Soc. J.* xxxi. 660).

On the action of potable waters and of saline solutions on lead, see also Fordos (*Compt. rend.* lxxvii. 1099; *Chem. Soc. J.* xxvii. 232; *Compt. rend.* lxxviii. 1108; *Chem. Soc. J.* xxvii. 872; *Jahresb. f. Chem.* 1874, 278).

According to J. Merriek (*Amer. Chemist*, iv. 289) lead is strongly acted upon by oil of turpentine.

On the action of nitric acid on lead, see NITRIC ACID.

Detection of Lead.—H. B. Cornwall (*Chem. News*, xxxiv. 27) recommends for this purpose the use of v. Kobell's test for bismuth, which consists in heating the substance under examination on charcoal, with a mixture of sulphur and potassium iodide (vii. 190), whereby a yellow sublimate of lead iodide is obtained. The great volatility of this compound renders it possible to detect lead by this reaction, even in presence of bismuth and other metals.

E. Klingelhöffer (*N. Jahrb. Pharm.* xxxix. 86) has observed the presence of lead in many commercial samples of tartaric acid. To detect it, the acid must be neutralised with ammonia before precipitating with hydrogen sulphide.

The presence of lead in tinned vessels may be detected by laying on the thickest part of the tinning a drop of nitric acid, removing the acid by gentle heating, and after the metal has cooled, laying on the pulverulent spot a small quantity of a dilute solution of potassium iodide. This solution is without action on stannic oxide, but it acts on lead nitrate, producing a yellow precipitate of lead iodide. The reaction is very delicate, giving a distinct yellow coloration even with only 1 per cent. of lead (Fordos, *Bull. Soc. Chim.* [2], xxiii. 346). With regard to this method, Fürckhauer observes that the nitric acid cannot be completely expelled by mere warming, and that consequently tin even quite free from lead will, when treated as above, exhibit a more or less distinct yellow coloration due to iodine separated by the still remaining acid. He therefore recommends that, previous to the addition of the potassium iodide solution, the spot be wetted with a very weak solution of potash. A similar process for the detection of lead in tinned vessels is given by A. Bobierre (*Compt. rend.* lxxx. 961), who, however, uses glacial acetic acid instead of nitric acid.

Estimation. 1. By *Electrolysis*.—Lead may be precipitated electrolytically in a coherent state and of a dull colour by operating on solutions, preferably alkaline, containing phosphoric and tartaric acids. The presence of acetic acid tends to keep the positive pole free from peroxide (Parodi a. Mascazzini, *Gazz. chim. ital.* vii. 222). See also Riche (*Compt. rend.* lxxxv. 226).

2. As *Iodate*.—Lead may be estimated as iodate in the absence of hydrochloric acid, or alkaline chlorides, bromides, or iodides, lead iodate being much less soluble in alcohol even than the sulphate. The lead iodate may be weighed, or it may be pre-

precipitated with a standard solution of iodic acid, the excess of which is estimated in the filtrate. The iodate solution must be standardised by means of a solution of pure lead nitrate. Hydrochloric acid rapidly dissolves lead iodate (C. Cameron, *Chem. News*, xxviii. 145).

Volumetric Estimation by Chromic Acid.—The lead salt dissolved in water is mixed with a little acetic acid, and excess of a standard chromate solution containing 14·761 grams of potassium dichromate per litre; the lead chromate is filtered off, and the excess of potassium dichromate is determined by acidulating with hydrochloric acid, and running in a solution of stannous chloride till the chromic acid is nearly but not entirely reduced. A few drops of starch paste and potassium iodide are then added, and stannous chloride cautiously poured in till the blue colour of the iodide of starch disappears (C. W. Hinman, *Am. J. Sci.* [3], xiv. 478). Pellet (*Bull. Soc. Chim.* [2], xxii. 246) adopts a similar process, but estimates the excess of dichromate by addition of a ferrous salt and titration with permanganate.

Estimation of traces of Lead in Waters.—The colorimetric estimation of traces of lead in waters, by passing hydrogen sulphide into the liquid yields very low results in presence of free hydrochloric or even of free acetic acid; indeed, traces of lead are frequently not converted into sulphide at all under these conditions. G. Bischof modifies the process by dissolving the water-residue, after it has been gently ignited, in as little hydrochloric acid as possible, filtering, and passing hydrogen sulphide for a short time through the filtrate and washings. The liquid is then mixed with a slight excess of ammonia, and again with excess of pure hydrochloric acid. The formation of ammonium sulphide in the liquid secures the conversion of all the lead present into sulphide, which then remains unchanged on again acidifying. In some cases it is preferable to unite the lead sulphide precipitate into lumps by shaking the liquid; filter this off; dissolve it in pure strong hydrochloric acid; and reprecipitate it as described above for the colorimetric estimation. This proceeding has the advantage of distinguishing lead sulphide from copper sulphide, the latter not dissolving in strong cold hydrochloric acid at all. The standard solution used for comparison is diluted if necessary in the test-glass until its colour intensity is the same as that of the test sample. Shaking of the solution after passing the hydrogen sulphide must be avoided, as the colour intensity is apt to be altered by the precipitate uniting into flakes (*Zeitschr. anal. Chem.* 1879, 73).

Assay of Lead Ores.—The following method is described by Mascazzini (*Dingl. pol. J.* cviii. 46). Pure ores are reduced with zinc and hydrochloric acid, and the metallic lead, after being separated by washing, is fused with an appropriate flux. Impure ores, containing zinc blende, copper pyrites, or iron pyrites, must first be gradually heated to redness with ammonium sulphate in order to convert the sulphides into sulphates. On subsequent treatment with sulphuric and hydrochloric acid, the lead remains as sulphate, the silver as chloride, and these compounds may be reduced with zinc, and the metals fused as above described. As a flux for fusing the spongy lead, Mascazzini recommends that proposed by Plattner, viz. 13 parts potassium carbonate, 10 sodium carbonate, 5 fused borax, and 5 dry starch. The same process may serve for the assay of lead ores rich in gold and silver, and, with certain modifications, for the valuation of antimony, tin, and copper ores.

To give greater exactness to the estimation of lead in sulphuretted ores, J. Löwe (*Dingl. pol. J.* cxix. 139), after treating the ore with nitric acid, whereby a residue is left containing more or less lead sulphate, exhausts this residue further with sodium thiosulphate, precipitates the lead thereby dissolved with hydrogen sulphide or ammonium sulphide, and converts the precipitated lead sulphide into sulphate. The amount of lead calculated therefrom is then added to the principal quantity contained in the nitric acid solution.

According to F. Mohr (*Zeitschr. anal. Chem.* 1873, 142) the decomposition of galena which Storer effects by the action of hydrochloric acid and zinc (vii. 727), may also be effected by the use of hydrochloric acid alone; and the separation of the lead in the metallic state, according to Storer's method, may take place even when the zinc is not in direct contact with the lead sulphide. The weighing of the lead in the metallic state is less exact, according to Mohr, than its estimation as sulphate or as oxalate, which latter salt is quite insoluble in excess of oxalic acid, and may be titrated with permanganate.

When galena is triturated with a solution of acid potassium sulphate, a brisk evolution of hydrogen sulphide takes place, whereas other sulphuretted minerals, with the exception of zinc-blende, do not exhibit this reaction. Acid potassium sulphate may therefore serve as a test for the recognition of galena in mixed ores (Jannettaz, *Compt. rend.* lxxvii. 838).

Lead Alloys. 1. With Antimony. The action of hydrochloric acid on alloys
Vol. VIII. 4 G

of lead and antimony has been examined by H. v. d. Planitz (*Deut. Chem. Ges. Ber.* vii. 1664). The alloys used in the experiments were formed by melting very soft lead with quantities of antimony such that the alloys contained 0.5, 1, 2, 5, 10 and 20 per cent. of antimony. They were cast in the form of rectangular plates, 6 cm. long, 2.5 broad, and 0.25 thick. In one series of experiments the plates were completely immersed in the acid, in another series only partially, so that they were partly in contact with the air. As soon as these plates were immersed in pure strong hydrochloric acid, evolution of gas began, slow with pure lead, quicker with the alloys in proportion to the quantity of antimony contained in them. The hydrogen evolved in the action of the acid on antimonietted lead contained hydrogen antimonide. After the action had continued for eight to fourteen days, a split showed itself on each edge of the plate and continually grew wider, and from the four narrowest faces of the plate four prisms separated, this effect in the case of the 20 per cent. alloy taking place after about 3 weeks. At the same time the rest of the alloy became considerably thicker, and altered in appearance, the surface becoming covered with shining scales of lead chloride. If the plates were left in the acid still longer, they ultimately split in halves, in the direction of the cleavage-face passing through the edges which were formed by the division of the prisms in the middle of the thickness of the original plates. In the alloy richest in antimony this division took place a week after the separation of the prisms. The plates had become rotten and even friable, and were penetrated throughout by chloride of lead. The same series of changes took place in the less highly antimonietted alloys, but more slowly, and in pure lead the action was scarcely perceptible. When, however, the plates were partly in contact with the air, the formation of lead chloride was facilitated, and a commencement of division was distinctly observed after some months, even in the case of pure lead.

2. With Bismuth. A case of spontaneous decomposition in an alloy of lead and bismuth is described by A. Vogel (*N. Rep. Pharm.* xxii. 471). Some castings of this alloy, of dark, nearly black colour, were covered on some points with excrescences due to oxidation, and on others the alteration had proceeded so far that the metal could be rubbed to a coarse powder between the fingers. At the same time the casting had lost its flat shape, and was curved to one side. The fresh fracture, when examined under the microscope, exhibited a grey colour, dotted here and there with metallically lustrous spangles. In every case the decomposition had commenced at one point, and spread therefrom as a centre through the entire mass. The analysis of three of these castings gave: (1). Lead 66, bismuth 34; (2). Lead 86, bismuth 14; (3). Lead 88, bismuth 12. The powder dissolved partially (20 to 30 per cent.) in acetic acid, with brisk evolution of carbon dioxide, yielding a solution containing bismuth as well as lead. The decomposition may perhaps be attributed to the well known tendency of bismuth to assume the crystalline form.

On the action of Water on Alloys of Lead and Tin, see p. 1167.

On Lead-amalgam. See MERCURY.

Lead Chloride, PbCl_2 . Roscoe (*Ber.* xi. 1196) has determined the vapour-density of this compound by heating it to bright redness in a long-necked porcelain globe. The following results were obtained:

Temperature	1046°	1089°	1077°	1070°
Specific gravity of vapour. . .	9.12	9.72	9.51	9.54

showing that the molecular formula of the compound is PbCl_2 , which gives for the calculated vapour-density the number 9.62.

Formation of Horn-lead in Historic Times.—This mineral has been found at Bourbonne-les-Bains, in prismatic crystals and thick crusts, coating two leaden pipes of Roman workmanship. One of these pipes is internally corroded even to perforation; the other encloses a bronze pipe—doubtless a repair rendered necessary by the corrosion of the latter. The bronze is coated on the inside with a layer of atacamite. Outside the crust of horn-lead is a coating of galena mixed with gypsum (Daurée, *Compt. rend.* lxxxii. 182).

Oxysalts. Carbonate.—On the occurrence and crystalline form of the native carbonate, see CERUSSITE (p. 425). On the formation of the crystallised carbonate on some objects found at Pompeii, and on the solubility of the salt in ammonium butyrate, see CARBONATES (p. 412). On the decomposition of lead carbonate by sodium oxalate and of lead oxalate by sodium carbonate, see CARBONATES (p. 410).

On the Preparation of White Lead, see K. v. Weise (*Dingl. pol. J.* ccviii. 434; *Chem. Soc. Jour.* xxvi. 1268); Wittstein (*Dingl.* ccxii. 223; *Jahresb. f. Chem.* 1874, 1119); W. Hampe (*Ann. Chem.* v. 241; *Jahresb. f. Chem.* 1875, 1074).

Sulphate.—Crystals of lead sulphate (anglesite) from the White Rose vein of

the Eleonora Mine at Langenstrieigis in Saxony, are described by A. Frenzel (*Jahrb. f. Min.* 1874, 684). They occur in three types: horizontally prismatic ($\frac{1}{2}P \infty \cdot \infty P$), pyramidal ($P \cdot 2P$, sometimes also ∞P), and upright prismatic ($\infty P \cdot \infty P2 \cdot \infty P \infty \cdot 0P$). Crystals of anglesite with numerous faces from the Hüttenberg mining district in Carinthia are described by v. Zepharovich (*Verh. geol. Reichsanst.* 1875, 75).

Sulphato-carbonate.—According to Laspeyres there are two distinct native sulphato-carbonates of lead, one anhydrous (leadhillite), the other hydrated (maxite): see vii. 732, 732; also MAXITE in this volume. Bertrand, on the other hand, regards maxite, not as a distinct mineral species, but as leadhillite altered by the action of water; and later experiments by C. Hinze (*Pogg. Ann.* clii. 256; *Jahrb. f. Min.* 1874, 974) point to the conclusion that the two minerals are identical, their composition being represented by the formula $2PbSO_4 \cdot 4PbCO_3 \cdot 2H_2O$. Both minerals when heated give off no water at 100° and only about 0.1 per cent. at 200° ; by prolonged heating, however, the following quantities of water—substantially the same for both—were obtained:

	1 h.	5 h.	10 h.	15 h.	20 h.
Leadhillite (Socotland).	0.489	0.848	0.978	1.346	1.735
Maxite (Sardinia)	0.445	0.850	0.966	1.353	1.739

The optical characters were also found to be identical. An analysis of maxite gave the values A, agreeing very nearly with those calculated from the formula above given, B:

	PbO	SO ^a	CO ^a	H ^a O	Sp. gr.
A.	80.80	8.17	9.18	2.00 = 100.15	6.547 at 18.9°
B.	80.76	8.27	9.11	1.86 = 100	

Tellurate of Lead. See TELLURIUM.

Sulphide, PbS. On the occurrence of galena in rods (so-called *Röhrenzerre*) at Raibl, see Posepny (*Jahresb. f. Chem.* 1873, 1146). On the crystallography of galena, see Sadebeck (*Zeitsch. geol. Ges.* xxvi. 617; *Jahrb. f. Min.* 1875, 86). On the occurrence of galena together with lead sulphate as an incrustation at Bourbonne-les-Bains, see p. 1170. On the decomposition of galena by zinc and hydrochloric acid, and by acid potassium sulphate, see p. 1169.

LEAD-CHAMBER CRYSTALS. See NITROSULPHONIC ACID.

LEADHILLITE. (*vid. sup.*)

LEAVES. See PLANTS.

LECANORA. The ethereal extract of *Lecanora atra*, collected in the neighbourhood of Palermo, yielded, on evaporation, a crystalline mass mixed with a soft brown resin, easily removed by washing with cold ether. The crystals are a mixture of two acids, which were separated by means of chloroform; one (*atranoric acid*) is colourless, and but slightly soluble in cold chloroform; whilst the other, which is yellow, is very soluble.

Atranoric acid crystallises from chloroform in small, colourless, transparent prisms, which melt at 190° , and are but very slightly soluble in cold alcohol or ether; it is moderately soluble in boiling chloroform. The results of its analysis correspond closely with the formula $C^{10}H^{16}O^8$. It has feeble acid characters, although it does not affect litmus, dissolving in alkaline solutions, and being reprecipitated by acids. Boiled with aniline and alcohol, it yields a compound crystallising in lustrous yellow needles, which melt at 156° . Heated with alcohol at 150° , it is converted into a crystalline substance, very soluble in alcohol. It forms long needles, which melt at 115° .

The yellow acid accompanying atranoric acid in this lichen, closely resembles usnic acid in appearance, general characters, and behaviour with solvents, but melts at 175° , whilst usnic acid melts at 195° – 197° . Heated with alcohol to 150° , it yields a substance crystallising in slender needles, and melting at 175° just like the decarbusnic acid obtained from usnic acid by this process. With aniline and alcohol it also behaves like usnic acid. The product of the dry distillation of the acid, when extracted with water and filtered from tar, gives a yellow colour with ammonia and potash, brown with ferric chloride, and deep red with sodic hypochlorite. Usnic acid (from *Zecora sordida*) gives results almost identical. This would tend to show that the acid is merely usnic acid whose melting point is lowered by the presence of some impurity in small quantity; the results of the analysis give carbon about 0.5 per cent. lower than that required by the formula $C^{10}H^{16}O^7$. It is perhaps the betausnic acid of Hesse; and the cladonic acid of Stenhouse, extracted from *Cladonia rangiferina*, may be merely impure usnic acid (Paternò a. Ogialoro, *Gazz. chem. ital.* 1877, 189).

LEDUM OIL. The volatile oil of the Marsh Wild Rosemary (*Ledum palustre*), when recently prepared, is yellowish, viscid, lighter than water, and has a pungent odour. When exposed to the air, the greater part of it solidifies to a crystalline mass soluble in alcohol. The fresh oil, when kept in closed vessels, gradually becomes thicker and finally solidifies to a gelatinous mass, which dissolves in alcohol and ether, and solidifies in large prisms when the solvent is evaporated. Chlorine, bromine, and iodine act strongly on the solidified oil (*Ledum camphor*); sulphuric acid dissolves it, forming a colourless liquid which is turned violet by nitric acid. The analysis of *Ledum camphor* leads to the formula $C^{28}H^{40}O$ (J. Trapp, *Russ. Zeitschr. Pharm.* 1874, 289; compare iii. 567).

N. Iwanow (*ibid.* 1876, 577) prepared *Ledum* oil from the plant growing in the neighbourhood of St. Petersburg, by distillation with water. The largest yield, consisting of a white crystalline mass saturated with oil, was obtained from the leaves and young twigs before flowering. By repeated crystallisation from alcohol, colourless prisms were obtained, having a faint odour, insoluble in water, but easily soluble in alcohol, ether, chloroform, and benzene; they melt at 101° to a liquid which boils at 174° ; their alcoholic solution is dextrogyrate. Their analysis led to the formula $C^8H^8O^2$. The oil which remained in the alcoholic mother-liquor yielded, on prolonged standing, another crop of crystals; the rest of the oil was not further examined. The aqueous distillate of the plant yielded, on agitation with ether, a mobile, yellowish-red, fragrant oil having the composition C^8H^{10} .

LEGUMIN. See PROTEIDS.

LEGUMINOSE. On the detection of the flour of leguminous seeds in wheat-flour, see p. 792.

LEMON-JUICE. *Adulteration with Nitric Acid.*—This acid, which has recently come into use as an adulterant of lemon-juice, to increase its acidity, converts the citric acid of the juice, wholly or partially, during the process of concentration by heat, into oxalic, acetic, and carbonic acids, so that, on neutralising the juice with milk of lime, there is obtained, instead of citrate, a mixture of oxalate, acetate, and carbonate of calcium. The nitric acid may be detected by adding to a small quantity of the juice in a test-tube, an aqueous solution of ferrous chloride strongly acidulated with pure hydrochloric acid and quite free from ferric salt; boiling the liquid for a few minutes; and testing it with potassium thiocyanate dissolved in water. If the liquid contains nitric acid, it will be coloured more or less deeply red, according to the quantity of ferric thiocyanate thus produced.

This process succeeds equally well if the juice likewise contains common salt, sulphuric acid, or tartaric acid. To apply it to boiled lemon-juice, the juice must be diluted with water in order that the colour produced by the thiocyanate may be distinctly visible (Scribani, *Gazz. chim. ital.* 1878, 284).

On the estimation of Citric Acid in Lemon-juice, see CITRIC ACID (p. 507).

LEMON-OIL. See TERPENES.

LEONHARDITE (iii. 571). Crystals of this mineral from Floitenthal are described by Brezina (*Jahrb. f. Min.* 1877, 644); they are from 1 to 4 cm. long, and exhibit the combination ∞P . OP. They have been analysed by A. Smita (*ibid.* 1878, 81), who found for the ignited substance the values given under A, agreeing nearly with the formula, $CaAl^2Si^4O^{12}$ or $CaO.Al^2O^3.4SiO^2$; (B) and for the substance heated over sulphuric acid till its weight became constant, the values C, leading to the formula $H^4CaAl^2Si^4O^{15}$ or $CaO.Al^2O^3.4SiO^2.3H^2O$ (D):

	SiO ²	Al ² O ³	CaO	H ² O	
A found. . .	60.15	25.91	14.19	—	= 100.25
B calc. . .	60.18	25.78	14.04	—	= 100
C found. . .	52.92	22.44	12.23	12.38	= 99.97
D calc. . .	53.00	22.70	12.37	11.93	= 100

Rammelsberg regards leonhardite as a laumontite (iii. 472) which has lost a molecule of water, and this view is confirmed by the experiments of Smita. Laumontite has the composition $H^4CaAl^2Si^4O^{14} + 2aq.$, and of its two molecules of crystallisation-water, one is given off slowly in dry air at ordinary temperatures, quickly at 100° , while the second requires a heat of 300° to expel it. The remainder of the water ($2H^2O$) is given off only at a red heat, and must be regarded as so-called water of constitution. Leonhardite is a laumontite which has lost about half the first molecule of crystallisation-water belonging to the latter, and therefore contains a quantity of water rather greater than that required by the formula $H^2CaAl^2Si^4O^{15}$ or $H^4CaAl^2Si^4O^{14} + aq.$, which, however, correctly represents its composition after it has been exposed for some time to dry air, or heated to 100° .

LEPIDIN, $C^{28}H^{20}O$ (also called *Lepidene*). This compound, discovered by Zinin in 1867, is formed, together with dibenzyl and an oily body, by heating benzoïn with fuming hydrochloric acid, and is separated from the other products by its sparing solubility in alcohol and ether. It crystallises from alcohol or acetic acid in feathery or laminar groups of flat needles, melts at a little above 175° , and boils at 220° . It is insoluble in water, soluble in 170 pts. of boiling alcohol, nearly insoluble in cold alcohol, soluble in 38 pts. of boiling and 92 pts. of cold ether, in 28 pts. of boiling and 500 pts. of cold glacial acetic acid (vi. 780). According to a later determination by Zinin (*Bull. Soc. Chim.* [2], xxv. 292) it dissolves at the boiling heat in 16 pts. of acetic acid of sp. gr. 1.0659.

Dibromolepidin, $C^{28}H^{18}Br^2O$, obtained by adding bromine to lepidin dissolved in acetic acid, forms needle-shaped crystals melting at 190° (vi. 781).

Chlorolepidins. The action of chlorine on lepidin dissolved in acetic acid is different from that of bromine, giving rise not to dichlorolepidin, but to needle-shaped oxylepidin (*infra*).

Dichlorolepidin, $C^{28}H^{16}Cl^2O$, is known in two modifications: (α). Lepidin heated with an equal weight of phosphorus pentachloride till all excess of the latter is distilled off, is converted into a resin, the solution of which in ether or in boiling acetic acid deposits crystals having the composition of dichlorolepidin, soluble in 66 parts of boiling alcohol, and melting at 169° . (β). The sparingly soluble modification of dichloroxylepidin (*infra*), boiled with zinc and acetic acid, dissolves readily, forming a solution which, when poured into water, yields a curdy precipitate, consisting of a mixture of two substances, one easily soluble in ether, the other insoluble; and on evaporating the solution obtained by treating this precipitate with ether, and recrystallising the residue from acetic acid, or better from alcohol, long, rather thick, white needles are obtained, consisting of an isomeric dichlorolepidin, which dissolves in 12.5 parts of boiling acetic acid, in 174 parts of boiling alcohol, and melts at 166° (Zinin, *Deut. Chem. Ges. Ber.* v. 1104; *N. Petersb. Acad. Bull.* xx. 547).

The higher chlorolepidins are obtained by heating oxylepidin in sealed tubes with pentachloride or oxychloride of phosphorus. $C^{28}H^{14}Cl^5O$ forms white crystals melting at 186° . $C^{28}H^{14}Cl^4O$ and $C^{28}H^{12}Cl^4O$ are amorphous, the former melting at 80° – 90° , the latter softening at 70° and melting at 97° (vi. 781).

Oxylepidin, $C^{28}H^{20}O^3$, formed by the action of nitric acid on a boiling solution of lepidin in glacial acetic acid, was originally obtained in yellow needles melting at 220° (vi. 781). Subsequent experiments by Zinin (*Deut. Chem. Ges. Ber.* v. 1104) have shown that it is susceptible of three modifications. When the compound obtained in the manner just mentioned is heated to 340° (slight evolution of gas then taking place), it solidifies on cooling to a resinous mass which dissolves in 8 to 10 parts of ether, and the solution yields on evaporation three kinds of crystals, viz. tablets, short four-sided prisms, and microscopic octohedrons.

Tabular oxylepidin crystallises in rhombs sometimes 10 mm. long. It dissolves in 4.5 parts of boiling alcohol of 95 per cent., and the solution may be concentrated to the strength of 1 in 45, whereupon the liquid boils up and solidifies completely. This variety of oxylepidin dissolves in 1 part of acetic acid. It may be heated to 130° without loss of weight, melts at 136° , and solidifies to an amorphous resin. Zinc does not act on its solution in acetic acid. When 20 grams of tabular oxylepidin are dissolved in a solution of 5 grams of potassium hydroxide in 40 grams of alcohol, a potassium salt is formed belonging to an acid $C^{28}H^{22}O^3$, which is insoluble in water, but dissolves in 3.5 parts of boiling alcohol, readily in ether, and separates from the boiling solutions of its salts, on acidulation, in the form of a soft resin. This acid crystallises in four-sided prisms or in hemispherical groups, and melts at 196° , with loss of water, leaving a residue of tabular oxylepidin (Zinin, *Ber.* v. 1104).

Octohedral oxylepidin, besides being formed, together with the other two modifications, in the manner above mentioned, is likewise produced by boiling the needle-shaped variety with alcoholic potash or soda. To prepare it, 20 parts of needle-shaped oxylepidin are heated in a reflux apparatus with 300 parts of 95 per cent. alcohol and about 15 parts caustic soda, till the crystalline mass, which has become granular, no longer exhibits any needles when examined by the microscope (12 to 15 hours). Should the liquid, which is usually light yellow, assume a dark brown colour during the boiling, it must be poured off from the deposit, and the latter, after washing with alcohol, boiled with a fresh portion of alcoholic soda solution. 20 grams of needle-shaped oxylepidin yield about 15 grams of the octohedral modification, which may be purified by washing with alcohol, water, and ether, and recrystallisation from acetic acid. Octohedral oxylepidin is very slightly soluble in boiling alcohol, and dissolves in 76 parts of boiling acetic acid. It melts at 232° to a liquid, which

solidifies again in the crystalline form at 200°. It is not acted on by boiling alcoholic potash.

By dry distillation all the three oxylepidins are converted into a body which may be purified by washing with a small quantity of ether, treatment with alcoholic potash, and recrystallisation from alcohol. This substance dissolves in 18 parts of boiling and 266 parts of cold 95 per cent. alcohol, and crystallises in four-sided plates which may be heated to 130° without loss of weight, and melt at 150°. It agrees in composition with the formula $C^{28}H^{20}O$, and is therefore isomeric with lepidin.

Dibromoxylepidin, $C^{28}H^{18}Br^2O^2$, is known in four modifications. One of them, which crystallises in needles, is obtained by adding bromine in excess, but by small portions, to a boiling solution of needle-shaped oxylepidin in glacial acetic acid. Another modification is produced by treating needle-shaped oxylepidin with bromine not in excess, also by the action of nitric acid on dibromolepidin dissolved in glacial acetic acid. It melts at 222°, dissolves in 40 parts of boiling acetic acid, and separates therefrom on cooling in the form of a radiate crystalline mass. When heated above its melting point, it is converted into a resinous substance, easily separable into two dibromoxylepidins isomeric with the preceding, and analogous to the two dichloroxylepidins produced in a similar manner (*infra*). One of them is very sparingly soluble, whilst the other is a resinous substance easily soluble in alcohol, ether, and glacial acetic acid, and converted by alcoholic potash into dibromoxylepidinic acid, which is monobasic, dissolves in boiling acetic acid, and crystallises therefrom on cooling in six-sided laminae.

The sparingly soluble modification is also produced by heating needle-shaped dibromoxylepidin with a quantity of alcoholic potash not sufficient to dissolve it completely: it is nearly insoluble in ether; a mixture of 66 parts acetic acid and 1000 parts boiling alcohol of 95 per cent. dissolves it partially, and the solution on cooling deposits it in rather thick, lemon-yellow rhombic plates, which melt at 239°, and are converted at a higher temperature into the resinous modification. Needle-shaped dibromoxylepidin, or its sparingly soluble isomeride, dissolved in 12 parts of acetic acid and subjected to the action of zinc, is converted into a mixture of dibromolepidin (m. p. 190°) and hydrodibromoxylepidin, $C^{28}H^{20}Br^2O^2$, which may be separated by precipitating them with water, drying the crude mass, and treating it with ether in which the dibromolepidin is very easily soluble. Needle-shaped dibromoxylepidin moistened with alcohol and treated with sodium-amalgam, and the sparingly soluble modification subjected to the action of zinc and acetic acid, behave like the corresponding dichloroxylepidins when similarly treated (Zinin, *N. Petersb. Bull.* xxi. 66).

Chloroxylepidins. *Monochloroxylepidin*, $C^{28}H^{19}ClO^2$, is formed by heating 2 parts tabular oxylepidin, 2 parts phosphorus pentachloride, and 1 part phosphorus oxychloride to 180°–200° for 12 hours, and remains, on treating the product with water and 4 or 5 vols. ether, as a white powder, which, after crystallisation from boiling acetic acid (1 part dissolving in 22.8 parts of the acid), resembles tetrachlorobenzene in appearance and solubility. It melts without loss of weight at 185° (Zinin, *Ber.* v. 1104).

Dichloroxylepidin, $C^{28}H^{18}Cl^2O^2$, like the corresponding bromine-compound, is known in several modifications. One of these is prepared by heating 1 part lepidin with 4 or 5 parts phosphorus pentachloride to 115°–120° till the whole is dissolved, pouring the hot product, which solidifies on cooling, into water, and washing the precipitate with ether; also by the action of oxidising agents on needle-shaped dichlorolepidin. It forms small needles, which melt without loss of weight at 20.2°, and dissolves in 90 parts boiling ether, in 13.7 parts boiling and 146 parts cold acetic acid (Zinin, *loc. cit.*); according to a later determination (*N. Petersb. Acad. Bull.* xxi. 66) it dissolves in 10.8 parts boiling acetic acid of sp. gr. 1.0659. When dissolved in acetic acid (1 part in 7) and boiled with zinc, it is converted into a mixture of dichlorolepidin (60 per cent.) and hydrodichloroxylepidin, $C^{28}H^{20}Cl^2O^2$ (15 per cent.), separable by ether, in which dichlorolepidin dissolves with great facility.

When this needle-shaped dichloroxylepidin is heated nearly to its boiling point, it is converted into two isomeric modifications, one of which is very soluble in alcohol, ether, and acetic acid, separates from its solutions in the form of a soft resin, and reacts with alcoholic potash, similarly to tabular oxylepidin (p. 1173), yielding a monobasic acid, viz. dichloroxylepidinic acid, $C^{28}H^{20}Cl^2O^3$ (p. 1175). The portion of the overheated dichloroxylepidin which is insoluble in ether (3 to 4 per cent. of the whole) is also a dichloroxylepidin, and is analogous in its characters to octohedral oxylepidin. When heated to commencing ebullition, it is converted into the easily soluble modification which yields dichloroxylepidinic acid. This modification, called by Zinin 'sparingly soluble dichloroxylepidin,' is also produced in large quantity by

the action of alcoholic potash or soda on needle-shaped dichloroxyepidid. To prepare it, a mixture of 20 grams needle shaped dichloroxyepidid, 200 alcohol and 15 sodium hydroxide is heated (for 20 to 24 hours) till the sediment, when examined by the microscope, appears free from needle-shaped dichloroxyepidid; the product amounts to 16 grams. It forms a granular powder, the individual grains of which appear under the microscope as groups of short thick four-sided prisms. It melts at 230° , is nearly insoluble in alcohol and in ether, and dissolves in 36 parts of boiling acetic acid, the solution on cooling retaining only 2 per cent. of the substance. It is identical with the modification obtained in small quantity by the action of heat on needle-shaped dichloroxyepidid.

Dichloroxyepididinic acid, $C^{28}H^{20}Cl^2O^2$.—When dichloroxyepidid heated above its melting point is treated with ether and the ether left to evaporate, the remaining resinous mass dissolved in boiling alcohol containing a little caustic potash, the solution largely diluted with water, and the filtered liquid mixed with acetic acid, a yellowish resin is precipitated which becomes hard and brittle on cooling. On pulverising it and adding a little acetic acid, the powder softens and partly dissolves, and suddenly there is formed a compact brittle mass, which is to be pulverised and washed with small quantities of cold acetic acid; the white mass which then remains is nearly pure dichloroxyepididinic acid. The crude resin, if treated with a sufficient quantity of acetic acid, readily dissolves, forming a solution which soon becomes turbid, and deposits a crystalline powder identical with that which is obtained by repeated washing.

Dichloroxyepididinic acid crystallises with difficulty from alcohol and ether, much more readily from acetic acid. 1 part of it dissolves in 16 parts of boiling acetic acid, and from the cooled solution, the acid after some time separates completely in rhombic laminae. It melts at 182° , gives off 1 mol. H^2O at a higher temperature (about 200°), and solidifies on cooling to a yellowish, transparent, hard, brittle, resinous mass, identical with the resinous product, which yields dichloroxyepididinic acid when treated with potash.

Hydroxyepidid, $C^{28}H^{22}O^2$. When 1 part of octohedral oxyepidid is boiled with 14 parts of acetic acid and a small quantity of zinc, the oxyepidid dissolves, and on pouring the solution, after a few minutes' boiling, into water, a precipitate is obtained, which when washed, dried, and drenched with thirty parts of ether, dissolves partially, leaving a residue of hydroxyepidid amounting to about 15 per cent. of the oxyepidid employed, while the larger portion which passes into solution consists of lepidin. Hydroxyepidid may also be prepared by mixing the solution of 1 part octohedral oxyepidid in 42 parts of boiling acetic acid with twice its volume of alcohol, adding small pieces of sodium-amalgam (Na^2Hg) till the liquid on cooling no longer deposits a granular crystalline precipitate, pouring the solution into water, and treating the precipitate with ether as above. The quantity of hydroxyepidid thus obtained is about 18 per cent. of the oxyepidid employed. Needle-shaped oxyepidid heated in acetic acid solution with zinc does not yield any product sparingly soluble in ether, but appears to be entirely reduced to lepidin. On the other hand, by boiling 1 part of needle-shaped oxyepidid with 20 parts of alcohol; gradually adding sodium-amalgam and acetic acid in such proportion as to keep the liquid constantly neutral; decanting the solution after some time ($1\frac{1}{2}$ hour per 10 grams of oxyepidid, after addition of 150 grams of sodium-amalgam) from the crystalline deposit (which amounts to a third of the weight of the oxyepidid employed); and crystallising this deposit from boiling acetic acid—hydroxyepidid is obtained, agreeing in its properties with that above described. The alcoholic solution decanted from the crystals contains lepidin.

Hydroxyepidid, after purification by washing with a little ether and crystallisation from acetic acid, forms long flat delicate needles, nearly insoluble in cold alcohol and ether. 112 parts of boiling acetic acid dissolve only 1* part of hydroxyepidid, and 99 per cent. of that which is dissolved crystallises out on cooling. It melts at 251° .

Hydrodichloroxyepidid, $C^{28}H^{20}Cl^2O^2$, is produced by boiling dichloroxyepidid—either the needle-shaped or the sparingly soluble modification (p. 1173)*—with zinc and acetic acid, and pouring the resulting solution into water, whereby a curdy precipitate is obtained which is a mixture of dichlorolepidin, m. p. 166° (p. 1173), soluble in ether, and hydrochloroxyepidid, which is insoluble in ether, and may be purified by crystallisation from acetic acid or xylene. The yield amounts to about

* Zinin's statements on this point are somewhat contradictory. In 1875 (*N. Petersb. Acad. Bull.* xx. 547) he stated that *needle-shaped* dichloroxyepidid dissolved in acetic acid does not appear to be altered even by prolonged boiling with zinc; but in 1876 (*ibid.* xxi. 66) he says this dichloroxyepidid is converted by the same treatment into dichlorolepidin and hydrodichloroxyepidid.

25 per cent. of the dichloroxyepid in employed. The same body is obtained by boiling sparingly soluble dichloroxyepid in with 40 parts alcohol, and adding sodium-amalgam and acetic acid by small portions, till the granular deposit is converted into a mass of minute needles: the yield is about 30 per cent. The best mode of preparation however is to boil 20 grams of needle-shaped dichloroxyepid in with 400 grams alcohol, adding sodium-amalgam and acetic acid in such proportions that the liquid may constantly remain acid. After two or three hours—during which time 150–200 grams amalgam will have been added—the liquid, while still hot, is decanted from the deposit; the latter, after washing on a filter, first with alcohol and then with a little water, is boiled with 180 grams acetic acid; and the solution is decanted hot, and again boiled with an equal quantity of acetic acid. The residue (8–9 grams) is nearly pure hydrodichloroxyepid in.

Hydrodichloroxyepid in is quite insoluble in alcohol and in ether, but dissolves in 205 parts boiling acetic acid, and separates therefrom in flat, rather long needles, melting at 261°.

Hydrodibromoxyepid in, $C^{28}H^{20}Br^2O^2$, is prepared, like its chlorine analogue, by the action of zinc and acetic acid on dibromoxyepid in (needle-shaped or sparingly soluble), the product being a mixture of dibromolepid in soluble and hydrodibromoxyepid in insoluble in ether. The latter is but very slightly soluble in alcohol as well as in ether, but dissolves in 172 parts of boiling acetic acid, and crystallises therefrom in needles.

Dioxyepid in, $C^{28}H^{20}O^3$, is known in two modifications, one formed from needle-shaped, the other from octohedral oxyepid in.

(1). Needle-shaped oxyepid in (25 grams) in fine powder is drenched with 20 grams acetic acid, a solution of 12 to 15 grams chromic acid in 150 grams glacial acetic acid is added, and the whole is cautiously heated to 90°–95°, till the liquid exhibits a yellow but not a blue colour. The resulting solution on cooling deposits the dioxyepid in in large rhombic, nearly square plates, which may be purified by washing with alcohol and recrystallisation from alcohol.

This dioxyepid in melts at 157°, and solidifies to a resin, which again becomes crystalline at 150°. It dissolves in 24 parts of 95 per cent. alcohol at the boiling heat, the cooled solution retaining only $\frac{1}{17}$ th part of it. It is nearly insoluble in cold crystallisable acetic acid, but dissolves in about its own weight of the same acid at the boiling heat. Chromic acid oxidises it to benzoic acid and benzile; reducing agents have no effect upon it. Alcoholic potash, even when dilute, resolves it into dioxybenzoin and benzoic acid:

whence its rational formula is $C^{14}H^{10}(C^{14}H^9O)^2O$ (Zinin, *Zeitschr. f. Chem.* vii. 483).

(2). The other modification of dioxyepid in, $C^{28}H^{20}O^3$, is obtained by boiling 1 part octohedral oxyepid in with 6 parts acetic acid, adding crystals of chromic acid by small quantities, the action of each being allowed to complete itself before a further portion is added, and pouring the liquid into water as soon as all the oxyepid in is dissolved, and no more crystals appear to form on cooling. By recrystallising the product from alcohol, dioxyepid in is obtained in white, nacreous, striated, rhombic plates, melting at 164°. The yield amounts to about a third of the oxyepid in used, the remainder being oxidised to benzoic acid. 1 part of this dioxyepid in dissolves in 10 parts boiling alcohol, and 4 parts boiling acetic acid. In ether it is less soluble than in alcohol. It is distinguished from the preceding modification by its melting point, and by its resistance to the action of alcoholic potash, which does not affect it, even when concentrated and at the boiling heat (Zinin, *N. Petersb. Bull.* xx. 547).

Isolepid in, $C^{28}H^{20}O$ (Zinin, *Bull. Soc. Chim.* [2], xxvii. 456; *Deut. Chem. Ges. Ber.* v. 1104; x. 80). This compound, isomeric with lepid in, is produced by the dry distillation of either of the three oxyepid ins above mentioned, and may be purified by washing the distillate with a small quantity of ether, treating it with alcoholic potash, and recrystallising from alcohol. It dissolves in 18 parts of boiling and 266 parts of cold alcohol of 95 per cent., and crystallises in four-sided plates, which do not lose weight at 130° and melt at 150°. It dissolves also in 2 pts. of boiling acetic acid. By distillation it is partly decomposed and converted into a resinous mass. Alcoholic potash does not affect it. By oxidising agents it is converted first into oxyisolepid in, and finally into benzophenone, with benzoic acid and a small quantity of benzile as secondary products.

Dihydro-isolepid in, $C^{28}H^{22}O$, is formed by the action of zinc-dust on a solution of isolepid in in 5 or 6 pts. of glacial acetic acid, and may be separated by pouring the green liquid portion of the product into water, whereby a precipitate is formed, which is to be washed, dried, and treated with ether (to remove a resinous colouring

matter), and finally purified by crystallisation from boiling alcohol. It is thus obtained in small rectangular prisms which melt at 182° , dissolve very slightly in ether, in 12½ pts. boiling acetic acid, and 95 parts alcohol of 95 per cent. It is very slowly attacked by chromic acid and other oxidisers; more easily by phosphorus pentachloride than isolepidin.

Tetrahydro-isolepidin, $C^{26}H^{24}O$, is produced by the action of sodium-amalgam on a boiling alcoholic solution of isolepidin (15 to 20 pts. Na^+Hg to 1 pt. isolepidin), or more advantageously on dihydro-isolepidin, and is separated from the crude product by distilling off the greater part of the alcohol, and pouring the residue immediately into water, whereby a precipitate is obtained, soft and resinous at first, but hardening after washing and prolonged boiling with water. On dissolving this mass in ether, and leaving the ether to evaporate, the tetrahydro-isolepidin separates, at first as a soft resinous mass, which afterwards coagulates in crystalline lumps. These melt at 182° , and resolidify to a translucent resin; they dissolve readily in acetic acid and in alcohol, somewhat less easily in ether. By chromic acid in acetic acid solution, tetrahydro-isolepidin is reconverted, even at ordinary temperatures, into dihydro-isolepidin.

Oxyisolepidin or **Isoxylepidin**, $C^{28}H^{20}O^2$. This compound, as already observed, is the first product of the action of oxidising agents on isolepidin. To prepare it, a solution of 3 pts. isolepidin in 40 pts. acetic acid is mixed with a solution of 3 pts. chromic acid in 30 pts. acetic acid, and the tufts of needles which separate in the course of 24 hours are separated from the supernatant liquid and purified by crystallisation from boiling alcohol. In preparing this compound, it is not advisable to operate on more than 5 grams of isolepidin at a time, as when larger quantities are used, a rise of temperature takes place, which leads to the formation of a large quantity of benzile as a bye-product.

Oxyisolepidin thus prepared crystallises in short, thin, dull-white needles, melts at 160° , dissolves in 40 pts. boiling and 600 pts. cold alcohol, in 4 pts. boiling acetic acid, freely also in boiling benzene, from which it crystallises in nodular groups of quadrangular plates. It is not altered by boiling alcoholic potash. It appears to be dimorphous, for when an ethereal or alcoholic solution of the compound, which no longer yields needles on cooling, is left to evaporate, it deposits wedge-shaped crystals with quadrangular base, having the same composition as the needles. The same crystals may be obtained directly by boiling the ordinary needle-shaped crystals for some time with a quantity of alcohol not sufficient to dissolve them completely, or more easily from a solution of the needles in alcoholic potash. The wedge-shaped oxyisolepidin melts at 162° , and when heated above its melting point till a rapid evolution of gas-bubbles takes place, assumes an orange-brown colour, and solidifies on cooling to a translucent resin, from which ether (10–15 pts. to 1 pt. of the resin) extracts a crystalline body; and this latter, when purified by washing with ether, and recrystallised from alcohol or glacial acetic acid, forms rhombic plates very slightly soluble in ether, dissolving in 13.5 pts. boiling acetic acid and 80 pts. boiling alcohol, and melting at 152° . This substance, which may also be obtained by distilling the oxyisolepidin above described, and exhausting the distillate with ether, appears from its composition and properties to be an isomeric oxyisolepidin.

Oxyisolepidin dissolved in acetic acid and treated with zinc is converted into the above-described dihydro-isolepidin. When oxidised by *chromic acid* (2 pts. to 1 pt. oxyisolepidin) in acetic acid solution at the boiling heat, it yields four bodies—namely, an oily substance in very small quantity, benzoic acid, benzile, and as chief product, benzophenone. The oily substance may be removed by subjecting the half-solidified mass to pressure, and the benzophenone may be separated by boiling the residue with a weak solution of potash in alcohol of 40 per cent., and precipitating with water.

Oxylepidinic acid, $C^{28}H^{22}O^3$, is formed as a secondary product in the preparation of isolepidin, and is found in the alcoholic potassic mother-liquor which remains after the purification of that substance (p. 1176); it may be obtained in larger quantity by exhausting the crude distillation product of the oxylepidins with ether, and boiling the resin which remains on evaporating the ether with alcoholic potash. The acid thereby dissolved may be separated by pouring the solution into water, heating the liquid to expel the alcohol, and precipitating with acetic acid; and purified by dissolving the crude product in aqueous potassium carbonate, precipitating fractionally with acetic acid, repeating these operations if necessary, and recrystallising the last precipitated portions from acetic acid. Oxylepidinic acid dissolves in 2 pts. of boiling acetic acid, and melts at 166° (Zinin).

LEPIDINE, $C^{30}H^{22}N$. When sodium-amalgam is added to lepidine, the mixture becomes hot, acquires a reddish-brown colour, and finally solidifies. Water added to

this product separates a yellowish oil, which, when boiled with water and an acid, yields a deep reddish-brown solution, depositing as it cools crystals of a splendid scarlet colour. These crystals must be dried in the dark, since they are altered in colour by light, as is also the case with silk or wool dyed with this substance. When nitric acid was used, the solution on cooling gave a crop of red crystals having the composition of *dilepidine nitrate*, $C^{20}H^{18}N^2.HNO^3$. Chinoline behaves in a similar manner, the red substance yielding with hydrochloric acid, crystals of *dichinoline hydrochloride*, $C^{18}H^{14}N^2.HCl$ (C. Greville Williams, *Chem. News*, xxxvii. 85).

LEPIDIUM. The volatile oil of garden cress (*L. sativum*) has been shown by Hofmann to consist of *α*-toluonitril, $C^6H^5.CH^2.CN$ (see *CRESS OILS*, viii. 584).

LEPIDOLITE. On the preparation of Lithium from this mineral, see **LITHIUM**.

LESLEYITE. This name has been applied to certain micaceous minerals, accompanying corundum in Chester Co., Pennsylvania, and in North Carolina, which have been regarded by some mineralogists as forming a distinct species, but according to Brush and Genth, are mixtures of corundum with damourite and *Æaspore*, or with damourite alone (see *Jahresb. f. Chem.* 1869, 1219; 1873, 1153).

LETTSSOMITE. This mineral, originally found, in small quantities, in the Bannat, has lately been obtained from the Garonne mine, Département du Var, where it occurs in radiate groups of capillary crystals forming thin coatings on slabs of sandstone. The following analysis by Pisani (*Compt. rend.* lxxvi. 1418) agrees closely with that by Percy of lettssomite from the Bannat:

SO ³	CaO	CaO	Al ² O ³	Fe ² O ³	H ² O
12.10	49.00	2.97	11.21	1.41	22.50 = 99.19

Pisani considers lettssomite as a distinct species, both on account of its fibrous structure, and of the close resemblance in composition shown by specimens collected from two localities so widely separated as those above mentioned.

LEUCANILINE, $C^{20}H^{21}N^3$ (iii. 574; vii. 733). A base supposed to be identical with leucaniline is formed, with evolution of ammonia, by heating rosaniline or its acetate to about 192° with excess of dimethylaniline. The product freed from dimethylaniline by distillation and treatment with steam, is a brownish resinous mass, from the solution of which in hydrochloric acid, the greater part of the impurities present may be thrown down by addition of common salt. By separating the base with an alkali, and repeating this treatment several times, it is obtained pure, and then melts at 86° (Nietzki, *Arch. Pharm.* [3], v. 41). According to Hofmann, leucaniline melts at 100°. Dale a. Schorlommer (*Deut. Chem. Ges. Ber.* x. 1016, 1123) obtain leucaniline by heating aurin with alcoholic ammonia at 150° for several days, or with aqueous ammonia to 120° for twenty hours. E. and O. Fischer (*Ber.* xi. 1079), by oxidising a solution of trinitrophenylmethane in glacial acetic acid with chromic acid, obtained a white crystalline trinitrocarbinol, $C^{10}H^{12}(NO^3)_3OH$, melting at 171°–172°, which, when treated with zinc dust, yielded paranitrorosaniline and finally leucaniline.

Diazoleucaniline Chloride, $C^{20}H^{18}N^6Cl^2$, prepared in the ordinary way, is a light yellow glutinous mass, which unites with auric chloride, forming the double salt $C^{20}H^{18}N^6Cl^2 + 3AuCl^3$. The chloride dissolves in water, forming a greenish-blue solution, which decomposes when boiled, depositing a dingy brown precipitate only partially soluble in potash.

The hydrocarbon, $C^{20}H^{18}$, corresponding with this diazo-compound, is not easily prepared from the latter when once it has been separated and thereby rendered sparingly soluble in alcohol; but it may be obtained by the following method: 300 grams of leucaniline are dissolved in 1500 g. strong sulphuric acid; the solution, in portions of 40 g. each, is treated with nitrous acid, and after the excess of the latter has been expelled by a strong current of air, each of these portions is slowly added to 250 g. boiling alcohol. The several portions of liquid are then united; the whole is neutralised with sulphuric acid; evaporated to one-fourth of its bulk; then largely diluted with water; and the oil thereby separated is extracted with ether. After the evaporation of the ether, there remains a dark brown oily residue which may be freed by soda-ley from sulphoacids and phenolic bodies. On again exhausting with ether and distilling, the greater part of the liquid (85 g.) passes over above the range of the mercurial thermometer, while a small carbonaceous residue remains in the retort. The liquid thus obtained, having been completely dehydrated with sodium and again rectified, yields 55 g. of a light yellow heavy oil which has a faint bluish fluorescence, and thickens in a freezing mixture without solidifying, but separates in the crystalline state after a few days from a hot saturated solution in methyl alcohol; the concentrated mother-liquors solidify partially after several months. By repeatedly crystallising this product from methyl alcohol, the hydrocarbon, $C^{20}H^{18}$, is obtained in spherical groups of colourless

prisms, melting at 58° , and boiling without decomposition at a temperature above 360° . It dissolves easily in ether, benzene, and ligroin, sparingly in cold alcohol, and shows but little tendency to crystallise. Treated in acetic acid solution with fuming nitric acid, and with bromine, it yields solid nitro- and bromo-derivatives which crystallise with difficulty. By oxidation with chromic acid it is converted into a ketone, $C^{20}H^{16}O$, which crystallises from hot ligroin in nodular groups of colourless laminae, softens at 143° , melts at 148° – 149° , and appears to be completely decomposed by further oxidation (E. and O. Fischer, *Ber.* ix. 891).

LEUCAURIN, $C^{20}H^{16}O^3$. See vol. vii. p. 119.

LEUCEIN. See PROTEIDS.

LEUCHTENBERGITE. This mineral, from Slatoust in the Ural, regarded by some mineralogists as a distinct species, by others as a variety of pennine or clinocllore (i. 914; iii. 575; vi. 782), has been further examined by Duke Nicholas von Leuchtenberg (*N. Petersb. Acad. Bull.* ix. 188; xxi. 509). The specimen analysed, and regarded as normal, was obtained from the Chichime mountains. It forms large hexagonal plates, easily split at right angles to the optic axis. The laminae thereby separated are translucent, with a fatty to nacreous lustre, white or faint greenish colour, and difficultly friable like talc; in polarised light they exhibit the appearance of uniaxial crystals. Hardness 2.5. Sp. gr. 2.61–2.64. Analysis gave the following composition, agreeing with Descloizeaux' formula for clinocllore, $5SiO^2.2Al^2O^3.9MgO + 7H^2O$:

SiO^2	Fe^2O^3	CaO	MgO	Al^2O^3	H^2O
30.46	2.22	0.11	34.52	19.74	12.74 = 99.79

Leuchtenbergite must accordingly be regarded as a distinct mineral species belonging to the chlorite family.

Microscopical examination of fresh and decomposed material showed the following enclosed minerals: garnets, cubic and prismatic forms, which were regarded as perowskite, and lastly needles, the species of which could not be determined. By weathering, the colour of the mineral is changed to yellowish and afterwards to dark green; the facility of cleavage is diminished; and in certain stages of the alteration, the mass appears interspersed with granules, some of which exhibit the optical characters of quartz.

LEUCIC ACID, $C^8H^{12}O^3$, and **LEUCINITRIL**, $C^8H^{11}NO$. Erlenmeyer a. Sigel (*Deut. Chem. Ges. Ber.* vii. 1109), by combining hydrogen cyanide with valeraldehyde, $C^4H^{10}O$, from fermentation amyl-alcohol, have obtained the true leucinitril, $(CH^3)^2CH.CH^2.CH(OH).CN$, differing essentially from the body to which that name has hitherto been attached (vi. 782; vii. 784), inasmuch as it is completely resolved by fuming hydrochloric acid into sal-ammoniac and leucic or oxycaproic acid:

$(CH^3)^2CH.CH^2.CH(OH).CN + HCl + 2H^2O = NH^4Cl + (CH^3)^2CH.CH^2.CH(OH).COOH$.

Leucinitril is a colourless oil of agreeable odour, lighter than water, not quite insoluble therein, soluble in all proportions of ether and alcohol. It does not alter at 100° , but is resolved at higher temperatures into valeraldehyde and hydrogen cyanide.

Leucic acid, obtained as above, may be separated from the sal-ammoniac solution by ether, and remains, on evaporating the ether, as a syrup which gradually solidifies to large transparent crystalline laminae. It is very soluble in water, alcohol, and ether.

N. Ley (*Ber.* x. 231) has also prepared from valeraldehyde, by means of hydrocyanic and hydrochloric acids, an acid which agrees in most respects with leucic acid, but melts at 54° – 55° , whereas leucic acid, according to Waage (iii. 576), melts at 73° . Ley's acid is oxidised by chromic acid mixture to carbon dioxide, an acid having the composition $C^8H^{10}O^2$, and valeral.

Putrefaction of Leucic Acid.—A mixture of 10 grams calcium leucate, 10 calcium carbonate and 50 putrid fibrin in 12 litres of water was found to yield, as gaseous products, CO^2 , CH^4 , and H_2 and as liquid products, caproic, butyric, and acetic acids (J. Stolnikoff, *Zeitschr. physiol. Chem.* i. 345).

LEUCINE or **AMIDOCAPROIC ACID**, $C^6H^{12}NO^2 = C^5H^{10}(NH^2)^2.CO^2H$.

Occurrence in Plants.—The juice of vetches grown in moist garden-soil and germinated in the dark—perfectly fresh and freed from albuminoids by boiling and partly also by dialysis—has been found to contain, together with asparagine, a not inconsiderable quantity of leucine, both these bodies being doubtless produced by transformation of proteids stored up in the seed. When the mother-liquor decanted from the asparagine was somewhat further concentrated, crystalline crusts separated, after a short time, on its surface, appearing under the microscope as groups of well-defined spherules, and exhibiting all the reactions of leucine (Gorup-Besanez, *Beil. Ber.* vii. 146; see

also Cossa, *Gazz. chim. ital.* 1875, 314). The basic substance called *chenopodine*, which Reinsch obtained from *Chenopodium album* (vii. 429), is regarded by Gornup-Besanez as identical with leucine.

Leucine has also been found in small quantities, together with tyrosine and glutamic acid, in young pumpkin-plants (Schulze a. Barbieri, *Ber.* xi. 1233).

On the occurrence of leucine in the aqueous extract of yeast, see FERMENTS (p. 783).

Formation.—*a.* Together with tyrosine, asparagine, glutamic acid, and ammonia, by the action of stannous chloride on albumin animal or vegetable, casein, and legumin dissolved in hydrochloric acid (Hlasiwetz a. Habermann), see PROTEINS. *β.* Together with ammonia, glycocine, tyrosine, a yellowish body called *gelatin peptone*, and a very small quantity of indole, by the pancreatic digestion of gelatin (Nencki, *Ber.* vii. 1593). Jeanneret (*J. pr. Chem.* [2], xv. 353), by subjecting gelatin for eleven days to the action of the organised ferments of the pancreas, in a vessel from which the air was excluded, obtained leucine, but when the air had access to the vessel, no formation of leucine was observed.

Density.—According to Engel a. Vilmain (*Bull. Soc. Chim.* [2], xiv. 279), the specific gravity of leucine is 1.293 at 18°.

Oxidation.—Leucine is converted by oxidation into carbamic acid, which indeed appears to be invariably produced by the oxidation of nitrogenous carbon-compounds in alkaline solution, or generally when carbon dioxide and ammonia come together in the nascent state (Drechsel, *J. pr. Chem.* [2], xii. 417). See also CARBAMIC ACID (p. 382).

Reaction with Urea.—When leucine and urea are fused together, a compound is formed which crystallises in needles and appears to consist of uramido-caproic acid (Huppert a. Hofmeister, *Ber.* vi. 1278).

Reaction with Benzoyl Chloride.—When thoroughly dried leucine is heated to 100° with benzoyl chloride, the mixture fuses and turns yellow, while benzoic acid separates on the surface in long needles, the reaction being terminated as soon as the evolution of hydrochloric acid ceases. On treating the mass with tepid water to remove the benzoic acid, a yellow substance is left partly soluble in hot alcohol, and the portion insoluble in that liquid consists of amidocaproic anhydride,

its formation being represented by the equation

Amidocaproic anhydride is a white amorphous body, which becomes gelatinous when repeatedly washed with boiling alcohol, and is not easily reconverted into leucine even by prolonged boiling with water. The portion soluble in alcohol consists of *dibenzoyl-amidocaproic anhydride*, $(\text{C}^6\text{H}^{11}\text{NO}.\text{C}^7\text{H}^5\text{O})^2\text{O}$. It is yellow and amorphous, soluble in alcohol, insoluble in water, melts at 85°, is resolved by boiling with water into benzoic acid and amidocaproic anhydride, and decomposes when heated on platinum foil, giving off benzoic acid (A. Destrem, *Compt. rend.* lxxxvi. 484).

LEUCINITRIL, see p. 1178.

LEUCITE. This mineral, hitherto known only as of European occurrence, has been found by Vogelsang—together with augite, plagioclase, sanidin, and small quantities of magnesia-mica and apatite—as a constituent of the basalt of Gunung Bantal Soesoem, on the small island of Bawean, near the north coast of Java (P. Zinkel, *Min. Mitth.* 1875, 227). According to F. A. Anger (*Min. Mitth.* 1875, 153) leucite is the chief constituent of the trass of Lake Laach and of the Ries.

Crystalline Form.—Vom Rath inferred, from the measurement of the angles of leucite, and from the striation of its faces, which indicates twin-formation, that it belongs, not to the regular system, as generally supposed, but to the quadratic system (vii. 787). Scacchi, on the other hand (*Zeitschr. geol. Ges.* xxiv. 503), regards the mineral as belonging to the regular system, and attributes the difference in the angular measurement to errors of observation. Hirschwald also (*Min. Mitth.* 1875, 227) regards leucite 'as a regular crystal-species with polysymmetric development in the direction of the quadratic system.' Vom Rath (*Pogg. Ann. Ergänzbd.* vi. 198) defends his conclusions respecting the quadratic form of leucite, and controverts the difference supposed by Scacchi to exist between implanted and imbedded leucite. He also demonstrates the quadratic form of the sublimed leucites occurring, as first observed by Scacchi, in small cavities, and formed by the disintegration of old leucites. The analysis of these sublimed crystals gave

56.5 per cent. SiO_2 , 25.3 Al_2O_3 , 16.2 K_2O , and 2.8 Na_2O .

H. Baumhauer (*Zeitschr. Kryst.* i. 257) confirms the views of vom Rath, particularly

with regard to the twin-formation of leucite. That the ordinary form of leucite is not a simple form, but a combination, is shown by the behaviour of the crystals to etching liquids, by which the ditetragonal pyramid-faces are more strongly attacked than the tetragonal faces. The optical characters of leucite also show that its form is not monometric. Tschermak (*Berl. Acad. Ber.* 1876, 695) examined a leucite free from twin-lamination, found in the lava of Acquacetosa near Rome, and found it to be negatively double-refracting. This leucite, analysed by Berwerth, gave 55.18 per cent. SiO_2 , 23.65 Al_2O_3 , 0.83 CaO , 19.40 K_2O , and 0.32 Na_2O (= 99.38), with traces of iron and magnesium.

LEUCOGALLOL, $\text{C}^{15}\text{H}^{10}\text{Cl}^{10}\text{O}^{12}$, or $\text{C}^{15}\text{H}^{10}\text{Cl}^{12}\text{O}^{14}$. A compound formed by the action of chlorine at low temperatures on pyrogallol in presence of acetic acid (see PYROGALLOL).

LEVULINIC ACID, $\text{C}^6\text{H}^8\text{NO}^3$ (J. Dewar, *Proc. Roy. Soc.* xxvi. 65). This acid is formed by oxidising leucoline sulphate (43 parts dissolved in 200 water) with potassium permanganate (100 in 1000 water). It crystallises in colourless lamellæ or needles melting at 162° ; is somewhat volatile in a stream of hydrogen at 110° , also in a stream of aqueous vapour, to which it imparts a peculiar aromatic odour; is slightly soluble in cold, more soluble in warm water; crystallises from alcohol and ether with a faint coloration due to slight oxidation. Its salts, excepting the plumbic, ferric, and mercurous salts, are easily soluble; the silver salt forms slender needle-shaped crystals. The acid heated above its melting point suffers partial decomposition, and yields a sublimate, probably consisting of the anhydride. Heated to low redness with soda-lime, it yields aniline, together with ammonia and a small quantity of picoline; when potash-lime is used, the aniline obtained is almost free from picoline. *Potassium leucanilate*, heated by itself yields aniline, water, potassium carbonate, free carbon dioxide, and carbon:

By fusion with excess of potash, the acid is resolved into carbon dioxide, ammonia, hydrogen, and salicylic acid, the last being probably formed from anthranilic acid produced in the first instance:

The acid, heated with glycerin to the boiling point of the latter, likewise yields aniline, together with small quantities of a substance having the properties of indole.

LEUCOPHANE and **MELINOPHANE**. Rammelsberg (*Berl. Acad. Ber.* 1876, 23) has analysed leucophane (Nos. 1-4) and melinophane (Nos. 6-10), and refers them to the following formulæ:

If we suppose $2\text{Na} = \text{R}'$, $\text{F}^2 = \text{O}$, and therefore $6\text{NaF} = 3\text{R}'\text{O}$, we shall have for these minerals the formulæ,

the analogy of which is perhaps more than accidental.

LEVUCOROSOLIC ACID. See ROSOLIC ACID.

LEVULINIC ACID, $\text{C}^6\text{H}^8\text{O}^3$ (Grote a. Tollens, *Deut. Chem. Ges. Ber.* vi. 1390; vii. 1375; x. 1440; *Liebig's Annalen*, clxxv. 181; F. Bente, *Ber.* viii. 416). This

acid is formed by boiling cane-sugar with sulphuric acid, the cane-sugar being first resolved into dextrose and levulose, the latter of which appears to be the chief source of the levulinic acid, inasmuch as when the acid produced as above described is neutralised with chalk and the resulting calcium salt is crystallised out, a mother-liquor is obtained containing dextrose, whereas the levulose disappears entirely. A small quantity of levulinic acid is however obtained by treating dextrose alone with sulphuric acid.

The method originally given by Grote a. Tollens for the preparation of levulinic acid was somewhat complex, but in their latest communication (*Ber.* x. 1440) the following simpler method is described. A mixture of 1000 grams of sugar-candy, 1000 grams of water, and 1000 grams of ordinary sulphuric acid, is heated in a salt bath for four days; the resulting liquid is agitated ten or twelve times with ether; the ether is distilled off, and the residue is heated on the water-bath, and afterwards distilled. Formic acid then passes over first, and afterwards between 218° and 225° levulinic acid, which solidifies after repeated distillation, its boiling point then rising to 235°-255°. The formation of levulinic and formic acids from cane-sugar is represented by the equation—

and

Filter paper and deal shavings boiled with sulphuric acid also yield levulinic acid, but in small quantity only; Caragheen moss yields about as much as cane-sugar (Bente).

Pure levulinic acid melts at 33·5°. It is optically inactive, dissolves in water in all proportions, is not perceptibly acted upon by bromine. Heated for three days in a salt bath with 20 times its weight of 5 per cent. sulphuric acid it turns yellow, but deposits only a few flocks.

Calcium levulinate, $(C^6H^7O^3)_2Ca.2H^2O$, obtained by neutralising the acid with calcium carbonate, crystallises in silky needles often a centimeter long, dissolves very freely in water, and forms syrupy solutions which deposit crystals but slowly. It melts at 100°, giving off the greater part of its water of crystallisation, the rest of which is expelled at 130°-140°. A salt with 1 mol. H^2O was likewise obtained, but Grote a. Tollens are not sure that it was pure. The *zinc salt*, $(C^6H^7O^3)_2Zn$, also prepared by neutralisation, crystallises in silvery needles or laminae, the latter of which appear under the microscope to be made up of needles. It dissolves easily in water and in alcohol, especially when warm, is slightly soluble in absolute alcohol, and forms syrupy solutions. The *silver salt*, $C^6H^7O^3Ag$, formed by precipitation, crystallises from a boiling solution in well-defined, elongated, six-sided plates, whose two acuter angles measure on the average 99° 6', and the four obtuser angles 131° 30'. It dissolves at 17° in about 150 parts of water. The *potassium salt*, prepared from the silver salt by double decomposition with potassium carbonate, solidifies over sulphuric acid to nodular groups of microscopic needles. The *ammonium salt* forms small needles; the *barium salt* was obtained only in the form of an uncrystallisable gummy mass.

Grote a. Tollens have also examined the so-called glucates, which Mulder prepared by the action of lime or baryta on glucose (ii. 488), and concludes that his acid calcium glucate is identical with the levulinate. His neutral glucates they regard as formed by the action of the lime or baryta on sugar contained in the mother-liquor of the crystallised calcium levulinate.

For the constitution of levulinic acid, Grote a. Tollens regard two views as possible: either that this acid contains a hydroxyl-group, in which case it may be represented by a ring-formula similar to that proposed by Limprielt for pyromucic acid (vi. 979); or (2) that one of its oxygen-atoms may be situated as in acetone or in ethylene oxide, in which case it must be regarded as a homologue of pyromucic acid, $CH^3.CO.COOH$. This latter view of its constitution is adopted by Conrad (*Liebig's Annalen*, clxxxviii. 223), who regards it as identical with β -acetopropionic acid, $CH^3.CO.CH^2.CH^2.COOH$, formed by the action of baryta-water on ethylic acetosuccinate (see PROPIONIC ACID). The close resemblance of these two acids in nearly all their properties has been further demonstrated by the recent experiments of Grote a. Tollens (*Ber.* x. 1440), thus:

Levulinic acid	β -Acetopropionic acid
m. p. 32·5-33·5	31°
b. p. 235°-255°	239°
Ethylic Ethers	
b. p. 200°-201°	203°-205°

The silver salts of both acids are slightly soluble; their other salts easily soluble. The only point of difference observed is in the calcium salts, the levulinate crystallising with 2 mol. water, whereas the β -acetopropionate is anhydrous.

LEVULOSE. See SUGARS.

LIBANITE. See RESINS, FOSSIL.

LICHENIN, $C^6H^{10}O^5$. This carbohydrate, and a substance turned blue by iodine, existing together with it in *Cetraria islandica* (iii. 586), have been further examined by Th. Berg (*Russ. Zeitsch. Pharm.* 1873, 129, 161). The lichen is repeatedly boiled with fresh portions of water till the extract is no longer rendered turbid by alcohol. The strained extracts when left at rest for twenty-four hours, deposit the lichenin as a jelly, which is freed from a bitter principle and the substance which gives the blue colour with iodine, by filtration through linen, and washed with water till the blue reaction with iodine is no longer visible. The jelly remaining on the filter is then dissolved in hydrochloric acid, precipitated with alcohol, pressed, and slowly dried; the filtrate is concentrated to a small bulk and precipitated with alcohol; and the precipitate of the substance turned blue by iodine, which soon becomes glutinous, is thoroughly washed with alcohol and then dried. Both the lichenin and the substance turned blue by iodine have the composition $C^6H^{10}O^5$. Lichenin does not yield sugar either when boiled with water or when treated with malt-extract, saliva, pancreas extract, or gastric juice, but it is converted into sugar by boiling with sulphuric or hydrochloric acid. The substance turned blue by iodine yields a little sugar when boiled for a long time with water, and is easily and completely converted into sugar by treatment with an acid. Lichenin, immersed in glacial acetic acid, swells up without dissolving, and on heating the liquid to 100° , a jelly is formed, having the composition $C^6H^7(C^2H^3O)^2O^5$. The substance turned blue by iodine is not altered by glacial acetic acid. Neither this latter substance nor lichenin is turned blue by treatment with sulphuric acid and iodine together; both dissolve in zinc chloride; Schweizer's reagent dissolves only the lichenin. Alcoholic potash at the boiling heat acts somewhat strongly on lichenin, very slightly on the substance turned blue by iodine. Lichenin forms compounds with potash and soda; the substance turned blue by iodine does not. No method has yet been found of converting either of these substances into the other.

LICHNOXANTHIN. See PLANTS, COLOURING MATTERS OF.

LIEVRITE. Analyses of this mineral from Elba by Städelé (*J. pr. Chem.* xcix. 70), and by Sipőcz (*Liebig's Annalen*, clxxviii. 196), lead to the conclusion that the water, formerly regarded as accidental (iii. 589), is an essential constituent, and that the mineral may be represented by the formula $6RO.Fe^2O^3.4SiO^2.H^2O$, in which $R = \frac{2}{3}Fe + \frac{1}{3}Ca$. Analysis (1) by Städelé, of black, shining, crystalline masses; sp. gr. 4.023; (2) by Sipőcz, mean of four, made on carefully selected material; sp. gr. 4.037:

SiO^2	Fe^2O^3	FeO	MnO	CaO	H^2O
29.20	20.74	35.15	—	12.90	2.36 = 100.35
29.67	21.26	33.09	0.74	13.33	2.32 = 100.41

Rammelsberg, on the other hand (*Zeitschr. geol. Ges.* xxii. 897), regards the water (1.65 per cent. according to nine experiments) as the result of weathering, and represents the anhydrous mineral by the formula $R^{12}Fe^4Si^9O^{36}$ or $12RO.2Fe^2O^3.9SiO^2$, in which $R = \frac{2}{3}Fe + \frac{1}{3}(Ca, Mn)$.

An analysis by W. Early of lievrite from Elba, in which especial attention was given to the determination of the two oxides of iron, is published by J. Emerson Reynolds (*Phil. Mag.* [5], iii. 287):

SiO^2	Al^2O^3	Fe^2O^3	FeO	MnO	CaO	MgO	K^2O	Na^2O	H^2O
29.93	0.36	20.16	31.83	3.02	13.71	0.30	0.20	0.29	0.42 = 100.22

Regarding the water as unessential, Reynolds represents the analytical numbers by the formula $6RO.R^2O^3.4SiO^2$, in which $6RO = 4(Fe, Mn)O + 2CaO$.

On the relations of form and composition of Lievrite and Humite, see Websky (*Berl. Acad. Ber.* 1876, 201; *Jahrb. f. Min.* 1876, 660; *Jahresb. f. Chem.* 1876, 1252; *Chem. Soc. Jour.* xxxii. 117).

LIGHT. 1. REFRACTION and DISPERSION.

A. Of Gases. Mascart (*Compt. rend.* lxxviii. 617; *Pogg. Ann.* cliii. 149) has worked out the following relations between the refractive power and density of gases, in which, instead of the refractive index n , the excess of refraction $n - 1$ is taken into account. This function, if the laws of Boyle and Gay-Lussac were strictly true, should be proportional to the pressure p . Instead of this, Mascart finds from his experiments that

$$n - 1 = a(1 + bp),$$

where a and b are constants. According to Regnault's tables, the density of a gas is very nearly represented by the formula

$$\frac{d}{p} = a'(1 + b'p),$$

so that, if the index of refraction were directly proportional to the pressure, b would be equal to b' , which, however, as shown by the following table, is true only as a very rough approximation. Between constant pressures, but at varying temperatures, t , the excess of refraction, $n-1$, should be inversely proportional to the factor $1+\alpha t$, instead of which a variable factor β was found for the several gases. The last column of the table shows the absolute values of 1000 times the excess of refraction ($n-1$) for the sodium-line at the temperature 0° and pressure 700 mm.:

Gases	Compressibility		Refraction		Influence of Temperature	1000(n_0-1)
	t	b	t	b	β	
Hydrogen	10°	-0.00057	22°	-0.00087	0.00381	0.1388
Air	5	+0.00107	22	+0.00072	0.00383	0.2923
Nitrogen	5	0.00068	21	0.00085	0.00382	0.2972
" Monoxide . . .	9.3	0.00754	13.5	0.0088	0.00388	0.5084
" Dioxide	—	0.00225	12	0.00070	0.00367	0.2967
Carbon Monoxide .	—	0.00435	—	0.00089	0.00367	0.3336
" Dioxide	3	0.00901	17	0.0072	0.00406	0.4494
Sulphur "	7.7	0.0322	13	0.025	0.00471	0.6820
Cyanogen	—	0.0322	25	0.027	—	0.8202

By the same method Mascart has determined the dispersion of several gases. From Cauchy's dispersion formula, according to which the index of refraction is

$$n = A \left(1 + \frac{B}{\lambda^2} \right),$$

λ being the wave-length, the constant B was found to have the following values:

for Atmospheric Air	0.0058
Nitrogen	0.0069
Hydrogen	0.0044
Nitrogen Monoxide	0.0127
Carbon "	0.0075
" Dioxide	0.0052
Cyanogen	0.0100

Nitrogen monoxide and cyanogen disperse more strongly than water; the dispersive power of atmospheric air is about $\frac{3}{5}$ of that of water, and its value above given agrees almost exactly with that previously found by Ketteler (*Ueber die Farbenstreuung der Gase*, Bonn, 1865).

The following formula for calculating the refractive indices of atmospheric air at different temperatures has been deduced by V. v. Lang (*Pogg. Ann.* cliii. 448) from very careful experiments:

$$n = n_0 - 0.000000905 t + 0.00000000235 t^2,$$

n_0 having, according to the observations of Biot and Arago, the value 1.0002945. These coefficients differ considerably from those of Mascart.

B. Of Liquids.—The influence of Compression on the Refractive Power of Water has been studied by Mascart (*Compt. rend.* lxxviii. 801; *Pogg. Ann.* cliii. 154). Assuming Grassi's coefficient of the compression of water to be correct, it follows from Mascart's experiments that the old law,—deduced from the emission-theory of light—affirming that the specific refractive power of bodies, $\frac{n^2-1}{d}$, is constant for all varia-

tions of density, is utterly wrong, and that the magnitude $\frac{n-1}{d}$, to which the name specific refractive energy is given by Dale a. Gladstone (iii. 625) approximates to a constant value, but not closely enough to be made the foundation of a law.

The method of observation adopted rendered it possible to measure by optical means the fall of temperature produced by sudden decrease of pressure. On the basis of Dale a. Gladstone's values for the decrease of the refractive index of water with rise of temperature (iii. 616), the rise consequent on an increase of pressure of 1 at. was found to be equal to 0.00110, a value agreeing almost exactly with that deduced from the mechanical theory of heat.

Compound Ethers.—The refractive indices of isomeric compound ethers (from fermentation alcohols) have been determined by Pierre a. Fuchot (*Compt. rend.* lxxvi. 1566). The ethers of each pair were compared together at the same temperature, a , of the surrounding medium, and the data thus obtained afforded the means of calculating the refractive index which the second ether in the pair would exhibit at a distance from its boiling point equal to that at which the determination was made for the first. As the differences of boiling point Δ never exceeded 1° , the alteration of the boiling point could, for this calculation, be regarded as proportional to the alteration of density. Four comparisons at temperatures a from 15° – 16° yielded the following results, in which t denotes the temperature of the liquid, d_0 , its density at 0° , d_t that at the boiling point, l_a the refractive index at the temperature a , and $l_{a-\Delta}$ that at the temperature $a - \Delta$.

	t	d_0	d_t	l_a	$l_{a-\Delta}$
Propyl Butyrate . . .	135.0	0.887	0.745	1.3972	1.3972
Butyl Propionate . . .	135.7	0.893	0.743	1.3981	1.3989
Ethyl Valerate . . .	135.5	0.886	0.744	1.3981	1.3981
Butyl Propionate . . .	135.7	0.893	0.743	1.3981	1.3983
Propyl Butyrate . . .	135.0	0.887	0.745	1.3972	1.3972
Ethyl Valerate . . .	135.5	0.886	0.744	1.3981	1.3973
Butyl Acetate . . .	116.5	0.905	0.778	1.3901	1.3901
Methyl Valerate . . .	117.5	0.901	0.774	1.3937	1.3921

C. Of Solids.—A new refractometer for measuring the refractive indices of glass plates and lenses by means of Newton's rings, is described by G. W. Royston-Pigott (*Proc. Roy. Soc.* xxiv. 393). Four kinds of glass gave the following values for mean rays:

Clear white Flint-glass	1.537
Yellow and heavy Flint-glass	1.6626
Yellowish and very heavy Flint-glass	1.723
Strong yellow, heaviest of all „	1.7555

The refractive index of collodion films (0.0081 to 0.088 mm. thick on glass plates) was found by E. Gripon (*Compt. rend.* lxxx. 882) to be 1.5108; polarising angle $56^\circ 25'$.

F. Kohlrausch (*Zeitschr. Kryst.* i. 100) has determined the following refractive indices by the method of total reflection (iii. 614):

Glass prism (at 23°):	Obsidian (at 23°)	1.4953
first face	Agate „	1.540
second face	Amber (at 21°)	1.522
by transmission	Sodium Chlorate (at 22°)	1.5145
Fluor spar:	Potash-alum, native (at 16°)	1.5461
crude, grey (at 23°)	Chrome-alum „ (at 22°)	1.481
black (at 19°)		

Refractive Power of Bodies which exhibit Anomalous Dispersion (vii. 742).—A. Kundt (*Pogg. Ann.* cxlv. 67, 164) has determined the refractive indices of the four following anomalously dispersive liquids: (1). Cyanin, 1.22 per cent. dissolved in alcohol of sp. gr. 0.822 at 15° . (2). Cyanin, concentrated solution in the same solvent. (3). Fuchsine, not quite saturated solution in the same solvent. (4). Potassium permanganate solution not quite saturated. The first column of the following table indicates the spectral lines; e.BI and e.Gr signify the extreme blue and extreme green that could be observed on both sides of the absorption-band; in fuchsine, e.BI has nearly the position of the line F. Δa and Δw denote the differences of the refractive indices as observed in the two solvents, alcohol (a) and water (w).

The values for fuchsine, which exhibits the greatest anomaly of dispersion, are somewhat different from those determined by Christiansen (vii. 742), partly perhaps in consequence of the different degrees of purity of the substances employed, and partly of the inaccuracy of Christiansen's determination of the index n_D , as acknowledged by himself (*Pogg. Ann.* cxlv. 154).

	Cyanin I		Cyanin II		Fuchsine		Potassium Permanganate	
	<i>n</i>	$\Delta\alpha$	<i>n</i>	$\Delta\alpha$	<i>n</i>	$\Delta\alpha$	<i>n</i>	Δn

W. Wernicke (*Pogg. Ann.* clvi. 87) has determined by a peculiar method, the indices of refraction and extinction of rays which are absorbed by metallically opaque bodies. The following table gives the indices of refraction *n*, corresponding with the wave-lengths λ for solid fuchsine:

λ	A	B	C	D	E	F	G	H
$\lambda = 760$	688	656	598	589	581	571	550	532
$n = 1.73$	1.81	1.90	2.293	—	2.326	2.372	2.016	1.875
$\lambda = 522$	489	485	483	489	460	448	438	429
$n = 1.755$	1.593	—	1.330	1.436	1.288	1.224	1.295	1.31

The variation in the values of *n* justifies Kundt's theoretical views of the nature of bodies which exhibit surface colours. In silver, the indices of refraction (vii. 743) vary, between C and G $\frac{1}{2}$ H, from 4.78 to 3.18, and the experiments show—in opposition to Cauchy's theory of metallic reflection—that the coefficient of extinction is independent of the angle of incidence.

Double Refraction. The following determinations have been made by Kohlrausch (*loc. cit.*) by the method of total reflection. In the uniaxial crystals, the faces—when it is not otherwise stated—were cut at right angles to the optic axis, and the refractive indices, ω and ϵ , of the ordinary and extraordinary rays, were determined. In the biaxial crystals, the face was cut at right angles to the first median line, and, in addition to the refractive indices α and γ , the apparent angle $2E$ of the optic axes was determined, and thence the third refractive index was calculated (iii. 665):

Optical Constants of Isomorphous Bodies.—The refractive indices, and, in the case of biaxial crystals, the angles of inclination of the optic axes, of a large number of isomorphous crystals, have been determined by Topsee & A. Christiansen (*Ann. Chim. Phys.* [4], xxxi. 1), the result of which has been to confirm the main conclusion deduced by Senarmont from experiments made in 1851 (*ibid.* [3], xxxiii. 391), namely, that the optical properties of bodies are not in any way dependent upon isomorphism. In the following tables the indices of refraction are given for the Fraunhofer lines C, D, and F. The first gives these indices for single-refracting crystals. In the second table, the letters H, T, following the names of the substances, denote the crystalline system to which they belong, H=hexagonal, T=tetragonal (dimetric, quadratic, pyramidal). The positive or negative optical character of the substances in this table follows from the value of $\frac{\omega}{\epsilon}$, the ratio of the ordinary and

extraordinary refractive indices of a ray traversing the crystal at right angles to the optic axis. If $\epsilon > \omega$, this ratio is less than unity, and the crystal is optically positive; if $\epsilon < \omega$, the ratio is greater than unity and the crystal optically negative. This ratio is always to be understood as referring to the line D, except in one case, where a C is attached to it, in which it refers to the line C. The first three columns of figures contain the refractive indices, ω above and ϵ below. In the third table, containing the rhombic biaxial crystals, there are given for each substance the three principal indices of refraction $\alpha < \beta < \gamma$ for rays which traverse the crystal parallel to the axes of optical elasticity $a > b > c$. 'Optical orientation' denotes the order in which the axes of elasticity correspond to the right-angled crystallographic axes. The sign \pm for the optical character is placed below that axis which bisects the acute angle of the two optic axes. In the monoclinic crystals included in the fourth table, the plane of the optic axes is always parallel to the plane of symmetry of the crystal. The optical orientation is determined by the angle which the line of bisection of the acute angle of the optic axes forms with the normal to the face 001 or ∞P (AB) denotes the apparent, AB the true angle of the optic axes.

Double Refraction of Various Substances.—Mercurous iodide, Hg_2I_2 , which Des Cloizeaux has shown to be isomorphous with mercuric iodide (*Compt. rend.* lxxxiv. 1418), is likewise strongly double-refracting; it is uniaxial and positive, whereas mercuric iodide is negative. Mercurous chloride is also positive.

Cupric Sulphate, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. The optical constants of this salt have been determined by C. Pape (*Pogg. Ann.* vi. 35; *Jahresb. f. Chem.* 1873, 137). The three principal refractive indices for sodium light (D) are:

$$\alpha = 1.51564 \quad \beta = 1.53940 \quad \gamma = 1.54639$$

The dispersion is small, as shown by the following values:

	D	E	F	G
for the lines α	1.51615	1.51983	1.52307	1.52872
γ	1.54604	1.54996	1.55351	1.55978

The angles between the optic axes are slightly diminished by rise of temperature, about $12.1'$ for a rise from 19.1° to 46.7° .

Cane-sugar. The three principal refractive indices, and the angles $2V$ of the optic axes for the sodium, lithium, and thallium lines, have been determined by L. Calderon (*Zeitschr. Kryst.* i. 73):

	α	β	γ	$2V$
Li . . .	1.5379	1.5638	1.5693	$47^\circ 56'$
Na . . .	1.5397	1.5667	1.5716	$48^\circ 0'$
Tl . . .	1.5422	1.5685	1.5734	$48^\circ 08'$

The dispersion of the median lines is almost nothing; that of the optic axes is weak.

F. Becke (*Min. Mittheil.* vii. 261) finds that for sodium light, the crystallographic axis c is inclined to the smallest optic axis at an angle of $23^\circ 23'$. For sodium-light, and for light which has passed through red and green monochromatic glasses respectively, he finds the following values for the refractive indices and the angle of the optic axes:

	α	β	γ	$2V$
Red . . .	1.5351	1.5630	1.5679	$47^\circ 42' 30''$
Yellow . . .	1.5371	1.5653	1.5705	$47^\circ 48' 20''$
Green . . .	1.5404	1.5687	1.5737	$47^\circ 57' 56''$

Terpin Hydrate, $\text{C}^{10}\text{H}^{14.3}\text{H}_2\text{O}$. This compound forms orthorhombic crystals having the axial ratio $a : b : c = 0.80722 : 1 : 0.47640$. The plane of the optic axes coincides with ∞P ; the first median line with the brachydiagonal a . The angle of the optic axes is for lithium-light $77^\circ 37'$; for sodium-light $77^\circ 27'$; for thallium-light $77^\circ 18'$; the dispersion of the optic axes is therefore very small (Arzruni, *Pogg. Ann.* clii. 282).

Influence of Temperature on the Refractive Indices of the Isomorphous Sulphates of Barium, Strontium, and Lead (Heavy Spar, Celestine, and Anglesite).—1. The three principal indices of refraction of these three sulphates vary, with change of temperature, by different amounts, but always decrease in magnitude as the temperature rises. 2. This decrease in the three compounds is analogous in so far that the largest index (α) suffers the greatest, and the medium index (β) the smallest amount of diminution. 3. In anglesite the refractive power diminishes with rise of temperature, but the dispersion increases. 4. The directions of the principal axes of expansion by heat do not stand in any direct relation to the magnitude of the axes of optic elasticity (Arzruni, *Zeitschr. Kryst.* i. 165).

Development of Double-refracting Structure by Electric Induction.—Isotropic media, solid or liquid, submitted to strong electric inductive action, become doubly refractive, their particles being apparently arranged in the direction of the lines of magnetic force. The structure thus acquired is uniaxial, the axis being parallel to the lines of force. Glass and quartz become positively double-refracting, resin negatively. Among liquids, carbon disulphide, benzene, paraffin, kerosene oil, and turpentine oil become positive, olive oil negative. Carbon disulphide acquires the strongest, paraffin oil and kerosene oil the weakest double refraction. In solid bodies, the development of double refraction by electric influence, takes a perceptible time (up to half a minute) and an equal time is required for its disappearance after the electric force has ceased to act; in liquids both the production and the disappearance of the double refraction are instantaneous (J. Korr, *Phil. Mag.* [4], i. 337, 446).

Fluorescence. The fluorescence of a large number of substances has been examined by E. Hagenbach (*Pogg. Ann.* cxlvi. 65, 232, 375, 508; *abstr. Chem. Soc. Jour.* xxv. 1058), with results confirming in every instance the two laws discovered

by Stokes, viz. (1) that the fluorescent rays are always less refrangible than the exciting rays; (2) that the same rays which are capable of producing fluorescence within a substance are also absorbed by that substance.

Light of every degree of refrangibility appears to be capable of exciting fluorescence, which, in the more refrangible part, extends beyond the line H, being there produced by lowering of refrangibility of the ultra-violet rays; on the other hand, any fluorescent light that might be produced by the extreme red rays, would, for obvious reasons, not be perceptible to our eyes. The number of maxima of fluorescence in the spectrum is very different for different substances; thus Hagenbach, by examining the spectrum of an illuminated slit, the light of which was thrown on different liquids, observed

7	maxima in a fresh solution of chlorophyll	
6	" in an altered solution of chlorophyll	
5	" in an extract of lamp-black	
4	" in barium platinocyanide	
3	" in naphthalene-red	} and in other substances.
2	" in oxidised brazilin	
1	" in the solution of marin-alumina	

Stokes's observation that the absorption-bands of fluorescent bodies correspond generally with the maxima of fluorescence has been confirmed by Hagenbach in nearly all cases, a few bodies in which absorption is not accompanied by fluorescence being, perhaps, mixtures of a fluorescent and a non-fluorescent substance. Uranic nitrate, however, which exhibits no maxima of fluorescence either in the solid state or in solution, seems to form a real exception to the rule, since it can scarcely be looked upon as a mixture.

The maxima of fluorescence in the spectrum of a body do not always correspond with those in the spectrum of the fluorescent light, or *fluorescence spectrum*; the solution of chlorophyll, for example, shows seven maxima of fluorescence in its spectrum, but only two in that of the fluorescent light.

The position of the maxima and minima of fluorescence vary more or less with the nature of the solvent employed, and some substances exhibit fluorescence only in one state of aggregation, whereas others are fluorescent both in the solid and in the liquid state.

Further experiments by Hagenbach (*Pogg. Ann.* Jubelbd. 1874, 303) have yielded the following results: A comparison of the fluorescence spectra of the alcoholic and ethereal extracts of chlorophyll shows that the maxima in the former are placed nearer to the red end than in the latter, and that the minimum between the two maxima is more distinct in the ethereal than in the alcoholic extract. Chlorophyll likewise exhibits fluorescence in the solid state, though not so strongly as when dissolved, the spectrum of the solid substance being less extended and notably displaced towards the side of lesser refrangibility.

The fluorescence-spectrum of solid anthracene exhibits seven maxima. The blue-violet fluorescent solutions of this substance in alcohol, ether, and light petroleum exhibit the displacement of the maxima towards the violet end, previously observed by Morton (p. 93 of this volume). Hagenbach, however, attributes the spectrum with six or seven maxima to pure anthracene, whereas Morton supposed that it was due to the presence of chrysogen. Hagenbach did not observe any absorption-bands in the spectrum of pure anthracene.

Thallene, a greenish-brown hydrocarbon discovered by Morton in petroleum-residues (*Chem. News*, xxvi. 272), exhibits a fluorescence very much like that of anthracene. Solid thallene exhibits no absorption-bands except those which are due to its splendid green fluorescence; its two spectra are exactly complementary one to the other. In all its solutions it exhibits a strong blue fluorescence, and all its bands appear displaced towards the more refrangible end of the spectrum in various degrees according to the solvent used. Prolonged insolation and rise of temperature give rise to the gradual disappearance of the fluorescence-bands from the red end onwards (Morton, *Phil. Mag.* [4], xlii. 89).

The fluorescence and absorption-spectrum of chrysene, both solid and in solution, is also very much like that of anthracene. Solid chrysene exhibits 4, dissolved chrysene 5 maxima in its fluorescence-spectrum, their arrangement being modified by the solvent (chloroform, benzene, turpentine-oil, ether). Two or three absorption-bands were also observed. Insolation displaces the maxima of solid chrysene in the direction of greater refrangibility, and develops a fifth maximum (Morton, *Amer. Chemist*, v. 115).

Ordinary white paper exhibits a whitish fluorescence, which is, moreover, continuous after the removal of the exciting rays, and has therefore the character of phosphorescence; it begins at the line G, attains its maximum at G, and extends to

the ultra-violet. This fluorescence-spectrum exhibits two rather strong maxima separated by a minimum (Hagenbach).

Hagenbach has also examined the fluorescence of the *platinocyanides* of the following metals:

Potassium	Strontium
Sodium	Strontium-potassium
Potassium-sodium	Calcium
Ammonium	Calcium-potassium
Sodium-ammonium	Magnesium
Barium	

The fluorescent appearances of these salts are very diversified, as each yields several hydrates differing both in their body-colour and in their fluorescence. The body-colour is determined chiefly by the rays which excite fluorescence. Most of these salts exhibit very fine surface-colours.

Ch. Horner (*Phil. Mag.* [4], xlviii. 165) recommends castor-oil as a solvent for fluorescent bodies which do not exhibit this property when dissolved in other liquids. Red indigo (Persio) dissolved in this oil exhibits a splendid orange fluorescence; camwood apple-green; logwood a similar colour but with a different spectrum; turmeric, emerald-green, at least three times as strong as in the alcoholic extract.

E. Lommel (*Pogg. Ann.* cxliii. 26; cliv. 514) infers, from observations on various fluorescent substances, that Stokes's law respecting the relative refrangibilities of the exciting and fluorescent rays is not universally true. His conclusions are as follows: (1). There are two kinds of fluorescence. In the first, each homogeneous exciting ray, which, as regards its refrangibility, falls within the limits of the fluorescence-spectrum, or a certain portion of it, is capable of exciting not only rays of greater or of equal wave-length, but also rays of lesser wave-length, so far as they are included within the same limits. In the second kind of fluorescence each homogeneous exciting ray produces only those rays of fluorescent light whose wave-lengths are greater or at least equal to its own. (2). In bodies which exhibit the first kind of fluorescence, such as naphthalene, chlorophyll, and iron, each exciting homogeneous ray calls into existence the entire fluorescence-spectrum: these bodies therefore do not conform to Stokes's law. (3). Most of the fluorescent bodies hitherto examined exhibit only the second kind of fluorescence, and therefore obey Stokes's law throughout the extent of their fluorescence-spectra. (4). There are also bodies which exhibit both kinds of fluorescence, the first in a certain part of their fluorescence-spectrum, the second kind in the remainder; these, therefore, conform partially to Stokes's law. Such are Griessmayer's chameleon-red, chameleon-blue, and chameleon-green produced by heating aniline hydrochloride with azobenzene (see PHENYL COLOURING MATTERS).

According to Hagenbach (p. 1194) and Lubarsch (*Pogg. Ann.* cliii. 420), on the other hand, the relation between the wave-lengths of the exciting and fluorescent rays is in all cases represented by Stokes's law. Lubarsch also infers from his own experiments: (1). That the fluorescence of each substance can be developed only by certain exciting rays. (2). That the most refrangible rays of the fluorescent light excited by sunlight correspond with the position of maximum absorption, provided that the fluorescence is *simple*. Various bodies, however (*e.g.* extract of Palisander wood, an ethereal solution of archil, and alcoholic tincture of litmus), exhibit a *double* or *multiple* fluorescence, due to the action of various groups of rays of the exciting light. Chlorophyll belongs to this class of bodies, but is probably a mixture of several substances, each of which exhibits only simple fluorescence.

Fluorescence, Phosphorescence and Absorption Spectra of Uranium Solutions.*—The light emitted by phosphorescent uranium compounds has been spectroscopically examined by E. Becquerel (*Ann. Chim. Phys.* [4], xxvii. 539). The experiments were made in some cases with the aid of Becquerel's phosphoscope† (*ibid.* [3], lvii. 101), while in others the bodies were illuminated exclusively by the violet and ultra-violet rays. Uranous chloride and sulphate thus treated do not emit any sensible light. Most uranic compounds, on the other hand, become phosphorescent, and almost all of them then give a series of groups of light and dark bands between C and F. The order of the bands in the several groups is determined chiefly by the acid present in the compound, and exhibits great diversity. In the double salts of any particular class, the double sulphates for example, the order in each group is the same, but the

* Phosphorescence is fluorescence continuing after the removal of the exciting cause.

† This is an instrument for facilitating the detection of phosphorescence in bodies which exhibit it for a very short time only. For description and figures, see E. Becquerel (*La Lumière, ses causes et ses effets*, i. 249, 334, 378; *Ann. Chim. Phys.* [3], lvii. 101; also *Traité de Physique* par A. Daguin, iv. 252).

index of refraction of the corresponding light and dark bands varies sometimes in one direction, sometimes in the opposite. In each individual spectrum the distance between the corresponding maxima and minima of light of the successive groups increases with the refrangibility. The differences of the corresponding wave-lengths divided by the square of the mean wave-length give quotients which are nearly equal for all uranium compounds. On the other hand, no simple relation could be discovered between the wave-lengths of homologous bands of the same group in different compounds and their chemical composition. When the compounds are illuminated by violet and ultra-violet light, the more refrangible part of the spectrum exhibits additional groups of absorption-bands, which are different in different compounds, and agree in their order of succession with those in the less refrangible part of the spectrum, appearing, indeed, like a continuation of the latter.

Bequerel's results have been confirmed by Morton A. Bolton (*American Chemist*, iii. 361, 401), whose observations extend to a larger number of uranium salts. They find that, whereas in the spectra of all these salts the similar and similarly distributed bands of the fluorescent light are situated between the lines C and F, there are also other absorption-bands situated between F and H, which are not due to fluorescence, but are, nevertheless, similar to those above mentioned, and somewhat regularly distributed. The intensity curves of the spectra exhibit characteristic differences between different salts, and may serve to distinguish them one from the other. In all cases the intensity of the bands decreases more quickly in one direction than in the opposite, and, for the most part, more quickly towards the more refrangible end. The character of one band is, for the most part, a type of all the bands in the same spectrum; exceptions to this rule are, however, afforded by most of the double acetates, especially sodio-uranic acetate. Double salts containing the same acid have in most, but not in all cases, bands of the same type; but simple and double salts of the same acids do not, for the most part, agree in the type of their bands. In many cases an internal decomposition of a salt by heat could be distinctly traced by the spectroscope. Thus when hydrated ammonio-uranic sulphate, $UO_2SO_3 \cdot (NH_4)^2OSO_3 + 2H_2O$, is heated, it is first converted into the anhydrous salt, and finally into a new salt, containing less ammonia, viz. $2UO_2SO_3 \cdot (NH_4)^2OSO_3$. The spectra of the three salts are similar, but are distinguished from one another by the arrangement and relative intensities of their bands. When the original hydrate is slowly heated, the spectrum of the anhydrous salt at first accompanies that of the hydrate, and with continually increasing intensity, while that of the hydrate gradually fades. The passage from the hydrate to the new double salt is accompanied by similar appearances.

The absorption-spectra of many uranic salts exhibit great diversities, the character of the absorption-bands being in many cases greatly influenced by the fluorescence, in others but slightly. The acetates, simple and double, which in the solid state give very different absorption-spectra, exhibit in solution almost exactly similar spectra, so that it may be inferred, with great probability, that double uranic acetates cannot exist in solution, but are decomposed in the act of dissolving. Different solvents displace the bands in various degrees.

Fluorescence is diminished by heat. In anhydrous ammonio-uranic sulphate the fluorescence is considerably weakened at 140° and destroyed at 260° . In sodio-uranic acetate all the fluorescence-bands disappear at 116° , and during the heating the bands are somewhat displaced towards the red end; as the salt cools, the optical phenomena regain their original character. Salts in solution lose their fluorescence at lower temperatures than in the solid state. Many uranic salts, especially the carbonates, exhibit, when heated, a downward displacement (? towards the red end) of their absorption-bands; others, especially the nitrates, and likewise the acetates, exhibit, when heated, not a displacement of the bands, but a distinct diminution of the general absorption.

Illumination of Transparent Bodies.—Lallemand's observations on this subject (vii. 745) have been continued (*Compt. rend.* lxxvii. 1216) with the following results: The rays which produce the illumination of transparent bodies are of two kinds:—those of the one kind, resulting from a direct lateral propagation of the incident light, have a wave-length equal to that of the latter, and are partly or completely polarised, according as the incident light is natural or polarised; while those of the other kind are always unpolarised, and often of less refrangibility than the original light: these are the rays which in transparent bodies produce fluorescence, and in opaque substances, body-colour. Fluorescence may be regarded as a universal property of bodies, being exhibited, even by the purest liquids, as, for example, sulphur dioxide or cyanogen condensed by pressure. The only bodies which are distinctly illuminated without fluorescing are perfectly pure quartz and rock-salt. Calc spar exhibits a reddish-orange fluorescence, somewhat brighter and of a deeper red with the ordinary than with the extraordinary ray; isochromatic illumination (vii. 745), however, is scarcely

perceptible in this substance. Colourless fluorspar exhibits both properties in a high degree; its fluorescence is of a violet-indigo colour. Pure naphthalene dissolved in alcohol gives a bright indigo-blue fluorescence, the spectrum of which shows all the colours, but most conspicuously the rays between F and G. When polarised light falls on glass which has been quickly cooled, the glass emits at certain points white partially polarised light, at others unpolarised light of yellowish-green or bluish-green colour, according to the fluorescence of the particular kind of glass. This effect is connected with the double refraction resulting from the internal tension of the particles.

Illumination of Opaque Bodies and External Diffusion.—The light scattered from the surfaces of these bodies consists of three parts: 1. That resulting from true diffusion, which obeys the same laws as the inner diffusion or illumination of transparent bodies. 2. That which is due to true reflection from the inequalities of the surface. 3. That which is due to fluorescence. Lamp-black is the substance in which the reflection is of smallest amount, indeed almost evanescent; nevertheless, this substance exhibits a faint yellowish fluorescence. In most other black substances the predominant appearance is reflection, most conspicuously in platinum-black. The number of really black bodies, that is to say of bodies which reflect and diffuse no coloured light, but only a faint white light, is, however, smaller than is commonly supposed, many apparently black precipitates, for example, exhibiting distinct colours when dried and spread out in thin layers; thus the sulphide and phosphide of copper are greenish-brown; lead sulphide and silver sulphide are bluish-grey, &c. Actually black are the following: well-washed aniline-black; mercury sulphide obtained by the action of hydrogen sulphide on mercuric chloride; uranium oxide, U^2O^5 ; cupric oxide precipitated from the nitrate by lime; platinum-black; iron reduced by hydrogen; finely pulverised arsenic oxidised by exposure to the air (Lallemand, *Ann. Chim. Phys.* [5], viii. 93).

Relations between Absorption and Dispersion in Mixtures.—When an ordinary transparent medium, whose refractive power n is related to the wave-length λ in the manner represented by the equation $n = a + \frac{b}{\lambda^2}$ is mixed with a strongly absorbing body, the absorption-bands of the mixture are in most cases displaced towards the red end of the spectrum, the displacement increasing with the value of b . This relation throws light on the hitherto obscure observations regarding the influence of solvents on absorption (e.g. in the chlorophyll spectrum); also on the observations made by Melde in 1865 (*Pogg. Ann.* cxxiv. 91; cxxvi. 265; *Jahresb.* 1865, 85) on the displacement and occasional disappearance of the absorption-bands of a substance consequent on the presence of another which does not act chemically on it, but is likewise capable of producing absorption-bands (Kundt, *Pogg. Ann.* Jubelbd. 615).

On the relations between the absorptive powers of Coloured Bodies in the Solid State and in Solution, see W. Ackroyd (*Chem. News*, xxxvi. 159).

Instruments for the observation of Absorption in Solutions are described by G. Govi (*Compt. rend.* lxxxv. 1046; *Jahresb. f. Chem.* 1877, 184).

On Absorption-spectra, see SPECTRAL ANALYSIS.

Colours of Bodies. The change of colour produced in bodies by heat, on which observations were made a few years ago by Houston (vii. 746), has been further investigated by W. Ackroyd (*Chem. News*, xxxiv. 75; *Phil. Mag.* [5], ii. 423; *Chem. Soc. Jour.* xxxi. 571), who designates it by the term *Metachromatism*. The colours were spectroscopically examined after the light had passed through a thin layer of the pulverised substance. Heating usually produces (as may be seen in the case of potassium dichromate) a contraction of the transmitted portion of the spectrum, in greater proportion towards the more refrangible than towards the less refrangible side, whereby a change of colour is produced in the direction of the red, which is, in fact, the general law of colour-change produced by heat. The series of colours must, however, be extended beyond the red to include brown and black, and beyond the violet to include white (or colourless). In a series of anhydrous binary compounds of the same two elements, those which contain the largest proportion of metal have the most refrangible, and those which contain the smallest proportion of metal have the least refrangible, colours. Metachromatism occurs in all states of aggregation; it is not necessarily connected with rise of temperature or with alteration of density, and may therefore be produced by increase or decrease of distance between the atoms within the molecule, in other words, with alteration of the atomic potential. A change from the white (violet) to the black (red) extremity of the spectrum indicates a separation of the atoms, the contrary change an approximation. If the alteration of the potential proceeds as far as chemical action, the former change of colour denotes combination, the second decomposition.

Dichroism.—The double-refracting orthorhombic crystals of iodine are dichroic in consequence of unequal absorption, appearing dark red or brownish yellow according to the direction in which they are viewed. The optic axis of the rhombic plates is parallel to the macrodiagonal. The ray polarised parallel to this axis suffers less absorption than that which is polarised at right angles thereto. The reflected light is polarised partly at right angles to the transmitted light, partly parallel to the plane of incidence. If the incident light is polarised parallel to the plane of incidence, and the angle of incidence is about 72° , the reflected light is of a bright blue colour, complementary to the transmitted light (Sir John Conroy, *Proc. Roy. Soc.* xxv. 51).

The absorption-spectra of iodine in the solid and fused states are nearly identical, and consist only of the red portion to a little short of D, beyond which absorption takes place very rapidly in fused, more slowly in solid iodine. The solutions, as formerly observed by Schultz-Sellack (vii. 672), are either red-brown or violet. To the former class belong the solutions in alcohol, ether, ethyl bromide, ethylene chloride, benzene, glycerin, aqueous potassium iodide, hydrochloric acid, &c.: they absorb the spectrum from the violet end to about the middle between σ D and E; to the latter, the solutions in disulphide, tetrachloride, and monochloride of carbon, chloroform, phosphorus trichloride, stannic chloride, and hot concentrated sulphuric acid: these solutions strongly absorb the rays of medium refrangibility, and their spectrum resembles that of iodine-vapour (vii. 672). In thin layers, or when somewhat dilute, they appear red; in thicker layers violet, because the violet rays are still transmitted after the red have been absorbed (Conroy, *Proc. Roy. Soc.* xxv. 46). The dichroism of iodine in alcoholic solution has also been observed by Andrews (*Chem. News*, xxiv. 75).

Temporary dichroism may be produced by tension in caoutchouc and gutta-percha, and in a slight degree in gelatin which has been made extensible by addition of glycerin and coloured by certain dye-stuffs (A. Kundt, *Pogg. Ann.* cli. 125).

Elliptic Polarisation and Surface-colours.—E. Wiedemann (*Pogg. Ann.* cli. 1) has determined the relation between the angle of incidence and the phase of retardation of the reflected ray (iii. 659) for five spectral colours, from reflecting surfaces of fuchsine, aniline-violet, and copper. Strong elliptic polarisation was observed also in light reflected from a concentrated solution of fuchsine. The changes of colour exhibited by bodies with surface-colour in contact with media of different refrangibility—first observed by Haidinger (*Wien. Akad. Ber.* viii. 97; *Jahresb. f. Chem.* 1852, 162), have been further studied by Wiedemann, whose experiments show that the surface-colour varies enormously according to the nature of the medium in contact with the body, and that the changes of colour in the light reflected from double-refracting crystals according to the inclination of the reflecting surface to the axis of the crystals—also studied by Haidinger (*Pogg. Ann.* lxxi. 321; *Jahresb.* 1847–48, 194)—are independent of any particular arrangement of the surface-particles. Amongst the relations brought to light by this investigation, the following may be especially mentioned: (1). That the colours most strongly reflected (in air) likewise exhibit the strongest elliptic polarisation; and (2) That the principal angle of incidence, or polarising angle (whose tangent is the index of refraction, iii. 653), is subject to the most rapid variations for wave-lengths nearly corresponding with absorption-bands (*comp.* Kundt, vii. 744). Semi-metallic bodies, in regard to the phases of retardation of light which falls upon them, behave like transparent bodies for the rays which they transmit, and like metals for those which they reflect.

II. CIRCULAR POLARISATION.*

Polarimeters, or Polaristrobometers (from *στροβος*, rotation).—**Saccharimeters.** Besides the Soleil Saccharimeter, a number of other instruments are now in use for determining the rotatory power of optically active substances, and may here be briefly described.

Soleil-Dubosq Saccharimeter.—The Soleil saccharimeter now manufactured by Dubosq of Paris is in all essential features identical with that already described (vol. iii. 674); the regulator *ni* (fig. 697, vol. iii. 674) is placed, however, at the eye-piece end of the instrument instead of behind the polariser *c*,† as will be evident on inspection of fig. 32, where P is the polariser, A the analyser, consisting of an achromatised

* In this section of the article 'Light' I am indebted to Dr. Armstrong, F.R.S., for many valuable additions and suggestions.

† In the description at p. 674, vol. III., it is stated (line 18 from top) that the incident light is polarised by the prism "the prism *c* is really the polariser."

calcspars prism, C the quartz-plate, and N the Nicol, which together constitute the regulator; the prism N is fitted in a milled collar B.

The scale of this instrument is constructed so that the space between 0 and 100 exactly represents the distance through which the quartz-wedges must be moved in

FIG. 32.

order to compensate the deviation produced by a plate of quartz 1 mm. thick placed between the polariser and analyser at right angles to their common axis, in the position ordinarily occupied by the substance under examination. Clerget in 1849 stated that a column 200 mm. in length of an aqueous solution containing 16.471 grams cane-sugar in 100 c.c., was capable of producing the same deviation of the polarised ray as such a plate of right-handed quartz; Dubrunfaut subsequently pointed out that only 16.390 grams were necessary, and the amount was afterwards still further reduced to 16.350 grams by a commission consisting of Barreswil, Duboscq, Pouillet and Schlösing.* The directions now issued with the instrument specify this last-named amount as that which is to be used in verifying the scale; and if this weight of a substance containing cane-sugar unmixed with any other optically active body be dissolved in water to 100 c.c., and the extent to which the wedges must be displaced in order to compensate the effect produced by a column 200 mm. in length of the solution be determined, the scale-reading directly represents the percentage of cane-sugar in the substance under examination †; if any other weight, w , of the substance be taken, and the extent to which the wedges must be displaced be ascertained, then calling this δ , the percentage of cane-sugar is given by the proportion

$$x = \frac{16.35}{w} \times \delta.$$

Soleil-Ventzke, or Soleil-Ventzke-Scheibler Saccharimeter.—The Soleil-Ventzke instrument differs from the Soleil only in possessing a different scale. The Soleil-Ventzke-Scheibler saccharimeter has in addition certain mechanical improvements introduced by Scheibler; the regulator is placed in front of the polariser, and only one wedge of the quartz compensator is movable. The disposition of the optical parts is shown in fig. 33.

FIG. 33.

The Soleil-Ventzke scale is graduated by means of a solution of cane-sugar of the density 1.1 at 17.5°; such a solution is prepared by dissolving 26.048 grams of sugar to 100 c.c. The space through which the compensator is moved from the zero position in order to neutralise the effect of a column 200 mm. in length of the solution is divided into 100 equal divisions, so that if 24.048 grams of a substance containing cane-sugar as the only optically active constituent be dissolved to 100 c.c., and the

* Schmitz and Tollens' experiments indicate 16.302 grams as the proper amount (*comp. Landolt, Das optische Drehungsvermögen organischer Substanzen*: Brunswick, 1879, p. 206).

† This of course is true only on the supposition that the rotatory power of cane-sugar in solution is independent of the concentration, which it is not entirely (see pp. 1205, 1206).

solution be examined in a 200 mm. tube, the scale-reading will at once indicate the percentage of sugar.

The Soleil saccharimeter furnishes exact results only in the case of bodies which like cane-sugar and dextrose have the same or nearly the same rotatory dispersive power as quartz (see p. 1206), as the two halves of the field cannot be obtained of the same tint when substances which do not exhibit the same rotatory dispersive power as quartz—especially such as produce a considerable rotation of the plane of polarisation—are interposed between the polariser and analyser. Moreover many persons are either colour-blind or have a difficulty in judging of colours. These objections do not apply to the instruments now to be described.

Mitscherlich's Polarimeter.—The simplest form of polarimeter, often called by this name, consists of a polarising and analysing Nicol with the addition of a lens in front of the former to concentrate the light, and produce a circular field, and of a small telescope in front of the analyser (iii. 673). The analyser is attached to a vernier, capable of moving round a graduated circle. To set the instrument, and determine its zero-point, a ray of homogeneous yellow light from a sodium flame is passed along the axis, and the analyser is turned till the field of view exhibits the greatest darkness. This takes place in two positions 180 degrees apart, namely, when the principal sections of the polarising and analysing Nicol's prisms are at right angles to each other. If, however, the field of view be rather large, it does not become entirely dark, but is crossed by a vertical black band, which gradually becomes lighter towards the edges. This band should be exactly in the centre of the field when the index points to 0° . If now, the analyser having been brought to the zero-point, a tube filled with an optically active liquid be placed between the prisms, the field will appear more or less bright; and to measure the angle of rotation, the analyser must be turned to the right or to the left till the field or the black band in its centre again attains its greatest darkness.

If, however, the direction of the rotation be not previously known, the interpretation of the phenomena requires attention to the following considerations. Suppose

Fig. 34.

the plane of polarisation, originally in the position A B (fig. 34), to be turned by the action of the liquid into the position C D, making an angle of 30° with A B. The greatest darkness will then occur when the index points either to 30° or to 210° , indicating either a dextro-rotation of 30° or a levorotation of $360^\circ - 210^\circ = 150^\circ$. In nearly all cases the true rotation is in the direction of the smaller deflection. This, however, would not be the case if the angle of rotation were greater than 90° , which might occur if the rotatory power of the liquid were very great, or the tube more than 2 decimeters long. In such cases the question may be decided by using a tube of only half the original length, or diluting the solution to half its original strength. The rotation will thereby be reduced to half its original amount, and its direction will be easily recognised. If, for example, the field becomes dark when the analyser is at 15° or 195° , the decrease takes place in the direction of dextro-rotation, whereas the angle measured to the left increases from 150° to 160° , which is inconsistent with the conditions of the experiment.

Wild's Polaristrobometer.—This instrument, invented by Wild in 1864 (*Ueber ein neues Polaristrobometer*, Bern, 1865), gives indications much more exact than those of Mitscherlich's apparatus. The essential feature of it is that between the polariser and analyser, the former of which is movable, there is inserted a Savart's polariscope, whereby a number of black interference bands are produced, which disappear in certain positions of the polariser. These positions, which can be sharply distinguished, afford the means of setting the instrument. The light used is that of the sodium flame screened by a plate of potassium bichromate.

The construction of the instrument is shown in figs. 35 and 36, the identical parts being indicated by small letters in the former, by capitals in the latter. The polarising and analysing arrangements are fixed at the ends of a brass frame Y, moving horizontally and vertically on the stand X. The light entering at *a* into the tube *b* passes first through the round diaphragm *c* (10 mm. in diameter), and then through the Nicol *d*. The mounting of these pieces is firmly attached to the circular disc *e*, and may be turned therewith round the axis. The polarised rays pass through the active liquid in the tube *f*, and lastly enter the fixed eye-piece. This part of the instrument, called the *polariscope*, contains: first, the part which yields the sensitive interference phenomena, namely, two plates of calcspar each 3 mm. thick, cut at an angle of 45°

to the optic axis, and cemented together in such a manner that their principal sections are at right angles to one another. Next follow two lenses *h* and *i* (of 120 mm. focal length), forming a telescope which magnifies about 5 times, with an arrangement for altering the distance of the latter. Between these, and in the focus of the object-lens *h*, is a circular diaphragm *k*, of about 4 mm. aperture, and provided with cross-wires

FIG. 35.

in the form of a cross. Lastly comes the Nicol's prism *l*, mounted with its principal section horizontal, and therefore inclined at 45° to the crossed principal sections of the double plate *k*. To keep the parts *g* and *l* in the same position, the movable part of the eye-piece containing the Nicol and the lens *i* is furnished with a guiding pin. The

FIG. 36.

entire polariscope slides within a tube *Z*, fixed on the horizontal frame *Y*, and can be rotated therein through a small angle, for which purpose the tube *z* is provided with a guiding slit, and two clamping screws *m m*. A circular screen is fixed at *n* to protect the eye of the observer from extraneous light.

To enable the polarising Nicol to be rotated, its mounting, together with the circular disc attached to it, moves within a ring, fixed to the frame *Y*. The disc carries, on the side next the observer, a toothed wheel, and in this works the pinion *o*, which can be moved by the button *p* at the end of the rod *g*. The disc is graduated nearer its circumference, and in front of the graduation is fixed a vernier, or the simple index *r*. The graduation is read off by the telescope *s*, at the end *v* of which is an obliquely placed metallic mirror, with circular aperture, which reflects to the vernier the light of a small gas-flame placed on a movable arm. The instrument is usually made for

holding tubes up to 220 mm. in length. If it is to be used for scientific purposes, the disc must be graduated all round; for use in saccharimetry, a graduation extending only over one or two quadrants may be sufficient.

To set the instrument, the zero-points must first be determined by placing an empty tube in position and drawing out the eye-piece of the polariscope till the X-formed cross-lines are distinctly seen. If the polariser is then turned round by means of the button *p* (fig. 35), a position will be found in which the field of view will be traversed by a number of black parallel bands or fringes (fig. 37*a*). On continuing to turn, these fringes gradually become paler, and a point is at length reached at which a portion of the field appears bright and free from bands. By a slight backward and forward movement of the button, this bright portion may be brought into the middle of the field, and the remains of the fringes will still be visible at equal distances right and left of the cross-lines (fig. 37*b*). This position serves as the starting point for reading off the graduation. On turning the Nicol further round, the fringes first become stronger up to a certain maximum, then fainter till they disappear, and in a complete revolution of the disc this appearance may be observed four times, at intervals of 90° . In each of these positions the residual fringes usually assume a distinct form, which must be impressed on the memory (*comp.* Landolt, *op. cit.* p. 106).

FIG. 37.

The disappearance of the fringes corresponds with those positions of the movable Nicol at which its principal section is either parallel or perpendicular to that of the first calcite plate of the polariscope, and, on the other hand, the greatest depth of the fringes takes place when these planes are inclined to one another at an angle of 45° . The optical parts of the instrument are adjusted by the maker in such a manner that the zero-points may fall nearly on the divisions 0° , 90° , 180° , and 270° ; they may, however, be shifted a little by means of the screws *m m*.

The movable Nicol having been brought to one of the four zero-points, the replacement of the empty tube by a tube filled with an active liquid, by which the plane of polarisation is turned through a certain angle, causes the interference-bands to reappear; and in order to bring the plane of polarisation back to parallelism or perpendicularity with that of the first plate of calcite, the Nicol must be turned round the opposite way, *i.e.* to the left or right accordingly as the active substance is dextro- or lævogyrates: the fringes will then reappear.

If the direction of rotation of the active liquid is not previously known, it is best ascertained by filling the tube with a dilute solution of the substance, so as to produce only a slight deviation, the direction of which, right or left, is easily distinguished. If, on the other hand, the deflections are of larger amount, doubts may arise as to

FIG. 38.

FIG. 39.

their direction, in the same manner as with Mitscherlich's apparatus. Suppose, for example, that the four zero-points are situated at

0° 90° 180° 270°

and that after insertion of the tube containing the active liquid, the fringes disappear at

30° 120° 210° 300°

then, as shown by figs. 38–41, the active liquid may be either dextrogyrate with an angle of 30° (fig. 39), or lævogyrates with an angle of 60° (fig. 38).

To decide the question, a second observation must be made either with a shorter tube or with a weaker solution. If, for example, the length of tube, or the concentration, in the second experiment, be only half that in the first, the angles of rotation will also be reduced to one-half their former magnitude. The fringes will therefore disappear at the positions

15° 105° 195° 285°
if the liquid is dextrogyrate (fig. 41), or at
60° 150° 240° 330°
if it is lævogyrate (fig. 40).

FIG. 40.

FIG. 41.

If, therefore, the observation with the shorter tube or weaker solution gives a number smaller than that obtained in the first experiment, the rotation is to the right; if, on the contrary, a larger number is obtained in the second experiment, the rotation is to the left.

In the examination of highly active liquids, it may happen that the angles of rotation exceed 90°, so that the readings fall in the following quadrants. To avoid errors in such cases, it is in like manner necessary to make observations with two tubes differing in length. Lævogyrate nicotine, for example, in a tube 100 mm. long, gave, in round numbers, the following results:—

	Quad. I	Quad. II	Quad. III	Quad. IV
Empty tube	90	180	270	360
Filled tube	18	108	198	288
Angle of Rotation	72	72	72	72

On repeating the observation with a tube 50 mm. long, the results were:—

	Quad. I	Quad. II	Quad. III	Quad. IV
Empty tube	90	180	270	360
Filled tube	9	99	189	279
Angle of Rotation	81	81	81	81

Instead, therefore, of the half-deflection expected in the latter case, a deflection was obtained even greater than that with the longer tube. If 50 mm. nicotine produce a deflection of 81°, 100 mm. should give 162°, and this result is, in reality, obtained when the zero-points in the second series of observations corresponding with this double length of tube are shifted one quadrant to the right. We have then:—

Empty tube	II 180	III 270	IV 360	I 90
Filled tube	I 18	II 108	III 198	IV + 72 (= 360-288)
Angle of Rotation	162	162	162	162

These relations may be made clearer by inspection of figs. 42 and 43, the former of which represents the rotation for a column 50 mm. long, the latter for 100 mm.

In all exact experiments it is necessary to carry out the observations in all the four quadrants. It will then be found that the observed angles of rotation differ from one another by somewhat considerable amounts, the differences arising from

defects in the construction of the Nicols, and from inexact mounting of the two calcite plates of the Savart's polariscope. These errors, however, may be made to disappear completely by taking the mean of the angles of rotation observed in the four quadrants.

FIG. 42.

FIG. 43.

Half-shadow Polarimeters (Polarimètres à penombre).—In these instruments, invented by Jelett, Cornu, and Laurent, the circular field of view is divided into two equal parts which, within certain positions of the analyser, are unequally darkened, but in one particular position exhibit a faint and equal degree of shading. This point, which may be very exactly observed, serves for setting the instrument. The light used is that of the sodium-flame.

The penumbral apparatus most in use, especially for saccharimetry, is that of Laurent (*Dingl. pol. J.* cccxiii. 608) represented in section in fig. 44, where *a* is a

FIG. 44.

thin plate of potassium dichromate, serving to free the yellow light from admixed green, blue, and violet light; *b* the polarising prism; *c* a diaphragm carrying a glass plate to which a thin plate of quartz, cut parallel to the axis, is affixed so as to cover exactly one half of the field; *d* the tube containing the active liquid; *e* the analysing Nicol's prism; and *f g* a Galilean telescope of low power. The analyser is moveable, the extent to which it is moved being read off on a divided circle. The observation is made with a sodium-flame.

The quartz plate is of such thickness that, in their passage through it, the yellow rays polarised parallel and perpendicular to its axis suffer a retardation of exactly

FIG. 45.

FIG. 46.

FIG. 47.

FIG. 48.

half a wave-length. When the polariser is set so that the entering rays are polarised in a plane *A B* parallel to the axis of the quartz plate *P Q*, fig. 45, both halves of the field are of the same relative intensity, whatever the position of the analyser; but if

the quartz plate be inclined at an angle α to A B, the rays passing through the plate are deflected to an equal extent α' , in the opposite direction, so that whenever the plane of polarisation is in the direction A C in the uncovered half of the field, it is in the direction A C' in the covered half. On turning the analyser, the rays polarised parallel to either A C or A C' are extinguished according as the plane of polarisation of the analyser comes into the position cc or $c'd'$ (figs. 46, 47); so that while one half of the field appears perfectly dark, the luminous intensity of the other half is only partially diminished; when it attains the position bb (fig. 48), the intensity is diminished to an equal extent in either half, and the whole field is uniform in tone; a very slight movement in either direction, however, then causes a perceptible difference in the intensity of the two halves.

When the polariser and analyser are set with their principal sections at right angles, the field of view appears darker the smaller the angle α at which the plane of polarisation of the polariser is inclined to the axis of the quartz plate. The instrument is provided with an adjustment which permits of a slight alteration of the position of the polariser relatively to the quartz plate; it is the more sensitive, however, the less the polariser is moved from the normal position.

Jelett-Cornu Shadow Polariscopes.—This consists of an ordinary Nicol's prism, as analyser, and a peculiarly constructed Nicol, devised by Jelett, as polariser; the analyser is movable, and is associated with a divided circle. Yellow monochromatic light is employed in making the observation, a plate of bichromate being placed before the polariser. The polariser is constructed by cutting through an ordinary Nicol across the shorter diagonal and grinding down the two cut surfaces 2.5° ; the two halves are then cemented together again, and thus form a double Nicol having two principal sections inclined at 5° . The field presents precisely the same appearance as that of the Laurent instrument; on turning the analyser until its principal section is at right angles to one of the principal sections of the polariser, the corresponding half of the field becomes perfectly dark; a rotation of 5° renders the other half dark instead, but at an intermediate position of the analyser, the two halves of the field, although perfectly dark, are of equal intensity. Both with this and the Laurent instrument it is necessary to use a light of considerable intensity, and it is of considerable advantage to concentrate the light by means of a lens interposed between the flame and the polariser.

Usually only one half the circle of the Wild, Laurent, and Jelett-Cornu polariscopes is divided into degrees, the other half bearing a sugar scale; but different scales are adopted by the various makers. Thus the sugar scale of the Jelett-Cornu instrument manufactured by Duboseq of Paris is similar to the Soleil saccharimeter scale, an arc of $21^{\circ} 40'$ being divided into 100 equal divisions, and each division indicating 1 per cent. of cane-sugar when the solution examined is prepared by dissolving 16.35 grams of substance to 100 c.c. The Laurent polariscope made by Schmidt and Haensch of Berlin is provided with the Ventzke scale, each division indicating 1 per cent. of sugar when 26.048 grams of substance is taken. The Wild polaristrometer, manufactured by Hermann and Pfister of Bern, has yet a different scale, based on the observation that a 200 mm. column of a solution containing 40 grams cane sugar in 100 c.c. has a rotatory power of 53.134° ; an arc of this extent is divided into 400 equal divisions, so that if 20 grams of substance be dissolved to 200 c.c. and the solution examined in a 200 mm. tube, the number of divisions of the scale through which the index is moved multiplied by 2 expresses the percentage of sugar present.

If it be desired to convert the scale-readings of either form of the Soleil saccharimeter into actual degrees, it is simply necessary to bear in mind that, according to Broch, a plate of quartz 1 mm. in thickness rotates the plane of polarisation of light of the refrangibility of the D lines 21.67° , and the medium yellow rays 24.5° ; therefore:

$$\begin{aligned} 1 \text{ division Soleil-Duboscq (j)} &= 0.2167^\circ \alpha_D \\ 1 \quad " \quad " \quad " &= 0.245^\circ \alpha_1 \end{aligned}$$

The divisions of the Soleil-Ventzke scale are $\frac{26.048}{16.35} = 1.593$ times as large as those of the Soleil-Duboseq scale.

As already pointed out, each division of the Soleil-Duboscq or Soleil-Ventzke scale represents the same amount of sugar, only if the rotatory power of cane sugar in solution be independent of the concentration; but the experiments of Schmitz and Tollens have shown that this is not quite the case. The following table shows the extent to which the scale readings of the Soleil-Duboscq instrument require correction (Landolt, *op. cit.* p. 167):

Scale reading	Corrected scale reading	Difference	Grams of sugar in 100 c.c. of solution		
			Uncorrected	Corrected	Difference
100	100.00	—	16.350	16.350	—
90	89.98	.02	14.715	14.712	.003
80	79.97	.03	13.080	13.075	.005
70	69.96	.04	11.445	11.438	.007
60	59.95	.05	9.810	9.802	.008
50	49.95	.05	8.175	8.167	.008
40	39.95	.05	6.540	6.532	.008
30	29.96	.04	4.905	4.898	.007
20	19.97	.03	3.270	3.265	.005
10	9.98	.02	1.635	1.632	.003

The correction is slightly higher in the case of the Soleil-Ventzke instrument, although for solutions containing less than 16 and above 85 per cent. it is so small that it may be neglected. Schmitz has calculated a table giving the correction for each scale division between 0 and 100 (see Landolt, *op. cit.* p. 156).

Determination of the Angle of Rotation for different Rays by Broch's (Fizeau and Foucault's) method.—The instruments above described allow only of the determination of the rotatory power for the medium yellow rays or for light of the refrangibility of the D lines; the rotatory power for rays of other wave-lengths may, however, be determined by the method indicated by Broch, and simultaneously by Fizeau and Foucault in 1846, by combining a spectroscope with an ordinary polariscope of two Nicol's prisms. By means of a heliostat, a horizontal beam of sunlight is reflected into a darkened room and allowed to fall on the polariser, and a spectroscope, the eyepiece of the observing telescope of which is provided with cross-wires, is placed in front of the analyser. In the first instance, the polariser and analyser are set with their principal sections at right angles, so that the light is completely extinguished. On introducing the substance, the rotatory power of which is to be measured, between the Nicols—since the planes of polarisation of the various components of the white light are deflected to a different extent in their passage through the active substance, and the colour whose plane of polarisation is perpendicular to that of the analyser is extinguished—the emergent light is coloured, and the spectrum seen on looking through the spectroscope contains, in addition to the ordinary Fraunhofer lines, a black band which shifts its position as the analyser is rotated. The observation consists in adjusting the cross-wires so as to coincide with one of the Fraunhofer lines, and then rotating the analyser until the centre of the black band is in the position previously occupied by the Fraunhofer line. The angle through which the analyser has been moved is then read off on the divided circle to which it is attached; and this reading represents the angular deviation of light of the wave-length of the particular line. V. von Lang has employed this method (*Pogg. Ann.* clvi. 422) in determining the rotatory power of quartz for light of the refrangibility of the red lithium line, the yellow sodium line, and the green thallium line, using artificial light, and this modified form of the method is probably of wide application. First a Bunsen flame is placed in front of the polariser, and a salt is heated in it capable of yielding a spectrum containing the line of the desired wave-length (a Geissler tube containing hydrogen may also be employed); the cross-wires of the spectroscope having been adjusted to this line, the Bunsen is replaced by an Argand burner, and the analyser rotated until the black band, which is seen on a background of continuous spectrum, is coincident with the cross-wires. In determining the rotatory power for rays near the limits of the visible spectrum, it is necessary to employ the lime light as the source of the continuous spectrum, as the light from an Argand burner is not rich enough in rays of extreme refrangibility to illuminate sufficiently the region on either side of the dark band. The chief objection to this method arises from the difficulty of determining exactly the position of the centre of the band, because of the gradual manner in which it shades off on either side: hence also consecutive readings are liable to differ to a greater extent than is usual with the instruments ordinarily employed. The method furnishes the most accurate results with substances of medium rotatory power (comp. Wiedemann, *Pogg. Ann.* (1851), lxxxi. 215).

Accuracy of various forms of Polariscope.—According to Landolt (*op. cit.* p. 117), equally accurate results may be obtained with either Wild's or Laurent's or even Mitscherlich's instrument, the numbers furnished by the three differing

at most in the second and very often only in the third place of decimals. The results of two practised observers with the same instrument agree to a few hundredths of a degree.

Influence of Wave-length on the Angle of Rotation.—The rotation of the plane of polarisation produced by the passage of a ray through a given thickness of an optically active substance, increases in nearly all cases as the wave-length diminishes, being least for red and greatest for violet light. Biot inferred, from observations on quartz, that the angle of rotation is inversely proportional to the square of the wave-length (iii. 672). Recent observations have shown, however, that this law is not exact, and Boltzmann (*Pogg. Ann. Jubelbd.* 1828, 28) has shown that the formula

$$\alpha = \frac{B}{\lambda^2} + \frac{C}{\lambda^4}$$

where A and B are constants to be determined by experiment, agrees very closely with the results of observation. From measurements by Stefan (*Pogg. Ann.* cxxii. 631) and v. Lang (*ibid.* clvi. 422), on the rotatory power of quartz for the several lines of the spectrum, Boltzmann has calculated the formula

$$\alpha = \frac{7.07018}{10^6 \lambda^2} + \frac{0.14983}{10^{12} \lambda^4}$$

which differs from the results of observation only by hundredths of a degree.

On comparing the angles of rotation for light of the refrangibility of several of the chief spectral lines in different bodies, it is found that, besides the absolute differences of value for the same ray in different bodies, there are also differences in the relative values: in other words, the rotatory dispersive power is different for different bodies. Thus taking the results of measurements of the rotatory powers of a number of substances specified in the following table:—

		B	C	D	E	F	G
Quartz . . .	1mm.	15.55°	17.22°	21.67°	27.46°	32.69	42.37°
Cane-sugar . . .	[α]	47.56	52.70	66.41	84.56	101.18	131.96
Cholic acid . . .	[α]	28.2	30.1	33.9	44.7	52.7	67.7
Cholesterin . . .	[α]	-20.63	25.54	31.59	39.91	48.65	62.37
French turpentine oil .	α 100 mm.	-21.5	23.4	29.3	36.8	43.6	55.9
Lemon oil . . .	α 110 mm.	34.0	37.9	48.5	63.3	77.5	106.0

and calculating the ratios of the rotation of rays of the refrangibility of the lines C D E F G to that for the line B, the results exhibited in the following table are obtained:—

	B	C	D	E	F	G
Quartz	1	1.11	1.39	1.77	2.10	2.72
Cane-sugar	1	1.11	1.40	1.78	2.13	2.77
Cholic acid	1	1.07	1.20	1.59	1.87	2.40
Cholesterin	1	1.24	1.53	1.93	2.36	3.02
French turpentine oil .	1	1.09	1.36	1.71	2.03	2.60
Lemon oil	1	1.11	1.43	1.86	2.28	3.12

Hoppe-Seyler has determined the specific rotatory power of dextroglucose for light of the refrangibility of the C, D, E, and F lines with the following results:—

[α] _C	[α] _D	[α] _E	[α] _F
42.45	53.45	67.9	81.3

and dividing these by the rotatory power of 1 mm. of quartz, the following ratios are obtained:—

2.46	2.47	2.47	2.49
------	------	------	------

These numbers show that quartz, cane-sugar, and dextroglucose have equal rotatory dispersive powers, whereas in other bodies the rotatory dispersion is either greater or less than in quartz. This circumstance is of importance with regard to the use of the Soleil saccharimeter (iii. 674), the construction of which is based on the assumption of the equality of dispersion of the substance under examination with that of quartz; and as this appears to be the case only with cane-sugar and dextroglucose, it follows that the rotatory powers of other bodies cannot be exactly determined with this form of instrument.

Anomalous Rotatory Dispersion.—Tartaric acid in both its modifications offers a remarkable exception to the rule above stated that the deviation which a polarised ray undergoes in its passage through an optically active substance is greater the shorter its wave-length. This was first observed by Biot, but Arndtsen established

the law of the phenomenon (*Ann. Chim. Phys.* [3], liv. 415). The rotatory power of tartaric acid in aqueous solution varies greatly with the concentration, but in such a manner that it may be represented by the linear equation

$$[\alpha] = A + Bc,$$

where c is the percentage of water present. From experiments with solutions containing from 5 to 50 per cent. of the dextro-acid, Arndtsen has deduced the following values of A and B for light of the refrangibility of the lines C, D, E, b, F, e.

$[\alpha]_C =$	$+ 2.748^\circ$	$+ 9.446^\circ$
$[\alpha]_D =$	1.950	$+ 13.030$
$[\alpha]_E =$	$.153$	$+ 17.514$
$[\alpha]_b =$	$-.832$	$+ 19.147$
$[\alpha]_F =$	-3.598	$+ 23.977$
$[\alpha]_e =$	-9.657	$+ 31.437$

The results are represented graphically in the following table:—

It will be noticed that solutions containing not less than about 85 per cent. of water exhibit a normal behaviour, exercising a maximum rotatory effect on the most refrangible rays, but that as the concentration increases, the point of maximum effect gradually passes to the other end of the spectrum, the most refrangible rays being the least rotated by a solution containing about 55 per cent. of the acid. Evidently the lines c, e, F F, and E E, if prolonged, would cut the base line at a point between 0 and 50: in other words, rays of these refrangibilities would suffer laevorotation in their passage through highly concentrated solutions of dextro tartaric acid. The rotatory power of the acid itself may be calculated to be as follows:

$$[\alpha] = + 2.748^\circ \quad 1.950^\circ \quad .153^\circ \quad -.832^\circ \quad -3.598^\circ \quad -9.657^\circ.$$

Solutions to which only a very small amount of boric acid has been added, or heated solutions, do not exhibit the above-described anomalous behaviour (Biot; Krecke).

Two optically active, chemically indifferent bodies of opposite rotatory power, having *different rotatory dispersive powers*, if mixed in certain proportions, would (as Biot has shown for a solution of dextrorotatory camphor in laevorotatory turpentine oil) exhibit phenomena similar to those manifested by tartaric acid solutions; hence the most probable explanation of the anomalous rotatory dispersive power of solutions of tartaric acid would appear to be that they contain, besides the acid, a compound of opposite rotatory power of the acid with water, in proportions varying according to the concentration and temperature of the solutions.

Influence of Temperature on Rotatory Power. According to Tuchschnid (*J. pr. Chem.* [2], ii. 235), the specific rotatory power of cane-sugar in aqueous solution is not affected by alterations of temperature; the same is true of the specific rotatory power of camphor in alcoholic solution (*ibid*), but the specific rotatory power of the majority of substances varies with the temperature, and most frequently diminishes as the temperature rises; laevulose is a notable example of this kind of alteration.

Gernez has investigated the alteration in specific rotatory power with rise of temperature of a number of terpenes and of camphor, and has extended his observations to temperatures above their boiling points. The results obtained for French turpentine and camphor are exhibited in the following table (*Ann. scient. de l'Ecole norm. sup.* i. 1):—

Temperature	Density referred to water d	Observed angular deviation α	Length of tube l	Sp. rot. power $[\alpha] = \frac{\alpha}{dl}$
<i>French Turpentine Oil.</i>				
Liquid . . .	$\left\{ \begin{array}{l} 11^{\circ} \\ 98^{\circ} \\ 154^{\circ} \end{array} \right.$	$\left\{ \begin{array}{l} \cdot 8712 \\ \cdot 7996 \\ \cdot 7505 \end{array} \right.$	$\left\{ \begin{array}{l} 15\cdot 97^{\circ} \\ 14\cdot 47^{\circ} \\ 13\cdot 50^{\circ} \end{array} \right.$	$\left\{ \begin{array}{l} \cdot 5018 \\ \cdot 50215 \\ \cdot 50237 \end{array} \right.$
Vapour . . .	$\left\{ \begin{array}{l} 168^{\circ} \end{array} \right.$	$\left\{ \begin{array}{l} \cdot 003987 \end{array} \right.$	$\left\{ \begin{array}{l} 5\cdot 76^{\circ} \\ 40\cdot 61 \end{array} \right.$	$\left\{ \begin{array}{l} 36\cdot 53 \\ 36\cdot 04 \\ 35\cdot 81 \\ 35\cdot 49 \end{array} \right.$
Vapour-density at $168^{\circ} = 4\cdot 981$. Theoretical density, $4\cdot 700$.				
<i>Camphor.</i>				
Fused . . .	$\left\{ \begin{array}{l} 204^{\circ} \end{array} \right.$	$\left\{ \begin{array}{l} \cdot 812 \end{array} \right.$	$\left\{ \begin{array}{l} 31\cdot 46^{\circ} \\ 40\cdot 63 \end{array} \right.$	$\left\{ \begin{array}{l} \cdot 5509 \end{array} \right.$
Vapour . . .	$\left\{ \begin{array}{l} 220^{\circ} \end{array} \right.$	$\left\{ \begin{array}{l} \cdot 003843 \end{array} \right.$		$\left\{ \begin{array}{l} 70\cdot 33 \\ 70\cdot 31 \end{array} \right.$
Vapour-density at $220^{\circ} = 5\cdot 369$. Theoretical density, $5\cdot 252$.				

These results are of especial importance, as they prove that the rotatory power of substances such as the terpenes is a property of the individual molecules, so that the optical differences between the various terpenes cannot be supposed to be due to their consisting of aggregates of different degrees of complexity.

Tartaric acid in aqueous solution exhibits a considerable increase of rotatory power with rise of temperature (Tuchschild, *loc. cit.*; Krecke, *Arch. Neerland.* vii. 97). The following results of a series of observations with three different solutions have been published by Krecke:

Temperature	Percentage of tartaric acid.		
	40	20	10
0°	$[\alpha]_D = 5\cdot 53^{\circ}$	$[\alpha]_D = 8\cdot 66^{\circ}$	$[\alpha]_D = 9\cdot 95^{\circ}$
10	7·49	9·96	10·94
20	8·32	11·57	12·25
30	9·62	12·49	13·93
40	11·03	13·65	15·68
50	12·27	15·01	17·11
60	12·63	16·18	18·31
70	13·38	17·16	19·42
80	14·27	18·40	20·72
90	15·91	19·99	22·22
100	17·66	21·48	23·79

According to Biot, whereas fused liquid tartaric acid has a considerable dextro-rotatory power, the solidified acid is feebly lævorotatory.

Influence of neutral solvents and of optically inactive substances on the rotatory power. Biot was originally led, by the investigation of the rotatory power of cane-sugar, to the conclusion that the rotatory power of a solution of an active substance in an inactive medium was directly proportional to the amount of active substance present. In 1838, however, he discovered the exceptional behaviour of tartaric acid, and in 1852 he showed that the specific rotatory power of oil of turpentine dissolved in alcohol increased, while that of camphor dissolved in alcohol or acetic acid diminished, on increased dilution; also that the specific rotatory power of camphor deduced from observations with an alcoholic solution did not agree with that deduced from observations with an equally concentrated acetic acid solution (*Ann. Chim. Phys.* [3], xxxvi. 257; comp. *ibid.* lix. 206). The modifying influence of

neutral solvents does not appear to have been generally recognised until Oudemanns in 1872 (*Liebig's Annalen*, clxvi. 65) and Hesse in 1875 (*ibid.* clxxvi. 89, 189) again directed attention to the subject.

The results of Oudemanns are given in the following table, in which p denotes the ratio of the weight of the dissolved substance to that of the solution; and $[\alpha]$ the specific rotatory power (see p. 1210). The numbers show that different substances are affected by the same solvent in very different degrees.

Substance	Solvent	p	$[\alpha]$
Cane-sugar . . .	Water . . .	0.056	+ 66.9°
" " . . .	Alcohol, 50 per cent. . .	0.050	+ 66.4

Mixtures of two solvents may modify the specific rotatory power in a manner quite different from what might be expected from their action when separate. In an alcoholic solution of cinchonine, about half the alcohol may be replaced by chloroform without any considerable alteration of the rotatory power, whereas in a solution of cinchonine in chloroform the replacement of only $\frac{1}{300}$ of that solvent by alcohol produces a difference of 4° in the specific rotatory power. This power is at its maximum ($\alpha = 237.3^\circ$) when the solvent consists of a mixture of 10 per cent. alcohol and 90 chloroform. These facts show the great care which is necessary in experiments of this kind, to ensure the perfect purity of the solvents used. All the bodies examined by Oudemanns exhibited the greatest rotatory power in those solvents in which they dissolved most abundantly.

Hesse's observations, extending to over 50 substances lead to precisely similar conclusions. For example, the following maximum and minimum values of $[\alpha]$ were found on examining solutions in various media of equal weights of the substances specified.

Elaborate observations on the influence of inactive solvents have also been made by Landolt (*Liebig's Annalen*, clxxxix. 241–337; *Deut. Chem. Ges. Ber.* ix. 901–914). This chemist has stated that a solution of tartaric acid in methylic alcohol is optically inactive (*ibid.* vi. 1078).

Tollens and Schmitz (*Deut. Chem. Ges. Ber.* x. 1403, 1414) have shown that the specific rotatory power of cane-sugar slightly increases, while, according to Tollens (*ibid.* ix. 1531), that of dextrose diminishes in a somewhat greater proportion with increased dilution.

	Maximum	Minimum	Difference
Tartaric Acid	+ 14.18°	+ 3.20°	10.98°
Quinic Acid	— 44.09	— 39.20	4.89
Santonine	— 176.50	— 171.53	4.97
Codeine	— 137.75	— 111.50	26.25
Laudanosine	— 105.00	— 56.00	49.00
Quinine	— 169.25	— 116.00	53.25
Cinchonidine	— 119.54	— 83.86	35.88
Cinchonine	+ 237.27	+ 226.48	10.79

Acids, alkalis, and mineral salts also in many cases greatly modify the rotatory power of active substances when added to their aqueous solutions. Thus mannite, which alone in an aqueous solution exercises a very slight levorotatory effect, manifests a considerably greater levorotatory power in presence of alkalis; acids have no influence, but it becomes dextrorotatory on the addition of borax, sodium chloride, or sodium sulphate. An aqueous solution of calcium dextrotartrate is dextrorotatory, but if this salt be dissolved in hydrochloric acid, a levorotatory solution is obtained. The rotatory power of tartaric acid is considerably increased by the addition of borax or boric acid, but diminished by the addition of hydrochloric or sulphuric acid. Many other similar cases of alteration in rotatory power have been observed (comp. Landolt, *op. cit.*)

Definition of Specific Rotatory Power. Apparent and Absolute Specific Rotatory Power. The specific rotatory power $[\alpha]$ of a substance for light of any particular refrangibility, according to Biot's definition, is the angular deviation imparted to the ray observed by a column of unit length and density, and is expressed by the formula

$$[\alpha] = \frac{\alpha}{l \cdot d},$$

where α is the observed angle, l the length of column—the decimeter being taken as the unit of length, and d the density of the substance; or, in other words, if the density be referred to water at 4°, the specific rotatory power is the angular deviation produced by a layer 1 decim. in length of a substance of which 1 gram occupies a volume of 1 c.c.

This formula, however, applies only to bodies which can be examined *per se*; if a solution of an active substance in an inactive solvent be employed for the determination, the specific rotatory power is deduced with the aid of the formula

$$[\alpha] = \frac{\alpha}{l \cdot c \cdot d},$$

where c is the amount of active substance in a unit of weight of solution, and d the density of the solution. If, as is frequently done, the amount of active substance in 100 parts by weight of the solution be determined, indicating this by p , the formula becomes

$$[\alpha] = \frac{100 \alpha}{l \cdot p \cdot d}.$$

But from the remarks made in the previous section it will be obvious that the specific rotatory power determined in this manner is not that of the substance itself, the specific rotatory power being in fact more or less modified by the association of the active substance with the inactive solvent, and the value obtained is applicable only to the solution of the particular strength and character observed. The value appertaining to the substance itself may be termed the *absolute* or *true specific rotatory power*, or simply the specific rotatory power; that appertaining to the substance in solution may in contradistinction be termed the *apparent specific rotatory power*. It may not be here out of place to insist on the fact that the former alone is a constant, and the only one which can be employed in the discussion of possible relations in rotatory power between optically active bodies.

In determining the *apparent* specific rotatory power, since $pd = c$, *i.e.* the concentration or number of grams of active substance in 100 c.c. of solution, the simpler formula

$$[\alpha] = \frac{100 \alpha}{l \cdot c}$$

is often employed.

The observed angular deviation is always indicated by the symbol α , the specific rotatory power by the symbol $[\alpha]$, the nature of the light for which the observation is made being represented by the index r, j, d , &c.; r applies to observations made with light which has passed through red glass, the use of which is now entirely abandoned; j applies to observations with the Soleil saccharimeter, where medium yellow light (*jaune moyen*) is employed; d indicates that light of the refrangibility of the D line is employed.

Tollens has suggested that the apparent specific rotatory power of a substance in a 10 per cent. solution should be termed the *conventional* specific rotatory power, and indicated by the symbol $[\alpha]_{10D}$; and that if so concentrated a solution cannot be obtained, a 5 or 2 per cent. solution should be employed, and the fact indicated by the use of the symbol $[\alpha]_{5D}$ or $[\alpha]_{2D}$ (*Deut. Chem. Ges. Ber.* x. 1412).

Kachler suggests (*Liebig's Annalen*, cxlvii. 88) that the rotatory power should be determined for solutions containing per litre a molecular proportion in grams of the respective active substances; inasmuch, however, as the rotatory power is not independent of the concentration, and the same solvent modifies the rotatory power of different bodies to very different extents, the advantage which such a proceeding offers of comparing the effects of equal numbers of molecules of the active substances is more apparent than real.

Determination of Absolute Specific Rotatory Power.—The mode of ascertaining the absolute specific rotatory power of bodies which cannot be examined *per se*, was first indicated by Biot (*Ann. Chim. Phys.* [3], xxviii. 236), but we are indebted to Landolt for a rigorous experimental examination of Biot's method (*Liebig's Annalen*, clxxxix. 241–337; *Deut. Chem. Ges. Ber.* ix. 901–914; *op. cit.* pp. 60–89). It consists in determining the apparent specific rotatory power for a series of solutions of various degrees of concentration, and thus ascertaining the influence of the solvent; the equation expressing the relation between the percentage of solvent q and the corresponding values of $[\alpha]$ is then sought, and this equation gives the value of $[\alpha]$, answering to $q = 0$.

Landolt has determined the values of $[\alpha]_D$ for American and French turpentine oils, ethyl dextrotartrate, and nicotine, from observations with the pure substances as well as with a number of their solutions, with the following results:

Ethyl Dextrotartrate.

Direct observation	$[\alpha]_D =$	8.31°	Difference
From observation of mixtures with ethyl alcohol		8.27	–.04°
" " " methyl "		8.42	–.22
" " " water		8.09	

Dextrorotatory Oil of Turpentine.

Direct observation		14.15	+ .02
From observation of mixtures with ethyl alcohol		14.87	

Lævorotatory Oil of Turpentine.

Direct observation		37.01	–.04
From observation of mixtures with alcohol		36.97	–.04
" " " benzene		36.97	–.12
" " " acetic acid		36.89	

Nicotine (lævorotatory).

Direct observation		161.55	–.72
From observation of mixtures with alcohol		160.83	–.26
" " " water		161.29	

It will be observed that the values deduced from observations of the solutions are practically identical with those furnished by the pure substances.

The successful application of this method, however, depends on a variety of circumstances, and especially on the solubility of the substance and the manner in which the rotatory power is modified by the solvent. Landolt's experiments with the above-named liquids show that if the variation in rotatory power can be expressed with sufficient accuracy by a linear equation $[\alpha] = A + Bq$, extremely concordant results are obtained when the most concentrated solution examined contains no more than 50 per cent. of active substance; but that if it be necessary to employ an equation of the form

$$[\alpha] = A + Bq + Cq^2,$$

the rotatory power thus determined differs by more than a degree from that observed for the pure substance if the amount of extrapolation exceed 50 per cent., and in such a case accurate results can be obtained only if solutions containing at least 80 per cent. of active substance are examined. Thus in the case of French oil of turpentine, the value of A —the rotatory power of the pure substance—as deduced from various solutions, differs from the value 37.01° directly observed for the pure substance to the extent shown in the following table:

Solvent	Amount of extrapolation	A	Difference from true value 37.01
Alcohol.	30 per cent	37.20°	+ .19
	50 "	35.15	-1.88
Benzene	35 "	37.26	+ .25
	63 "	35.42	-1.59
Acetic Acid.	22 "	36.65	- .36
	49 "	36.00	-1.01

When, as in the case of nicotine dissolved in water, the rotatory power is very considerably modified by the solvent, and the curve representing the variation is hyperbolic, the absolute specific rotatory power can be calculated, with any approach to accuracy, only from observations with the most concentrated solutions, by an equation of the form $[\alpha] = A + Bq + Cq^2$; thus the value of $[\alpha]^p$ calculated from observations with three solutions containing respectively about 90, 78, and 66 per cent. of nicotine is 163.17 , the true value being 161.55 . The equation to the entire curve for nicotine and water is as follows:

$$[\alpha]_D = 115.019 - 1.70607q + \sqrt{2140.8 - 108.867q + 2.5572q^2}.$$

For pure nicotine ($q = 0$) this gives the value $[\alpha]_D = 161.29$, that directly observed being 161.55° . For $q = 100$, the value of $[\alpha]_D$ is 74.13 , so that the rotatory power of nicotine is diminished by more than one-half by great dilution.

In practice it is, therefore, necessary in the first place to select the solvent in which the substance to be examined most readily dissolves, and at least three solutions of different degrees of concentration are then examined. If, on representing the results graphically, making the percentages of solvent q the abscissae and the corresponding values of $[\alpha]$ the ordinates, the three points of intersection are found to lie in the same straight line, the linear equation $[\alpha] = A + Bq$ capable of expressing the observations is calculated, and the constant A in this equation will be the specific rotatory power of the pure substance. If, however, the three points do not lie in the same straight line, further observations must be made in order to establish the character of the curve as completely as possible, and the equation to the curve is then sought. It is always desirable to examine solutions of the substance in a variety of media; if the values of A are fairly concordant, their mean is taken as the true value; but if they exhibit considerable discrepancies, the determination of the specific rotatory power in this manner must be abandoned. It appears to be useless to attempt the application of the method to substances of which solutions containing at least 50 per cent. of active substance cannot be prepared.

Landolt has determined the absolute specific rotatory power of camphor in this way (see p. 374), and Tollens has applied the method to dextroglucose and cane-sugar, the absolute specific rotatory power of the latter having also been determined by Schmitz (see pp. 1206, 1211). These are the only solid substances of which the absolute specific rotatory power is at present known.

Molecular Rotatory Power.—F. W. Krecke (*J. pr. Chem.* [2], v. 6) has made an extensive series of experiments on the effect of chemical combination on the molecular rotatory power (*i.e.* the product of the specific rotatory power* and the molecular weight) of organic bodies, and on the relations of molecular rotatory power in isomeric and allied bodies, from which he deduces the following conclusions: (1). When an optically active carbon-compound combines with an inactive body, or when it is modified by chemical reagents, the molecular rotatory power either remains unaltered, or is increased to a simple multiple of that of the primitive substance (see *Tartaric*

* In order to simplify the comparison of the numbers, Krecke, however, adopts the millimeter instead of the decimeter as the unit of length; the molecular rotatory power is therefore expressed by the formula,

$$[m] = \frac{[\alpha] \cdot m}{100},$$

where m is the molecular weight.

acid, p. 1219). (2). The molecular rotatory powers of isomeric bodies are multiples of one and the same number.

Krecke's conclusions are based, however, on the comparison of the apparent specific rotatory powers of the various substances, and little weight, therefore, can be attached to them. He points out that whereas the molecular rotatory powers of the various carbohydrates of the cane-sugar group are multiples of the mean factor 24.9, the molecular rotatory powers of the allied carbohydrates of the dextrose group are in like manner multiples of a mean factor which is about twice as great (48.5). It is noteworthy that the molecular rotatory powers of dextrose and cane-sugar calculated from Tollens's determination of the absolute specific rotatory powers of these bodies are approximately related in a somewhat similar manner, thus:

$$\begin{array}{l} \text{Dextrose } [\alpha]_D = 58.70 \\ \text{Cane-sugar } [\alpha]_D = 63.90 \end{array}$$

hence

$$\begin{array}{l} \text{Dextrose } [m]_D = \frac{58.7 \times 180}{100} = 105.6 = 21.1 \times 5 \\ \text{Cane-sugar } [m]_D = \frac{63.9 \times 342}{100} = 218.8 = 20.8 \times 10. \end{array}$$

Theory of the Constitution of Optically Active Bodies. Of the three classes of crystalline circularly polarising bodies, nearly all those of the first class (vii. 748) occur in enantiomorphous hemihedral or tetartoedral forms; * and since bodies of this class are destitute of optical activity in the amorphous and liquid states, the property of circular polarisation must be ascribed to a peculiar arrangement of the molecules composing the crystals and not to any speciality of constitution of the molecules themselves. The constant correlation of the position of the hemihedral faces on the crystal and the direction in which the plane of polarisation is deflected by a substance, led Pasteur to infer that the molecules are arranged in such crystals in a right or left-hand spiral, a view which has been adopted by Rammeisberg and others, and has received much support from Sohneke's recent observations (*Pogg. Ann. Erg. Bd. viii. 16*) that by arranging a number of thin plates of optically biaxial mica so that the principal section of each plate is equally inclined (by an angle of 45°, 60°, 90°, or 120°) to that of the previous plate, a combination may be obtained which behaves like an optically active crystal, rotating the plane of polarisation either to the right or to the left according to the direction in which the combination is arranged.

Pasteur also inferred (*Recherches sur la dissymétrie moléculaire des produits organiques naturels*. Leçons de Chimie professées en 1860, Paris, 1861), that a similar want of symmetry or opposition of structure characterises the molecules themselves of bodies which are optically active in the amorphous or liquid but not in the crystalline state,† and more recently this hypothesis has been further developed by Le Bel and van't Hoff, who have gone so far as to point out the special character in constitution of optically active bodies.

According to Le Bel (*Bull. Soc. Chim.* [2], xxii. 337), if in a compound of the form MA₄, where M is a simple or compound radicle associated with four replaceable monad atoms A, three of the four atoms A are replaced by three dissimilar monad radicles, simple or compound, the resulting molecule will be unsymmetrical, and as such will manifest the power of causing circular polarisation, provided (1) that in the original molecule the four groups A are not all disposed in a single plane of symmetry; and (2) that the group introduced in place of the third atom A is not of the same composition as the entire group with which it becomes associated; in this case, the compound will be inactive if the two equal groups exercise an opposite effect on polarised light. Thus in inactive tartaric acid it may be supposed that the two groups CH(OH).COOH are of opposite activity, and hence neutralise each other, whereas in the dextro- and lævo-rotatory acids they are identical and their effects are added. Le

* According to Groth (*Pogg. Ann.* cxxxvii. 433), we are entitled to assume that all such bodies are subject to enantiomorphous hemihedry or tetartoedry. Pasteur's researches (*Ann. Chim. Phys.* [3], xxxviii. 437) have, in fact, shown that many compounds of the second class, which under ordinary circumstances exhibit no signs of hemihedry, may be caused to furnish crystals with hemihedral faces by slightly modifying the conditions. Thus acid calcium malate, which invariably separates from a pure aqueous solution in holohedral forms derived from a right rhombic prism, at once exhibits hemihedral faces if crystallised from weak nitric acid.

† The bodies which, like tartaric acid, are optically active only in the amorphous condition or in solution, are all optically biaxial, and, as Landolt points out (*op. cit.*), there is no direction in which such crystals are single-refracting, so that the circular double refraction is masked by the much stronger ordinary double refraction. It is not therefore conclusively proved that they are inactive in the crystalline state.

Bel points out that the constitution of the saturated compounds of the fatty series which are optically active, is such that in all cases the conditions of his hypothesis are satisfied.

The same idea has been more fully worked out and applied to numerous examples by van' t Hoff in connection with his hypothesis of the orientation of atoms in space (see the article *Isomerism* in this volume, p. 1136).

According to this hypothesis, a body of the type CR^4 may be represented by a tetrahedron having the four radicles R, simple or compound, situated at the four summits and the carbon-atom in the middle; and if these four radicles are all different, they will, in consequence of unequal attraction, be situated at different distances from the carbon-atom, so that the compound $CR_1R_2R_3R_4$ will form an irregular tetrahedron having no planes of symmetry and capable of exhibiting enantiomorphous forms. Moreover, two tetrahedrons thus related exhibit, in relation to an axis drawn parallel to the corresponding edges, a screw-shaped grouping of the four summits, turning to the right in one form and to the left in the other. A carbon-atom thus united with four different radicles—called by van' t Hoff 'asymmetric'—may therefore give rise to optical activity, and to the production of two modifications possessing equal and opposite rotatory power. A comparison of the formulæ of those optically active compounds derived from the paraffins, whose constitution is well established, shows that they all contain one or more asymmetric carbon-atoms, as will be evident from the examples given in the following table in which the asymmetric carbon-atoms are denoted by italic *C*'s:

C^3 group.	
Lactic acid	$CH^3-CH(OH)-COOH$
C^4 group.	
Malic acid	$COOH-CH^2-CH(OH)-COOH$
Malamide	$CONH^2-CH^2-CH(OH)-COOH$
Aspartic acid	$COOH-CH^2-CH(NH^2)-COOH$
Asparagine	$CONH^2-CH^2-CH(NH^2)-COOH$
Tartaric acid	$COOH-CH(OH)-CH(OH)-COOH$
Tartramide	$CONH^2-CH(OH)-CH(OH)-CONH^2$
C^5 group	
Secondary Butyl carbinol	$CH^3-CH^2-CH(CH^3)-CH^2OH$
Methylethylacetic acid	$CH^3-CH^2-CH(CH^3)-COOH$
Hydroxyglutaric acid	$COOH-CH^2-CH^2-CHOH-COOH$
Glutamic acid	$COOH-CH^2-CH^2-CHNH^2-COOH$
C^6 group.	
Secondary Butylacetic acid	$CH^3-CH^2-CH(CH^3)-CH^2-COOH$
Mannitol	$CH^2OH-(CHOH)^4-CH^2OH$
Glucose	$CH^2OH-(CHOH)^4-COH$
Saccharic acid	$COOH-(CHOH)^4-COOH$
Phenylhydroxyacetic (mandelic) acid	$C^6H^5-CHOH-COOH$

Two other interesting examples may be quoted, viz. quercitol and quinic acid. These compounds are very probably derivatives of a closed-chain hydrocarbon of the formula C^6H^{12} , derived from benzene, and if they are thus represented, it will be obvious that the groups are unsymmetrically arranged relatively to a plane of symmetry containing two of the hydroxyl groups:

The carbohydrates of the cane-sugar group and those of the empirical formula $C^6H^{10}O^5$, which are all closely allied in constitution to the glucoses, but of greater molecular complexity, as well as the glucosides, are undoubtedly to be represented by formulæ containing asymmetric carbon-atoms; and it is highly probable that this will also be found to be the case when the rational formulæ of the terpenes, camphors, alkaloids, albuminoids, and other complex optically active bodies become known.

There is nothing to indicate whether the mere presence of an asymmetric carbon-

atom in a compound is sufficient to endue it with optical activity, or whether it is necessary that the radicles associated with the asymmetric carbon-atom should be of a particular character. Different radicles evidently exert very different effects; no more striking example of this can be found than that afforded by so-called tartar-emetie, $K(SbO)C^H^iO^e$, as compared with the other metallic tartrates (see TARTARIC ACID, p. 1219).

A compound of unsymmetrical formula containing n asymmetric carbon-atoms may exist in (2^n) isomeric modifications (p. 1138). Thus a compound of the form $C(R_1R_2R_3)C(R_4R_5R_6)$ may exist in the four modifications indicated by the symbol

$$\begin{array}{cccc} 1) & \begin{array}{c} +A \\ +B \end{array} & 2) & \begin{array}{c} -A \\ +B \end{array} & 3) & \begin{array}{c} +A \\ -B \end{array} & 4) & \begin{array}{c} -A \\ -B \end{array} \end{array}$$

Representing the rotatory power of the group A by the symbol $+A$ or $-A$, and that of the group B by $+B$ or $-B$, the rotatory power of each of these modifications will be as follows:

$$1) \ A + B \quad 2) \ -A + B \quad 3) \ A - B \quad 4) \ -A - B$$

Hence 1) and 4) and 2) and 3) will have equal but opposite rotatory powers. In a similar manner it may be shown that, always in the case of compounds of unsymmetrical formula, one half the isomerides are of equal but opposite rotatory power to the other half.

In the case of a compound of symmetrical formula containing two asymmetric carbon-atoms, three modifications are possible (p. 1138), the rotatory powers of which are as follows:

$$1) \ A + A = 2A \quad 2) \ A - A = 0 \quad 3) \ -A - A = 2(-A)$$

Two only of the three modifications of such a compound will therefore manifest optical activity, the third being inactive owing to what may conveniently be termed 'internal compensation;' and of this we have a most striking example in the three tartaric acids—dextro-, levo-, and mesotartaric acid—which may be regarded as the three possible modifications of the compound of the formula

Racemic acid, if a definite compound, has at least double the molecular weight of tartaric acid. Berthelot and Jungfleisch's experiments (*Ann. Chim. Phys.* [5], iv. 147) render it probable that mere dissolution in water decomposes it into dextro- and levotartaric acid. But whatever may be its nature, its inactivity is readily accounted for, since it consists of equal amounts of the two acids of equal but opposite activity. The inactivity of bodies which, like racemic acid, are readily formed by the mere admixture of two active substances, or which are resolved into inactive substances by similar—and almost by mechanical—means, may conveniently be said to arise from 'external compensation.'

A large number of bodies are represented by formulæ indicating that they contain asymmetric carbon-atoms, but, nevertheless, they appear to be destitute of optical activity. From the preceding remarks it will be obvious that this may be the result of either 'internal' or 'external' compensation. Moreover many substances have been not at all, or but very imperfectly, examined with regard to their power of deflecting polarised rays, and their rotatory power may be so slight, or so difficult to observe on account of sparing solubility, that it has hitherto been overlooked.

Both Le Bel and van't Hoff have pointed out that, if a body which does not contain an asymmetric carbon-atom is converted, either by substitution or addition, into a compound containing one or more asymmetric carbon-atoms, it is to be expected that isomerides of equal and opposite rotatory power will be produced in equal quantities; and, as a matter of fact, racemic and mesotartaric acids have been produced artificially in a number of ways, but neither of the active modifications has ever been obtained by synthetical means.* On the other hand, according to van't Hoff, there is little hope of obtaining an optically active body from a compound of symmetrical formula which is inactive through internal compensation, by destroying its symmetrical character. For example, erythritol,

* Pasteur long ago showed that dextrotartaric acid was more readily destroyed than levotartaric acid by certain minute organisms (*Penicillium glaucum*), a solution of racemic acid in which they were contained soon acquiring a levorotatory power. In a similar manner, according to Le Bel, the inactive alcohol obtained by dissolving levorotatory fermentation amylic alcohol with sodium hydrate, yields dextro-rotatory amylic alcohol when submitted to the action of *Penicillium*. As this article is passing through the press, Le Bel announces that it is possible also to obtain in this way an optically active (levorotatory) methylpropylcarbinol from the optically inactive methylpropylcarbinol prepared by reducing methylpropyl ketone (*Compt. rend.* lxxxix. 312).

may be converted, by distillation with formic acid, into the glycol

and as this is a body of unsymmetrical formula, and contains an asymmetric carbon-atom, it should be optically active. But it is probable that while the group A of a certain number of erythritol molecules would be attacked, the group -A of an equal number of other molecules would undergo a similar change, and consequently the product would be an inactive mixture of bodies of equal but opposite rotatory power; thus

would give

Nevertheless there are a number of facts which appear to indicate that this may not always be the case. Thus mannitol, which probably is inactive in the pure state (see Müntz and Aubin, *Ann. Chim. Phys.* [5], x. 533), acquires a considerable dextro-rotatory power in presence of boric acid or borax, but is lævorotatory in presence of alkalis; and the dichlorhydrin, $\text{C}^2\text{H}^2\text{Cl}^2(\text{OH})^2$, obtained by heating it with hydrochloric acid is lævorotatory. Mannitol, however, is in many respects peculiar; if its inactivity is to be ascribed to 'internal compensation, a symmetrical alteration in its composition should not have the effect of converting it into an optically active body; but, as a matter of fact, mannite hexacetate, hexnitrate, and hexsulphate (*J. pr. Chem.* [2], xx. 13) manifest considerable dextro-rotatory power. The examination of the mannitol regenerated from these compounds appears desirable.

Mannitol is not the only substance whose behaviour is in some respects difficult to harmonise with the hypothesis under discussion. Thus malic acid, which in a pure aqueous solution exhibits slight lævorotation, acquires an increased lævorotatory power on the addition of boric acid, but its solution in nitric acid is dextro-rotatory; it cannot be supposed, in explanation of these phenomena, that, as in the case of mannite, the molecule consists of two symmetrical halves, +A and -A, and that the rotatory power of the one half is influenced by the boric acid and that of the other half by the nitric acid, since malic acid, $\text{COOH}-\text{CH}^2-\text{CHOH}-\text{COOH}$, contains only a single asymmetric carbon-atom. Again, asparagine and aspartic acid are dextro-rotatory in acid solutions but lævorotatory in alkaline solutions. It is not easy to understand this behaviour on the hypothesis that they are derived from a single molecule of succinic acid and therefore contain only a single asymmetric carbon-atom, and the difficulty remains even if it be assumed that, as appears probable on other grounds, they are derived from a double molecule of succinic acid. Again, as already mentioned, the anomalous rotatory dispersive power of solutions of tartaric acid almost necessitates the assumption that the acid forms a compound with water opposite to itself in rotatory power; the formation of a body having a reversed rotatory power as compared with that of the parent substance from a compound like dextrotartaric acid which, according to van't Hoff's hypothesis has the constitution 2A, *i.e.* is composed of two similar dextro-rotatory groups, is, however, not easy to understand.

One of the most remarkable facts in connection with optically active substances is the readiness with which many of them undergo alteration in rotatory power. Thus tartaric acid, as Pasteur and Jungfleisch have shown, may be converted by mere heating into mesotartaric and racemic acid, and in the same way mesotartaric acid may be transformed into racemic acid. According to Montgolfier, the hydrogenation of camphor gives rise to two distinct camphols of equal and opposite rotatory powers, both of which, however, give the same dextrocamphor on oxidation. In these cases the change produced in the direction of rotatory power persists as long as the compound is not destroyed, whereas in the cases above mentioned the change is dependent on the presence of another substance, and is in nowise perfect.

Whether facts such as these we have mentioned can be satisfactorily explained in accordance with the Le Bel-van't Hoff hypothesis has yet to be shown; the hypothesis appears, however, to be sufficiently in harmony with much of our knowledge to merit the most careful consideration.

Specific Rotatory Powers of various Bodies. *Quartz.*—The following table shows the angles of rotation (α) of the several spectral lines produced by a plate of quartz 1 mm. thick, according to the measurements of Stefan (*Pogg. Ann.* cxvii. 631), and for the lithium, sodium, and thallium lines by v. Lang (*ibid.* clvi. 422); also the corresponding wave-lengths λ , in ten-thousandths of a millimeter,

	B	C	D	E	F	G	H
λ	6871	6560	5888	5269	4860	4309	3967
α	15.55°	17.22°	21.67°	27.46°	32.69°	42.37°	50.98°
		Li	Na	TI			
λ		6703	5888	5346			
α		16.43°	21.64°	25.59°			

The values for the line D found by different observers are as follows:

Biot	.	.	.	20.98°	Wild	.	.	.	21.67°
Broch	.	.	.	21.67 ± 0.11	v. Lang (at 13.3°)	.	.	.	21.64
Stefan	.	.	.	21.67	Soret a. Sarasin (at about 35°)	.	.	.	21.80

v. Lang has shown that the rotatory power of quartz increases with rise of temperature, and that the relative alteration is the same for all colours: at 0° the values are—

	Li	Na	Th
α_0	16.402°	21.597°	26.533°

and for any temperature t —

$$\alpha_t = \alpha_0(1 + 0.000149 t).$$

According to later experiments by Sohneke (*Ann. Phys. Chem.* [2], iii. 516), the alteration caused by temperature is more correctly represented by the formula

$$\alpha_t = \alpha_0(1 + 0.000999 t + 0.00000318 t^2).$$

Soret a. Sarasin (*Compt. rend.* lxxxi. 610) have measured the rotation produced by a plate of quartz for the ultra-violet rays as far as the line N, and have obtained values agreeing very nearly with Boltzmann's formula (p. 1207). The absolute values are somewhat smaller than those formerly obtained by Stefan (*Wien. Akad. Ber.* l. 88). The observations have been extended by Croullebois (*Compt. rend.* lxxxi. 666) as far as O, and subsequently by Soret a. Sarasin (*ibid.* lxxxiii. 818) as far as R.

Dithionates.—For the rotatory powers of the potassium, lead, strontium, and calcium salts, values have been obtained by E. Bichat (*Bull. Soc. Chim.* [2], xx. 436) agreeing very nearly with those determined by Pape (vii. 748). If the rotatory power of quartz be expressed by 100, those of the first three dithionates above mentioned will be 40, 24, and 8.

Cinnamene.—For the rotatory powers gave $[\alpha]_D = -3.1$ and -3.4 . For solid meta-cinnamene $[\alpha]_D = -2.2$ (Berthelot, *Compt. rend.* lxxxii. 441; lxxxv. 1191). Van't Hoff (*Deut. Chem. Ges. Ber.* ix. 5) maintains, however, that cinnamene has no rotatory power, and that the optical activity of that examined by Berthelot was due to an impurity.

Volatile Oils. These oils are for the most part mixtures of active and inactive constituents, so that their total rotatory power is the sum or difference of the rotatory powers of these constituents, modified by all the influences of solvents and other inactive substances above noticed. Moreover, the proportion of the several constituents often varies in the same oil, and chemical alterations may arise on keeping. All these circumstances influence the rotatory power, which is therefore by no means a trustworthy guide in distinguishing one volatile oil from another (Flückiger, *Arch. Pharm.* [3], x. 193).

Camphor. On the specific rotatory power of this substance in the solid state and in solution, see pp. 373, 374; of the Isomerides and Derivatives of Camphor and Camphol: Montgolfier (*Ann. Chim. Phys.* [5], xiv. 5-118; *Chem. Soc. J.* xxxiv. 891-903).

Camphor or Stearoptene of Matico-oil. The crystals of this substance belong to the trapezo-tetartohedral division of the hexagonal system. The rotation of a ray passing through a plate 1 mm. thick parallel to the axis is for red, yellow, and green light as follows:

Line	Li	Na	TI
Rotation	1° 41'	2° 4'	2° 28'

No decided rotation was observed in a concentrated solution (Hintze, *Pogg. Ann.* clvii. 127).

Amyl-compounds. See vol. vii. p. 62.

Tartaric acid and Tartrates.—The influence of temperature on the rotatory power of these compounds has been examined by F. W. Krecke (*Archiv. néerl.* vii. 97), who has obtained the following results: (1). The specific rotatory power increases, in the case of tartaric acid, for all rays of the spectrum, but in very different degrees in solutions of different concentration. If the value at 0° = 1, that at 100° for the rays,

	C	D	E	b	F
is, in 50 per cent. Tartaric acid	2.3	2.5	2.7	3.1	3.4
„ 40 „	3.2	3.2	3.0	—	3.2

In the last case therefore it remains constant for the different colours; in the first it increases with the refrangibility. (2). In the 50 per cent. solution the line whose plane of polarisation is most turned round is situated, at 0° between D and E, at 25° close to E, and at 50° and higher temperatures it is advanced so far towards the violet, that in the experiments under consideration, it fell beyond the observed portion of the spectrum. The anomaly, peculiar to tartaric acid, of rotating the green rays more strongly than those either of greater or of lesser refrangibility, disappears therefore with rise of temperature and with progressive dilution. (3). The product of the specific rotatory power into the square of the wave-length which, according to Biot's law (iii. 672), should be constant, increases from the red to the violet. (4). The tartrates of potassium, sodium, and ammonium, Rochelle salt, and tartar emetic follow Biot's laws; their rotatory power increases or diminishes with the temperature in various degrees. The molecular rotatory power of the salts, with the exception of tartar emetic, is nearly three times as great as that of tartaric acid in the dilute state. (6). In the salts examined, the product of the specific rotatory power into the square of the wave-length is a maximum for the green or for the yellow rays.

Landolt (*Deutsch. Chem. Ges. Ber.* vi. 1073) has also determined the molecular rotatory powers of a number of tartrates, and compared them with that of tartaric acid, for which he has calculated a new empirical formula representing the alteration of the specific rotatory power with the concentration. If $[\alpha]_D$ denote the specific rotatory power for the sodium-line D, the formula in question is

$$[\alpha]_D = 15.06 - 1.031 c,$$

in which c denotes the number of grams of tartaric acid in 100 c.c. of the solution. In the following table of results, $[M]_D$ denotes the molecular rotatory power of the salts, *i.e.* the product of the specific rotatory power and molecular weight. The solutions were prepared so as to contain 1 molecule of the salt to 100 molecules or water, *i.e.* in the case of pure tartaric acid, 7.69 grams to 100 c.c. The last column contains the quotients (Q), obtained by dividing $[M]_D$ by the rotatory power of the solution of tartaric acid just mentioned, viz. 21.08. P is the molecular weight.

Substance	P	$[\alpha]_D$	$[M]_D$	Q
$\text{LiHC}^4\text{H}^4\text{O}^6$	156	27.43	42.79	2.03
$(\text{NH}^4)\text{HC}^4\text{H}^4\text{O}^6$	167	25.65	42.84	2.03
$\text{NaHC}^4\text{H}^4\text{O}^6$	172	23.95	41.19	1.95
$\text{KHC}^4\text{H}^4\text{O}^6$	188.1	22.61	42.53	2.02
$\text{Li}^2\text{C}^4\text{H}^4\text{O}^6$	162	35.84	58.06	2.76
$(\text{NH}^4)^2\text{C}^4\text{H}^4\text{O}^6$	184	34.28	63.04	2.99
$\text{Na}^2\text{C}^4\text{H}^4\text{O}^6$	194	30.85	59.85	2.84
$\text{K}^2\text{C}^4\text{H}^4\text{O}^6$	226.2	28.48	64.42	3.06
$(\text{NH}^4)\text{NaC}^4\text{H}^4\text{O}^6$	189	32.65	61.71	2.93
$(\text{NH}^4)\text{KC}^4\text{H}^4\text{O}^6$	205.1	31.11	63.81	3.03
$\text{NaKC}^4\text{H}^4\text{O}^6$	210.1	29.67	62.34	2.96
$\text{MgC}^4\text{H}^4\text{O}^6$	172	35.86	61.68	2.93
$(\text{AsO})\text{HC}^4\text{H}^4\text{O}^6$	240	16.91	40.58	1.93
$(\text{AsO})\text{KC}^4\text{H}^4\text{O}^6$	278.1	21.13	58.76	2.79
$\text{K}(\text{SbO})\text{C}^4\text{H}^4\text{O}^6$	323	142.76	461.11	21.87
$\text{K}(\text{C}^2\text{H}^3)\text{C}^4\text{H}^4\text{O}^6$	216.1	29.91	64.64	3.07
$\text{Ba}^{\frac{1}{2}}(\text{C}^2\text{H}^3)\text{C}^4\text{H}^4\text{O}^6$	245.5	25.68	63.04	2.99

The numbers in the last column exhibit an approximation to the relation of simple multiples required by the law enunciated by Mulder and Krecke, but as pointed out by Oudemans (*Ber.* vi. 1166, 1447) they are not exactly in accordance with it. It must be recollected, however, that the numbers in this table refer only to the *apparent* and not to the *absolute* specific rotatory power of the acid and its salts; properly speaking, only the absolute specific rotatory powers should be employed in such a discussion. The rotatory power of tartrates containing two different metals is equal to the arithmetical mean between the two corresponding simple salts, *e.g.*

	$[\alpha]_D$	$[M]_D$
$\text{K}^2\text{C}^4\text{H}^4\text{O}^6$	28.48	64.42
$\text{Na}^2\text{C}^4\text{H}^4\text{O}^6$	30.85	59.85
Mean	29.66	62.13
Found for $\text{KNa.C}^4\text{H}^4\text{O}^6$	29.67	62.34
4 K 2		

Other salts, *e.g.* the compounds of potassium and sodium tartrate with the corresponding borates, exhibit, with increasing dilution, a rapid decrease of their originally strong specific rotation. In tartar-emetic the specific rotation is moderately constant and very large. For a solution of 7.892 grams in 100 c.c.:

$$[\alpha]_D = 143.01 \quad [M]_D = 464.93 \quad Q = 22 \text{ nearly.}$$

A different relation is exhibited by the tartaric ethers. In ethyl tartrate, $(C^2H^3)^2C^2H^4O^6$, the specific rotation in aqueous solution increases with progressive dilution, nearly in the same proportion as in aqueous tartaric acid, so that the two may be compared in equivalent degrees of concentration. In this manner the following numbers are obtained:

Ethyl Tartrate in 100 c.c. solution	$[\alpha]_D$	$[M]_D$	Eq. Concentration of Tartaric acid Solution	$[M]_D$ of Tartaric acid	$\frac{[M]_D \text{ ether}}{[M]_D \text{ acid}}$
10.489 grams	25.92	53.40	7.6376	21.09	2.53
5.2445 "	25.86	55.33	3.8188	21.84	2.53
2.6223 "	27.37	56.38	1.9094	22.22	2.54

Hence it appears that the molecular rotatory power of ethyl tartrate is about $2\frac{1}{2}$ times that of tartaric acid. It is possible, however, that this low value may be due to decomposition of the salt by water. A similar behaviour is exhibited by methyl tartrate.

The specific rotatory power of tartaric acid is much smaller in alcoholic than in aqueous solution. For a solution of 7.69 grams in 100 c.c. alcohol, $[\alpha]_D = 5.0$ and $[M]_D = 7.5$; the rotatory power is however increased by heating the solution in a sealed tube. Tartaric acid dissolved in methyl alcohol loses its rotatory power completely, but becomes active again when the solution is diluted with water.

Hesse (*Liebig's Annalen*, clxxvi. 119) finds, for solutions of tartaric acid in which the value of c (the number of grams of substance in 100 c.c. of solution) is between 5 and 15, and temperature 15° , that $[\alpha]_D = 14.90 - 0.14c$, and increases with the temperature by about a quarter of a degree to 7.5° C. Two experiments in which an aqueous solution of tartaric acid ($c=15$) was mixed with 4 and 8 molecules (m) of hydrochloric acid gave $[\alpha]_D = 12.8 - 12m$. For $c=5$ in fuming hydrochloric acid, $[\alpha]_D = 4.2$. Neutral sodium tartrate, dissolved in water at 22.5° , gave, for values of c between 5 and 15, $[\alpha]_D = 27.85 - 0.17c$. If, however, the solvent contains 1 or 2 mols. free soda to 5 grams of tartaric acid, the rotatory power is reduced to 26.36° or 25.6° respectively. The relations observed by Landolt (p. 1219) are, according to Hesse's observations, only approximately true.

Quinic acid, in aqueous solution ($c=2$ to 10), gave $[\alpha]_D = 43.9^\circ$, and after two days 0.5° more. A solution in 80 v.p.c. alcohol ($c=5$) gave $[\alpha]_D = -39.2^\circ$, the aqueous solution ($c=2$), with 1 mol. Na_2O , gave $[\alpha]_D = -4.7^\circ$.

Sugars.—1. *Cane-sugar.* The specific rotatory power of this substance is $[\alpha]_D = 66.064^\circ$ according to L. Weiss (*Wien. Akad. Ber.* [2 Abth.], lxxix. 1); 67.18° according to De Luynes a. Girard (*Compt. rend.* lxxx. 1354). According to Hesse (*Liebig's Annalen*, clxxvi. 95) it is represented, for aqueous solutions, at the temperature 15° , and from $c=0$ to $c=10$ by the formula

$$[\alpha]_D = + 68.65^\circ - 0.828c + 0.1154c^2 + 0.005417c^3.$$

For higher values of c , the rotatory power is nearly constant and equal to 66.5° . A rise of temperature of 10° makes no alteration in the value.

For solutions in 50 v. p. c. alcohol in which $c = 5$. . . $[\alpha]_D = 66.70^\circ$
 In water containing 1 mol. SO^2 . . . $[\alpha]_D = 66.67^\circ$
 " " 1 mol. Na_2O . . . $[\alpha]_D = 60.00^\circ$

Tollens (*Deut. Chem. Ges. Ber.* x. 1403) gives the following formulæ, in which p denotes the number of grams of sugar in 100 grams of solution: I. for $p=0$ to 18, II. for $p=18$ to 69, as the results of a series of most carefully conducted experiments:

$$\begin{aligned} \text{I. } [\alpha]_D &= 66.8102 - 0.015553p - 0.000052462p^2 \\ \text{II. } [\alpha]_D &= 66.386 + 0.015035p - 0.0003986p^2 \end{aligned}$$

According to Landolt's notation (p. 1211) in which $q=100-p$, these formulæ become:

$$\begin{aligned} \text{Ia. } [\alpha]_D &= 64.7303 + 0.026045q - 0.000052462q^2 \\ \text{IIa. } [\alpha]_D &= 63.9035 + 0.064685q - 0.0003986q^2 \end{aligned}$$

The weakest solution examined was that in which $p=3.8$.

The term 'conventional specific rotation' is proposed by Tollens to denote, for most circularly polarising bodies, the apparent specific rotation produced in a 10 per cent. solution, this magnitude being represented for sodium light by the symbol $[\alpha]_{10}^v$. For cane-sugar the value of $[\alpha]_{10}^v$ is 66.65° . Fused anhydrous cane-sugar exhibits in the solid state a rotatory power $= 46.91^\circ$; in solution 48.00° , but since such a product strongly reduces an alkaline solution of a cupric salt, there is no doubt that the sugar is in part decomposed.

M. Schmitz (*Ber. x. 1414*), who has also very carefully determined the rotatory power of solutions of various degrees of concentration, finds for the temperature 20° , and for $p = 10$ to $p = 86^\circ$:

$$[\alpha]_D = 66.453 - 0.00123621p - 0.000117037p^2.$$

For weak solutions, $p = 2.5$ to 2.76 , the following is sufficiently exact:

$$[\alpha]_D = 66.541 - 0.00841532p.$$

According to Tollens's experiments, the absolute specific rotatory power of cane-sugar is $[\alpha]_D = 63.9^\circ$; according to Schmitz's experiments it is $[\alpha]_D = 64.156^\circ$.

Experiments by H. Pellet (*Bull. Soc. Chim. [2], xxviii. 250*) on the influence of alkalis on the rotatory power of sugar have shown that this influence is much more powerful in concentrated than in dilute solutions. The following table shows how many grams of sugar in solutions of 17.3 and 5.4 per cent. respectively are rendered optically inactive by the addition of 1 gram of the substances mentioned in the first column:

	17.3 p. c. solution	5.4 p. c. solution
Sodium Carbonate	0.132	0.040
Sodium Phosphate (crystallised)	0.036	0.016
Caustic Soda (Na_2O)	0.450	0.14
Ammonia (NH_3)	0.085	0.073
Ammonium Carbamate (NH_4CO_2)	0.067	0.040
Potash (K_2O)	0.50	0.17
Potassium Carbonate	0.065	0.044
Lime	1.00	0.9
Baryta	0.43	0.19

2. *Milk-sugar*.—Ordinary milk-sugar, or α -Lactose, with 1 mol. H_2O , gives for $p = 2$ and 3 , respectively, the values $[\alpha]_D = 80.68$ and 79.70 . β -Lactose, which is formed from the preceding by long standing or by boiling, and is $\frac{3}{2}$ -times more soluble than α -lactose, gave between $p = 0$ and $p = 12$:

$$[\alpha]_D = + 54.54^\circ - 0.557c + 0.05475c^2 + 0.001774c^3.$$

The rotatory powers of the two modifications are to one another in the ratio $3 : 2$, which is the inverse of that of their solubilities. On addition of 1 mol. Na_2O to the solvent, the rotatory power sinks considerably after some time, and its original value indicates that in alkaline solution milk-sugar exists only as the β -modification (Hesse, *Annalen*, clxxxi. 98). According to Mills and Hogarth (*Proc. Roy. Soc. xxviii. 273*), the initial specific rotatory power of milk-sugar in solution (? dilute) is $[\alpha]_D = 83.16^\circ$, and its permanent specific rotatory power $[\alpha]_D = 53.12^\circ$. They have examined the law for the change of rotation in a freshly prepared solution, and find that it can be expressed by a mathematical equation. The initial solubility of milk-sugar, according to these chemists, is 1 pt. in 10.64 pts. water of 17° , and the permanent solubility 1 pt. in 3.23 pts. water.

3. *Dextrose, Dextroglucose, or Crystallised Grape-sugar*.—Tollens has examined with great care the rotatory powers of nineteen different solutions of pure dextrose (*Deut. Chem. Ges. Ber. x. 1413*), and finds that the specific rotatory power in solution increases with the concentration; thus in a solution containing 7.68 per cent., the value of $[\alpha]_D$ is 52.89° , while in a solution containing 82.6 per cent. it is 57.8° .

The specific rotatory power in solutions of the anhydrous substance may be calculated from the equations:

$$\begin{aligned} [\alpha]_D &= 52.718 + .017087p + .0004271p^2 \\ [\alpha]_D &= 58.69 - .10251q + .0004271q^2 \end{aligned}$$

Diminishing these values one-tenth, the following numbers give the rotatory power of the hydrate $\text{C}^6\text{H}_{12}\text{O}_6 + \text{H}_2\text{O}$:

$$\begin{aligned} [\alpha]_D &= 47.925 + .015534p + .0003883p^2 \\ [\alpha]_D &= 53.362 - .093194q + .0003883q^2. \end{aligned}$$

The absolute rotatory power deduced from these equations is:

$$\begin{aligned} [\alpha]_D &= 58.7^\circ \text{ for } \text{C}^6\text{H}_{12}\text{O}_6 \\ [\alpha]_D &= 53.36^\circ \text{ ,, } \text{C}^6\text{H}_{12}\text{O}_6 + \text{H}_2\text{O} \end{aligned}$$

Hesse (*Annalen*, clxxvi. 102) has determined the specific rotatory powers of several varieties of dextrose at 15°, with the following results:

Glucose-hydrate <i>c</i>	Honey-sugar	Grape-sugar	Starch-sugar	Salicin-sugar
1	49.77	—	50.00	50.00
3	47.33	47.87	48.03	48.48
6	46.58	—	46.79	47.96
12	46.34	—	46.83	47.66
Anhydrous	—	51.78 for <i>c</i> = 2.8	51.67 for <i>c</i> = 3	51.80 for <i>c</i> = 2.5

These sugars are therefore identical. Closely allied to them is amygdalin-sugar, which, as hydrate, gives for *c* = 2, $[\alpha]_D = 49.25$. Hydrated phlorizin-sugar, on the other hand, exhibits a smaller rotation, viz. for *c* = 3, $[\alpha]_D = 40.9$, and for *c* = 6, $[\alpha]_D = 40.08$. Another preparation gave for *c* = 8, $[\alpha]_D = 39.9$, and for *c* = 10.52, $[\alpha]_D = 39.7$ (Hesse, *Annalen*, cxcii. 174).

The rotatory power of glucose is diminished by the presence of lime. A solution, which in 100 c.c. contained 0.98 grm. lime to 6.9 grm. dextrose, gave for the transition-tint $[\alpha]_j = 33.3$ (Jodin, *Compt. rend.* lviii. 613).

4. *Mannitol*, $C^6H^{14}O^6$. L. Vignon (*Ann. Chim. Phys.* [5], ii. 433) finds that perfectly pure mannitol is inactive to polarised light. If, however, it be mixed in aqueous solution with boric acid or borates, it becomes dextrorotary, and a given quantity of borax develops a stronger rotatory power when combined with bases than in the free state. Thus a solution of mannitol containing borax, which originally exhibited a rotation $\alpha = +1.38$, showed, when saturated with carbonate of sodium, potassium, and ammonium respectively, a deflection $\alpha = +5.813$, $\alpha = +6.63$, and $\alpha = +6.73$. The rotatory power increases with time. Arsenic acid and alkaline arsenates likewise develop rotatory power in mannitol. Arsenic acid induces a weak levorotatory power which increases with time. If the solution be then gradually saturated with sodium carbonate, it becomes continually more and more levogyrate. Neutral sodium arsenate induces a dextrorotatory power which does not increase perceptibly with time. Acid potassium arsenate induces levorotation, which likewise increases with time up to a certain limit. Relatively larger quantities of the acid arsenate also develop stronger rotatory powers. On addition of a large quantity of the arsenate, the solution, if left at rest for some time, or more quickly if boiled, becomes perfectly solid, without losing its transparency. The mass thus formed is very friable, easily soluble in water, has an acid reaction, and is strongly levogyrate. From these results Vignon infers that mannitol in itself is active to polarised light. With boric acid and water, without entering into chemical combination therewith—for the evaporated solution leaves a mixture of mannitol and boric acid—it forms dissymmetric molecules which then exhibit rotation. Arsenic and its acid potassium salts, on the other hand, induce a chemical action, in consequence of which the rotations, which are produced only in consequence of unsymmetrical arrangement of the molecules, become altered. The specific rotatory power of mannitol for the transition-tint is $[\alpha]_j = +36.5^\circ$; that of nitromannitol = $+53.26^\circ$ (Vignon).

Müntz & Aubin (*Compt. rend.* lxxxiii. 1213) find that not only borax, but metallic salts in general, and especially the salts of the alkalis and alkaline earths, develop a dextrorotatory power in mannitol, whereas free alkalis develop a levorotatory power. The action is not permanent, for when the salt is removed, the mannitol again becomes inactive or nearly so, and if the alkali be saturated by an acid, the levorotatory power becomes dextrorotatory. Mannitol from various sources was found to be inactive in an aqueous solution containing 10 grams in 100 c.c.; but on addition of 12.8 grams of borax, it gave a mean deviation = $+22.3^\circ$. A solution containing in 100 c.c. 8 grams mannitol and 8 sodium hydrate gave a mean deviation = -3.4° . Nitro-mannitol, 3 grams in 100 c.c. of absolute alcohol, gave a deviation of $+12.4^\circ$.

Bouchardat, on the other hand (*Compt. rend.* lxxx. 120; lxxxiv. 34), finds that mannitol in pure aqueous solution is slightly levogyrate, its specific rotatory power for the transition-tint being $[\alpha]_j = -0^\circ 15'$. Vignon's method of determining it in a solution of mannitol containing borax, is regarded by Bouchardat as fallacious, because chemical compounds are formed in this solution. When acid calcium borate, which is insoluble in water, is added to a solution of mannitol, it is dissolved in the proportion of 1 eq. of the salt to 1 eq. mannitol, and the rotatory power of the very stable compound thus produced is $+28.6^\circ$. Caustic soda renders mannitol solution

laevogyrate with a rotatory power of -5.17° . The various ethers of mannitol prepared from glucose or from invert-sugar exhibit, when dissolved in acetic acid, the same rotatory power as the corresponding derivatives of natural mannitol from the ash, and likewise agree with them in other physical properties (see MANNITOL, p. 1268).

Glucosides (Hesse, *Annalen*, clxxvi. 116, 125). *Phlorizin*, $C^{21}H^{30}O^{11}.2H^2O$, dissolved in alcohol of 97 v.p.c., gives for $c=1$ and 5, $[\alpha]_D = -(49.40 + 2.41 c)$.

Phloretin, $C^{15}H^{14}O^3$, dissolved in alcohol of the same strength, gave for $c=1$ and 3 no deflection of the plane of polarisation.

Salicin, dissolved in water ($c=1$ to 3), gave $[\alpha]_D = -(65.17 - 0.63 c)$.

Santonin, $C^{15}H^{18}O^3$, in 97 v. p. c. alcohol, ($c=1$ and 2), gave $[\alpha]_D = -173.81^\circ$; in 90 v. p. c. alcohol, -175.4° ; in 80 v. p. c. alcohol, -176.5° ($c=2$ in both cases); in chloroform ($c=2$ to 10), mean value of $[\alpha]_D = -171.53^\circ$, apparently independent of temperature and concentration.

Dichlorosantonin, in 97 v. p. c. alcohol, showed for $c=1$ a rotatory power of only -2.3° . *Santonio acid*, $C^{15}H^{20}O^4$, at 22.5° in 97 v. p. c. alcohol ($p=1$ and 3) gave $[\alpha]_D = -25.82$, and in 80 v.p.c. alcohol ($c=2$ and 3), $[\alpha]_D = -26.46^\circ$. *Sodium santonate*, at 22.5° in aqueous solution between $p=2$ and $p=10$, gave $[\alpha]_D = -(18.70 + 0.33 c)$, slightly increasing with the temperature. In 80 v.p.c. alcohol, this salt exhibits the same rotatory power as in water, but on addition of sulphuric acid, the rotation quickly approximates to that of santonin.

Opium Bases (Hesse, *Annalen*, clxxvi. 189). 1. Morphine. The *hydrochloride*, $C^{17}H^{19}NO^3.HCl + 3H^2O$, at 22.5° , gave in aqueous solution ($c=1$ to 4), $[\alpha]_D = -(100.67 - 1.14 c)$; in presence of 10 mols. HCl ($c=2$) the value of $[\alpha]_D$ was -94.31 . The *sulphate*, $(C^{17}H^{19}NO^3)_2SH^2O^4 + 5H^2O$, in water at the same temperature ($c=1$ to 4), gave $[\alpha]_D = -(100.47 - 0.96 c)$. The free alkaloid, $C^{17}H^{19}NO^3 + H^2O$, at 25° , in an aqueous solution containing 1 mol. Na^2O ($c=2$), gave $[\alpha]_D = -67.5^\circ$; with 5 mols. Na^2O and $c=2$, the value was -70.23° , and with $c=5$ it was -71.00° .

2. Codeine, $C^{18}H^{21}NO^3$, dissolved in 97 v.p.c. alcohol, gave for a solution in which c was between 2 and 8, a rotatory power $= -135.8^\circ$, not influenced by concentration; in 80 v. p. c. alcohol ($c=2$) the value was -137.75° ; in chloroform ($c=2$) it was -111.5° . The *hydrochloride*, $C^{18}H^{21}NO^3.HCl + 2H^2O$, in aqueous solution ($c=2$), gave $[\alpha]_D = -108.18^\circ$, or calculated for the alkaloid, -126.89° ; a solution of the same strength containing 10 mols. HCl gave $[\alpha]_D = -105.22^\circ$; in 80 v.p.c. alcohol ($c=2$) this salt gave -108° . The sulphate in aqueous solution between the temperatures of 15° and 25° gave $[\alpha]_D = -106.9$.

3. Narcotine. Experiments were made at 22.5° with the following solvents: Alcohol (97 v. p. c.); the same mixed with 2 vols. chloroform; chloroform; water with 2 mols. and 10 mols. HCl; 80 v. p. c. alcohol with 2 mols. HCl. The following were the mean results obtained:

	Alcohol	Chloroform + Alcohol	Chloroform	Water + 2HCl	Water + 10HCl	Alcohol + 2HCl
$c =$	0.74	2	2 and 5	2 and 5	2	2
$[\alpha]_D = -$	185.0	-191.5	-207.35	-46.7	-50.0	-104.5

4. Hydrocotarnine, Meconin, Narceine, and Cryptopine were not found to exert any action on polarised light, whatever might be the solvent employed, and even after addition of acids.

5. Pseudomorphine. The *hydrochloride*, $C^{17}H^{19}NO^3.HCl + H^2O$, in aqueous solution, acidulated with 1 mol. HCl at 22.5° , gave for $c=0.8$ to 1.6 , $[\alpha]_D = -(114.76 - 4.96 c)$. In a solution ($c=2$) containing 1 mol. pseudomorphine, 5 mols. Na^2O , and 1 mol. NaCl. $[\alpha]_D = -198.86^\circ$. For the alkaloid, the value calculated from this result is -235.1° , whereas according to the experiment with the hydrochloride, calculated for $c=2$, the value for the alkaloid is only -123.6° .

6. Thebaine, $C^{19}H^{21}NO^3$, dissolved in alcohol of 97 v.p.c., exhibits between $c=1$ and $c=2$ a rotatory power independent of the concentration, but diminishing from -218.6° to -215.5° , when the temperature is raised from 15° to 25° . In a chloroform solution ($c=5$), $[\alpha]_D = -229.5^\circ$. The *hydrochloride*, for $c=2$ to 4, gives $[\alpha]_D = -(168.32 - 2.33 c)$, the value being apparently somewhat diminished by rise of temperature. On addition of 10 mols. HCl, the value of $[\alpha]_D$ is reduced to -158.64° .

7. Papaverine dissolved in 97 v. p. c. alcohol ($c=2$), gave $[\alpha]_D = -4^\circ$; in chloroform ($c=5$) it gave -5.7 . The hydrochloride gave no rotation even after addition of free hydrochloric acid.

8. Laudanine, at 22.5°, dissolved in chloroform ($c=2$), gave $[\alpha]_D = -13.5$; in aqueous solution ($c=1$) containing 2 mols. Na²O to 1 mol. alkaloïd, $[\alpha]_D = -11.36^\circ$. The hydrochloride gave no rotation either in aqueous, alcoholic, or hydrochloric acid solution.

9. Laudanosine gave the following values:

Solvent	97 v. p. c. Alcohol	Chloroform	Water + 2 mols. HCl
Temperature	15°	22.5°	22.5°
Concentration	$c = 2.79$	2	2
	$[\alpha]_D = +103.23^\circ$	105.00°	56.00° 108.41°

Cinchona Bases (Hesse, *Annalen*, clxxvi. 203-233). All the following determinations were made at the temperature of 15°.

1. Quinine Hydrate, $C^{20}H^{24}N^2O^2 + 3H^2O$:

In ether (sp. gr. = 0.7296; $c=1.5$ to 6,	$[\alpha]_D = -(158.7 - 1.911 c)$
„ 97 v. p. c. alcohol $c=1$ „ 10	„ $-(145.2 - 0.657 c)$
„ 80 „ „ $c=1$ „ 6	„ $-(165.81 - 8.203c + 1.0654 c^2 - 0.04644 c^3)$
„ chloroform + alcohol 2 „ 5	-140.7

The influence of temperature between 15° and 25° lowers the absolute rotatory power, for $c=3$, by 1.56°.

2. Quinine Anhydride, $C^{20}H^{24}N^2O^2$:

Solvent	97 v. p. c. alcohol	Chloroform
$c =$	$\begin{matrix} 1 & 2 \end{matrix}$	$\begin{matrix} 2 & 5 \end{matrix}$
$[\alpha]_D =$	$\begin{matrix} -170.5 & -169.25 \end{matrix}$	$\begin{matrix} -116.00 & -106.6 \end{matrix}$

Calculation based on the results obtained with the hydrate gives smaller numbers for the anhydride, showing that the entrance of water into the quinine molecule diminishes the rotatory power.

3. Quinine Hydrochloride, $C^{20}H^{24}N^2O^2.HCl + 2H^2O$:

In water $c=1$ to 3,	$[\alpha]_D = -(147.31 - 4.96 p + 0.343 c^2)$
„ 97 v. p. c. alcohol, $c=1$ „ 10,	„ $-(147.30 - 1.9584 p + 0.1039 c^2 - 0.00211 c^3)$
2 chloroform + 1 alcohol, $c=2$	„ $= -126.25$

In mixtures of alcohol and water ($c=2$) the rotatory power rises from -138.75, its value in pure water, to the maximum -187.75 in alcohol of about 60 v. p. c., and diminishes down to -143.86 in 97 v. p. c. alcohol. In mixtures of water and hydrochloric acid ($c=2$), a maximum = -225.68 occurs for 2 mols. HCl to 1 mol. water; with 16 mols. HCl, $[\alpha]_D$ is still = -209.54, and in fuming hydrochloric acid -158.75. The anhydrous hydrochloride gives for $c=0.9$ to 9:

$$[\alpha]_D = - (81.81 - 23.756 c + 3.9556 c^2 - 0.21981 c^3).$$

A rise of temperature of 10° produces no perceptible alteration in the rotatory power of the alcoholic solution.

4. Quinine Sulphates. The *bi-basic sulphate*, $2C^{20}H^{24}N^2O^2.SH^2O^4 + 8H^2O$, gives, for $c=2$ in 80 v. p. c. alcohol, $[\alpha]_D = -162.95$; in 60 v. p. c. alcohol, -166.36; in a mixture of chloroform and alcohol ($c=1$ to 5), $[\alpha]_D = -(157.5 - 0.27 c)$.

The *monosulphate*, $C^{20}H^{24}N^2O^2.SH^2O^4 + 7H^2O$, gave with water ($c=1$ to 6) $[\alpha]_D = -(164.85 - 0.31 p)$. In other solvents the following values were obtained:

	c	$[\alpha]_D$
Water with 2 mols. SO ³	2	-166.36
„ „ 12 „ „	2	-175.67
„ „ 4 „ „ HCl	2	-168.25
9 v. p. c. alcohol	2	-134.75
80 „ „	1	-143.63
80 „ „	2	-142.75
60 „ „	2	-155.91
2 vols. chloroform + 1 vol. alcohol	2	-138.75

Quinine Bisulphate, $C^{20}H^{21}N^2O^2 \cdot 2SH^2O^1 + 5H^2O$, in water ($c=2$ to 10), gave $[\alpha]_D = -(170.3 - 0.94c)$; with addition of 12 mols. SO^3 ($c=2$), $[\alpha]_D = -171.0$, and in 80 v.p.c. alcohol, for $c=1$ and 3 respectively, $[\alpha]_D = -154.54$ and 153.34 .
5 Quinine Oxalate, $2C^{20}H^{21}N^2O^2 \cdot C^2H^2O^4 + 6H^2O$, dissolved in a mixture of alcohol and chloroform, gave for $c=1$ to 3, $[\alpha]_D = -(141.58 - 0.58c)$.

5. Cinchonidine gave:

	c	$[\alpha]_D$
In 97 v. p. c. alcohol	1 to 5	— (107.48 — 0.297 c)

80 " "	2	202.95
60 " "	2	204.14
Chloroform-alcohol	2	185.25

15. Cinchonine Oxalate, dissolved in chloroform-alcohol ($c=1$ to 3), gave $[\alpha]_D = 165.46 - 0.763 c$.

16. Cinchotennine Hydrate, $C^{18}H^{20}N^2O^3 + 3H^2O$, dissolved in chloroform-alcohol ($c=2$), gave $[\alpha]_D = +115.5$, which gives by calculation for the anhydrous base the number 135.52; in water with 2 mol. SO^2 , the corresponding numbers were 175.5 and 205.9.

The specific rotatory power of the cinchona alkaloids has also been carefully examined by A. C. Oudemans, junr. (*Arch. nêrl.* x. 193). (1). Quinine.—The following are the values obtained for the solution of this base in various inactive liquids, m denoting the number of grams dissolved in 20 c.c. of this solvent:

	Pure Alcohol	Benzene	Toluene	Chloroform	Chloroform
$m =$	0.328	0.122	0.078	0.293	0.155
$[\alpha]_D =$	— 167.5	— 136	— 127	— 117	— 1.26

For the solution in pure alcohol, the value of $[\alpha]_D$ at 0° diminishes from $m=0.1$ to $m=1.2$ from 172.3 to 162.4. For the temperature 21° , the corresponding numbers for the same two concentrations are 169.0 and 159.7. Equally variable is the specific rotatory power under otherwise similar circumstances in solutions of 1 molecule = 0.324 grm. in 20 c.c. of aqueous alcohol of various strengths. From the proportion 95 alcohol and 5 water to that of 65 alcohol and 35 water, the value of $[\alpha]_D$ rises steadily from 169.7 to 176.5.

Solutions of quinine salts gave the following results, the specific rotatory power of the salt being denoted by $(\alpha)_s$, and that of quinine itself, as above, by $[\alpha]_D$.

Solution in Pure Alcohol.

	$(\alpha)_s$	$[\alpha]_D$
Normal Sulphate, $(C^{20}H^{24}N^2O^2)^2.SH^2O \cdot 7\frac{1}{2}H^2O$	— 157.4	— 214.9
Acid Sulphate, $C^{20}H^{24}N^2O^2.SH^2O \cdot 7H^2O$	— 134.5	— 227.6
Normal Hydrochloride, $C^{20}H^{24}N^2O^2.HCl.2H^2O$	— 138.0	— 169.0
Acid Oxalate, $C^{20}H^{24}N^2O^2.C^2H^2O^4.3H^2O$	— 131.4	— 160.5

Solution in Water.

Acid Sulphate	— 213.7	— 278.1
Normal Hydrochloride	— 133.7	— 163.6

The specific rotatory power of quinine is variously altered by addition of different acids, attaining its maximum in sulphuric, nitric, hydrochloric, and chloric acid, when the quantity of acid added is exactly equal to, or a little less than, that which is required to form an acid salt; with phosphoric and oxalic acids, on the other hand, the maximum is attained only when a larger quantity of acid has been added (4 mol. phosphoric and 3 mol. oxalic); in the case of formic acid, with 28 to 30 mol.

acid; and in that of acetic acid not till 64 mol. acid have been added. In each of these experiments 0.324 grm. quinine was dissolved in the respective quantity of acid, and the solution was diluted with water to 20 c.c. The maxima of rotatory power attained were as follows:

In Oxalic acid	271.7°	In Formic acid	280.6°
„ Sulphuric acid	278.8	„ Nitric „	284.2
„ Acetic „	278.9	„ Chloric „	285.7
„ Hydrochloric acid	279.2	„ Perchloric acid	287.6
„ Phosphoric „	280.0		

(2). Quinidine, $C^{20}H^{21}N^2O^2 + 2\frac{1}{2}H^2O$. The solution of 0.324 grm. in 20 c.c. of different solvents gave the following values of the specific rotatory power:

Solvents	Pure Alcohol	Chloroform	Benzene	Toluene
$[\alpha]_D =$	+255.4	+228.8	+195.2	+206.6

At the temperature of 17°, in solutions in pure alcohol, whose concentration varies from 0.1925 to 0.3740, the specific rotatory power decreases from 258.1 to 255.4, but remains nearly constant on further concentration to 0.64. As the temperature rises it becomes somewhat smaller. In mixtures of alcohol and water (always containing 0.324 grm. quinidine in 20 c.c.):

Percentage } of water }	0	4.7	9.5	15	20	25
$[\alpha]_D =$	255.4	257.6	259.0	259.4	259.3	259.4

Beyond 10 per cent. water, therefore, the variation is but small. The salts of quinidine gave the following results:

Salt	Formula	Solvent	$(\alpha)_D$	$[\alpha]_D$
Sulphate	$(C^{20}H^{21}N^2O^2)2SH^2O^4.2H^2O$	Pure Alcohol	+211.5°	+255.2°
Nitrate	$C^{20}H^{21}N^2O^2.NHO^3$	„	199.3	232.6
Hydrochloride	$C^{20}H^{21}N^2O^2.HCl.2H^2O$	Water	190.8	244.1
		Pure Alcohol	199.4	233.6
		90.5 p. c. Alc.	213.0	260.7

Quinidine when dissolved in excess behaves almost exactly like quinine, excepting that the maxima do not follow one another quite in the same order.

(3). Cinchonine. The values of $[\alpha]_D$ for this base in alcoholic and chloroform solution, as determined by Oudemans, have been already given (p. 1209). Cinchonine is but slightly soluble in pure alcohol, and its rotatory power does not appear to be affected by the degree of concentration of the solution. In a solution containing 0.1 grm. in 20 c.c., the value of $[\alpha]_D$ is 234.9 at 0°, 224.7 at 15°, 221.1 at 20°. In 90 per cent. alcohol at 17°, $[\alpha]_D = 228.8$. Now Erdmann's *huankine* (iii. 175), under the same conditions, gave 228.0, so that, in this, as in other respects, this base is identical with cinchonine. In chloroform the rotatory power of cinchonine appears to diminish as the concentration increases; in solutions whose concentration is between 0.0914 and 0.1115, the rotatory power varies from +214.8 to 209.6. The influence of various solvents at different degrees of concentration on the rotatory power of cinchonine has already been stated (p. 1209). For medium concentration and temperature, the specific rotatory power of cinchonine in its salts is found by calculation to have the following values:

Salt	Solvent	$[\alpha]_D$
Cinchonine Sulphate	Water	+204.2°
„ „	Pure Alcohol	232.9
„ Hydrochloride	Water	201.0
	Pure Alcohol	204.4
	93 p. c. „	216.1
	29 „ „	229.1
„ Nitrate	Water	190.0
	Pure Alcohol	212.2
	93 p. c. „	225.7

A solution of 0.308 grm. cinchonine in 20 c.c. of each of these solvents behaves with excess of different acids analogously to quinine and quinidine.

(4). Cinchonidine. A solution of 0.304 grm. of the pure base in 20 c.c. of pure alcohol exhibited at 0° a specific rotatory power of -112.8° ; a nearly similar solution (0.308 grm.) gave at 17° the value -109.6 . At the latter temperature the value of $[\alpha]_D$ further decreased with increasing concentration, being -108.5 at 0.5182 grm., and -107.8 at 0.771 grm. At the same temperature and a concentration of 0.3 grm. addition of water to the alcohol, from 0 to 40 per cent. (by weight) increased the specific rotatory power from -109.6 to -191.1° . In chloroform solution the specific rotatory power of cinchonine is very much diminished by concentration, being -77.4 at a concentration of 0.3089, and -74.0 at 0.6823 grm. The salts of cinchonidine behave in a similar manner. The hydrochloride, nitrate, and sulphate gave at 17° the following values:

Concentration . [α] _D = . .	In Water			In pure Alcohol			In 89 p.c. Alcohol	In 80 p. c. Alcohol
	0.3712	0.4798	0.6023	0.3499	0.5074	0.6213	0.3529	0.3635
	-104.6°	102.3	99.3	99.9	97.5	96.2	119.6	128.7

Concentration . [α] _D = . .	Nitrate				Sulphate		
	Water	Pure Alcohol	89 p. c. Alcohol	80 p. c. Alcohol	Pure Alcohol	89 p. c. Alcohol	80 p. c. Alcohol
	0.3377	0.3658	0.3788	0.3691	0.34 to 0.38	0.3622	0.3686
	-99.9	103.2	119.0	127.0	118.7	128.7	131.2

Hence it appears that cinchonidine has a greater rotatory power in its salts than in the free state. With acids in excess it behaves like the three other alkaloids. The peculiar behaviour of the four cinchona alkaloids with excess of acid is regarded by Oudemans as connected with their easy decomposibility by water, which probably takes place to a slight extent whenever an acid salt of one of these bases is dissolved in water. It is only by further addition of acid that this decomposition can be prevented, and the entire quantity of alkaloid retained in the form of acid salt, in which its specific rotatory power appears to be a maximum. This point, however, is more quickly attained in proportion as the acid is stronger or combines more readily with the alkaloid.

The results obtained by Oudemans agree well for the most part with those of Hesse, so far as the two admit of comparison, and the differences between them appear to be in most cases due to the circumstance that the alcohol used as a solvent by Hesse was not quite anhydrous. With due attention to all the disturbing causes pointed out by Oudemans, the optical method of investigation may serve, contrary to Hesse's opinion, as a valuable aid in the quantitative analysis of mixtures of alkaloids.

Circular Polarisation induced by Magnetic Action. H. Becquerel (*Ann. Chim. Phys.* [5], xii. 5-88) has determined, by observations on a large number of diamagnetic bodies, the relations which exist between the magnetic rotation of the plane of polarisation of a ray of light and the index of refraction. In the following table, R denotes the magnetic rotation, n the index of refraction, and v the ratio

$$\frac{R}{n^2(n^2-1)}.$$

From the numbers in this table the following laws may be deduced :

1. For all diamagnetic bodies, the ratio $R : n^2(n^2-1)$ is comprised within comparatively narrow limits, viz. 0.11 to 0.46, or 1 to 4, whereas the magnetic rotation varies from 0.2 to 14.06, that is from 1 to 70.

2. For bodies belonging to the same chemical family, or composed of the same chemical elements, this ratio is nearly the same; thus the highly oxygenated acids, such as nitric and sulphuric acid, give very small numbers near to 0.11. The fatty alcohols and chloroform give numbers near 0.16. For sulphur, and its compounds with hydrogen and phosphorus, the value is near 0.188; and for the compounds of chlorine with carbon, sulphur, silicon, and phosphorus, it does not differ much from 0.22.

For solutions, the value of $R : n^2(n^2-1)$ is intermediate between that of the solvent and that which would hold good for the dissolved body, and approaches more nearly to the latter as the solution is more concentrated.

In strongly magnetic bodies, such as the salts of iron, if the indices of refraction vary only within narrow limits, the variations of rotation corresponding with the change of refractive index are masked by the great variations dependent on the specific magnetism of the body, which in most cases is strong enough to reverse the direction of the rotation: hence in these bodies there is no apparent relation between the rotation and the index of refraction.

Certain crystallised bodies, as fluorspar, ruby, spinel, and diamond, deviate absolutely from the general law above stated, and exhibit only a very small rotation in proportion to their index of refraction.

In highly dispersive bodies, such as carbon bisulphide and phosphorus monosulphide, the magnitude of the rotation is nearly in the inverse ratio of the square of the wave-length.

III. CHEMICAL ACTION OF LIGHT.

J. W. Draper (*Sill. Amer. J.* [3], v. 25, 91) has published the experimental evidence forming the basis of his conclusions respecting the distribution of chemical energy in the spectrum (vii. 749). That all the rays of the spectrum are capable of producing chemical action is shown: (1). By the behaviour of silver iodide (on a daguerreotype plate), which, when exposed to the pure spectrum, is affected first and most strongly in the most refrangible parts, but afterwards also in the less refrangible portions. These last-mentioned rays, however, exert a different action if the plate is exposed to the action of faint diffused daylight, either simultaneously with the action of the spectrum or just before it. After the image has been developed by mercury-vapour, it is seen that all the rays of the spectrum have acted on the plate, even the lines α , β , γ in the ultra-red being visible. The finished photograph shows on a light ground an image of the spectrum, the more refrangible portion of which is bluish or olive-coloured, while the less refrangible portion appears deep black with white Fraunhofer lines. The appearance of the plate shows that the more refrangible rays assist the action of diffused daylight, while the less refrangible retard it. (2). By the behaviour of bitumens and resins: when West Indian bitumen

dissolved in light petroleum is irradiated by the spectrum for five minutes and then treated with a mixture of light petroleum and alcohol, an image of the spectrum is formed extending from below A to above H. (3). By the part which light plays in the decomposition of carbon dioxide in plants, which, according to Draper's experiments, is produced chiefly by the rays between B and F, with a maximum in the yellow; the same rays develop the green colouring of leaves. (4). By the decomposing action of light on the colours of flowers, which takes place in such a manner that each colour is destroyed by those rays the mixture of which produces the tint complementary to itself. (5). By the well-known fact that the combination of chlorine and hydrogen is effected by all rays, though in different degrees. (6). By the fact, first observed by Gardner, that when a row of young plants germinated in the dark is illuminated by a spectrum, they all bend towards the one which is illuminated by the indigo-rays, and this latter bends towards the rays themselves.

The statement that a substance is chemically affected by the particular rays which it absorbs, is supported by the following facts: (1). The behaviour of silver iodide. The variously-coloured layers produced by the action of iodine-vapour on a silver plate in different lengths of time, are sensitive to light in very different degrees, each being unaffected by the rays which it reflects, and affected only by those which it absorbs. The sensibility to light depends therefore not only on the chemical but also on the optical nature of the iodide. A certain amount of rays must be absorbed before the action begins, but when once begun, it goes on proportionally to the time. (2). The fact, established by older as well as by recent experiments, that the rays absorbed by chlorine gas are exactly those which induce the combination of chlorine and hydrogen.

P. Chastaing (*Ann. Chim. Phys.* [5], xi. 145-224) has made a large number of experiments on the chemical effect of variously coloured rays on compounds both inorganic and organic, from which he draws the following conclusions: (1). That the action of the differently coloured rays on inorganic bodies varies in kind as well as in degree, according to their refrangibility, the violet and blue, and sometimes also the green rays, exerting a reducing action, the red and yellow rays an oxidising action, and that between the spectral lines D and E, at the boundary of the green and yellow, there is a neutral point, at which the light exerts no chemical action whatever. 2. The chemical action of light on organic bodies is in all cases an oxidising action, increasing from darkness through the red to a maximum in the violet.

These conclusions have however been controverted by H. W. Vogel (*Deut. Chem. Ges. Ber.* x. 1638) by reference partly to Chastaing's own experiments, partly to facts which have long been established. Vogel finds, indeed, that rays of all colours are capable of exerting either an oxidising or a reducing action according to the nature of the body by which they are absorbed, and that the so-called neutral point where, according to Chastaing, no chemical action takes place, has no existence.

That the violet rays do not invariably exert a reducing action is sufficiently shown by the well-known fact that chlorine and hydrogen combine energetically under the influence of these rays; and that, on the other hand, the less refrangible rays can exert a reducing action is shown by Vogel's experiments on chloride, bromide, and iodide of silver, from which it appears that the alteration of these compounds in the red and yellow rays of the spectrum is qualitatively identical with that which takes place in the blue and violet, namely a reduction. The statement that light of all colours exerts an oxidising action on organic bodies is sufficiently refuted by the well-known fact of the decomposition of carbon dioxide by green plants under the influence of light. This process, which is attended with elimination of oxygen, is undoubtedly a reduction, and according to recent experiments by Timiriazeff (*Compt. rend.* lxxxiv. 1236) takes place most rapidly in red light at the chief absorption-band of chlorophyll.

The experiments of H. Vogel on the increase in the sensibility to light of haloïd silver salts produced by addition of optically absorbing substances (vii. 750) have been repeated, with confirmation of their results, by E. Becquerel (*Compt. rend.* lxxix. 185). On mixing a solution of chlorophyll with the collodion of the film of silver bromide or iodide, he obtained, in the red and yellow regions of the spectrum, several maxima of action, the strongest of which, situated between B and C, corresponded nearly with the principal absorption-band of chlorophyll; the others, between C and D, with the other absorption-bands of that substance.

Further experiments by Vogel (*Pogg. Ann.* clii. 218; *Deut. Chem. Ges. Ber.* vii. 545, 976) on the sensibility of the haloïd salts of silver to light have led to the following results: (1). Chloride, bromide, and iodide of silver are sensitive, not only to the more refrangible, but also, though in a far inferior degree, to the less refrangible rays of the spectrum. (2). The sensitiveness of silver haloïd salts to the different spectral colours depends, not only on their optical absorption-capacity for these rays,

but likewise on the optical absorption-capacity of admixed substances. (3). Coloured bodies—naphthalene-red, for example—which assist the photographic reduction process, and at the same time absorb certain spectral colours, give rise, when properly applied, to a great increase in the sensitiveness of silver salts to the absorbed rays. In this way, the sensitiveness of silver salts to the red, yellow, and green rays may be greatly heightened. (4). Mixtures of different colouring matters produce an effect equal to the sum of the effects of their several constituents. (5). Certain colourless bodies also (e.g. silver nitrate and morphine) which promote photographic reduction, exert a considerable modifying influence on the colour-sensitiveness of silver salts. (6). The photographic action of absorbent substances exhibits a certain analogy to anomalous dispersion (vii. 742), inasmuch as the sensitiveness increases or diminishes with the index of refraction. Hence perfectly indifferent bodies, collodion, for example, which influence the index of refraction, displace both the absorption-band and the point of strongest photographic action. (7). The action of light reflected from coloured pigments is very different from that of the spectral colours, being affected not only by the optical composition of the pigment colours, but likewise by their far inferior brightness.

The third of these laws respecting the effect of coloured bodies on the sensitiveness of silver haloid salts has been called in question by M. Carey Lea (*Sill. Am. J.* [3], vii. 200; ix. 355), who points out especially that, according to this law, naphthalene and corallin ought to increase the sensitiveness of silver bromide to the green rays, whereas Vogel found that they gave increased sensitiveness only for the yellow rays. According to Lea, corallin greatly increases the sensitiveness of silver bromide for the red rays, moderately for the yellow, and not at all for the green. Vogel finds by further experiments (*Deut. Chem. Ges. Ber.* viii. 95, 1635) that different silver salts are variously affected by one and the same colouring matter. Naphthalene-red added to silver bromide increases its sensitiveness to the yellow, and produces a similar and greater effect on the chlorido. Fuchsin acts with silver bromide in a manner exactly corresponding with its absorption, and almost in the same way as naphthalene; with silver chloride it does not greatly increase the sensitiveness to any rays except the violet. A similar behaviour is exhibited by colourless bodies, like morphine, which increases the action on silver bromide in the green, blue, and violet, but has no effect on the bromide. Pyrogallol acts nearly in the same manner.

The following conditions are laid down by Vogel as necessary to insure the conformity of a colouring matter to his law above mentioned: (1). It must optically absorb that particular kind of light for which it is to make the collodion sensitive. (2). It must be capable of combining chemically with free bromine or iodine. (3). It must not decompose silver nitrate, as in that case it would interfere with the preparation of the plates.

Methyl-violet and cyanine were found to strengthen the action on silver bromide of the rays which they absorb, the latter intensifying the action of the orange-rays in a very high degree; picric acid, aniline-blue, night-blue, pensée-lac, indigotin, and purpurin, on the contrary, did not exhibit any such intensifying action. The coloration of a film of silver bromide by colours which are destroyed by the action of free acids in the collodion or in the silver-bath may be most readily effected by wetting the prepared bromide of silver plates with an alcoholic solution of the colouring matter, and leaving them to dry.

Vogel also finds (*Ber.* ix. 667) that silver bromide (like the iodide) exhibits a very different degree of sensitiveness to light, accordingly as it has been precipitated with excess of silver nitrate or of potassium bromide. The bromide by itself is much more sensitive than the iodide, but its sensitiveness is not increased by the action of intensifying substances, whereas all such bodies heighten the sensitiveness of the iodide in a very great degree. Plates prepared with excess of potassium bromide showed no action in the yellow, whereas when immersed in a bath of silver nitrate and then coated with naphthalene-red, they became sensitive to yellow light. A similar effect was produced by cyanine. Vogel accordingly draws a distinction between bodies which increase the sensitiveness of silver bromide or iodide by their power of optical absorption, and those which, like tannin, act chemically by combining with the bromine or iodine.

According to Carey Lea (*Sill. Am. J.* [3], xi. 459; xii. 48), the optical absorbing power of sensitising substances has very little to do with their property of rendering silver bromide sensitive to rays of lower refrangibility. Of fourteen red colouring matters examined, corallin alone rendered that compound sensitive in the green, which effect, however, cannot be due to its power of absorbing the green rays, since it renders the silver bromide still more sensitive to the red rays which it transmits; moreover, its sensitising action is not destroyed by the action of acetic or gallic acid, which turns it yellow. The following colouring matters, which are more or less non-absorbent

for the green rays, nevertheless heighten the sensitiveness of silver bromide for these rays: potassium arsenite, silver arsenite, salicin, codeine, morphine acetate, tincture of capsicum, ammonium valerate, and caffeine (?) Many alkaloids diminish the sensitiveness for the green. The only body which acts nearly in accordance with Vogel's law is chlorophyll.

Lea has also examined the sensitiveness of a number of silver-salts to light, chiefly with the view of ascertaining which of them, besides the chloride, bromide, and iodide, can be used for photography. Paper was impregnated with soluble salts of acids capable of forming insoluble compounds with silver, then floated on the surface of silver nitrate; some of the paper was also treated with gallotannic acid. It was then exposed to diffused light for seven to twelve seconds, and the image developed by pyrogallol, ammonium carbonate, and potassium bromide. None of the substances examined gave strong images, with the exception of the platinocyanide and the arsenite. Tannin was not found to exert any beneficial action (*Sill. Am. J.* [3], xiii. 369).

Photographing of the Ultra-red and Violet Rays.—J. Waterhouse (*Proc. Roy. Soc.* xxiv. 186) has obtained reversed photographs of the extreme red and ultra-red rays of the solar spectrum on silver bromide collodion plates, which were exposed for a second to diffused daylight before being subjected to the action of the spectrum. The blue and violet rays between F and H were also frequently reversed on silver bromide plates coloured and uncoloured, after prolonged exposition.

Waterhouse also finds that silver bromide plates, coloured with eosin, are most sensitive to the green and yellow rays, a fact which accords with Vogel's theory; for the pigment, when dissolved in water or alcohol, is of a light orange-red colour with greenish-yellow fluorescence. The absorption-spectrum of the dilute aqueous solution shows a darkening from below E to above F. Plates coated with bromiodide of silver exhibited only a slight increase of action in the green and yellow. For the photographing of coloured objects, plates thus coloured were found to be not well adapted, on account of the retardation of the action consequent on the colouring.

Production of Coloured Spectra by the Action of Light.—Examples of the production of natural colours by the agency of light were shown some time ago by Becquerel; and Captain Abney, in a paper lately communicated to the Royal Society (June 19, 1879), reports that he has succeeded in obtaining coloured pictures of the solar spectrum both on silver plates and on compounds of silver held in position by collodion. The spectrum imprints itself in approximately natural colours, which are more brilliant on the silver plate than on the collodion film, but those on the latter can be seen by transmitted as well as by reflected light. These colours are produced by oxidation of silver-compounds placed in the spectrum, an exposure of two minutes with a wide slit being sufficient for their development (*Chem. News*, xxxix. 282).

Action of Light on Potassium Iodide.—Vidan (*Pharm. J. Trans.* [3], v. 383, 393) observes that a neutral solution of potassium iodide is decomposed by bright sunshine. The pure solution turns yellow from separation of iodine; paper soaked in solution of potassium iodide and starch-paste, and sealed up in a glass tube, is turned bright blue when exposed to sunshine for an hour. On this account the use of iodised starch-paper as a test for ozone may lead to very uncertain results, as formerly pointed out by Cloez (*Compt. rend.* xliii. 38) and by Campani (*Cimento*, iv. 112). On the Decomposition of Hydrogen Iodide by Sunlight, see CHEMICAL ACTION (p. 429).

Action on Vanadium Salts.—Acid potassium vanadate, in contact with organic substances, is turned by light first green and finally blue; when not in contact with organic matter it is unaffected by light. Neutral sodium vanadate laid on glass in a colourless film and exposed to sunshine is somewhat browned, but becomes colourless again when left for some hours in the dark and in a draughty place. Paper moistened with its solution acquires a slate colour, and if then dipped into solution of silver nitrate, instantly becomes dark brown to black, according to the time of exposure. This salt may therefore be used for photography.

Action on Sulphurous Acid.—Dilute solutions of sulphurous acid, exposed to sunshine for a whole summer in sealed glass tubes, remained clear for two months, but afterwards exhibited a continually increasing turbidity, sulphur being separated and the liberated oxygen converting the remaining sulphurous acid into sulphuric acid. Solutions of sulphuric acid, sulphates, and sulphites, under similar circumstances, showed no sign of alteration.

Action of different rays on Chlorophyll.—The following experiments have been made by J. Wiesner (*Pogg. Ann.* clii. 496; cliii. 622) with reference to the much

disputed question as to which rays of the spectrum are most active in the decomposition of chlorophyll. Equal and similarly disposed quantities of chlorophyll-solution were subjected to the action of rays which had passed through equally thick layers, either: (1) of a white turbid liquid (water in which calcium oxalate was suspended); or (2) of a yellow solution of potassium dichromate; or (3) of a green ethereal solution of chlorophyll; or (4) of a red solution of aesculin-orcein; or (5) of a blue solution of cuprammonium sulphate, particular care having been taken to make the five solutions equally transparent. It was found that the action was strongest when the light had passed through the first medium, and diminished for each of the successive media in the order above stated, so that the yellow rays from C to E must be regarded as the most effective, a result likewise obtained by Pfoffer (*infra*). Xanthophyll, however, which, when an alcoholic solution of chlorophyll is shaken up with light petroleum or carbon sulphide, alone remains dissolved in the alcohol, is most quickly decomposed by rays which have passed through cuprammonium sulphate. Wiesner infers from his experiments that the decomposition of dissolved chlorophyll under the influence of light is an oxidation process from beginning to end, whereas Gerland regarded the presence of oxygen as necessary only to start the action (vii. 327).

E. Lommel (*Pogg. Ann.* cxliii. 568; cxlv. 142) infers, from experiments on the influence of coloured light in promoting the decomposition of carbon dioxide by plants, that this action is greatest for the rays which correspond in refrangibility with the absorption-band of chlorophyll between B and C. Pfeffer, on the other hand (*ibid.* cxlviii. 86), disputes this conclusion, and finds that the curve of decomposition has its maximum in the yellow, and descends regularly on both sides from that point. His experiments were made by exposing a green plant (*Elodea Canadensis*) in a glass tube filled with water to the several parts of a spectrum formed by light passing through a slit 5 mm. wide, and counting the gas bubbles evolved in given time. More exact experiments have however been made by Timirjaseff (*Ann. Chim. Phys.* [5], xii. 255), who exposed strips of bamboo-leaf of equal width contained in narrow test-tubes, and enclosed in an atmosphere containing 5 per cent. CO₂, to the action of the several parts of a spectrum produced with a slit only 1 mm. broad and a prism of carbon disulphide, and subjected the gases evolved after five hours' insolation to a very careful analysis. The result of his experiments is to show decidedly that the maximum decomposition is produced by the rays corresponding with the characteristic absorption-band of chlorophyll in the red, and that the rays for some distance before E (yellowish-green) have no influence whatever. The contrary results obtained by Pfeffer are attributed by Timirjaseff to the necessarily impure spectrum obtained with an aperture 5 mm. wide, and to the inexact measurement of the products of decomposition. The same part of the spectrum appears also to correspond with the greatest mechanical energy of the luminous vibrations; moreover, absorption-bands are produced in this neighbourhood by carbon dioxide and water-vapour. The fact that blue and violet light, which are likewise absorbed by chlorophyll, nevertheless exert no influence on the assimilative power of plants, requires special explanation, which has not yet been obtained.

Measurement of the Chemical Intensity of Sunlight.—E. Marchand (*Ann. Chim. Phys.* [4], xxx. 302; *Monit. Scient.* [3], vi. 979) uses for this purpose a mixture of ferric chloride and oxalic acid in equivalent proportions, which, under the influence of insolation, is decomposed as represented by the equation:

The quantity of carbon dioxide evolved in a minute corresponds with a certain quantity of heat evolved (according to Favre, the oxidation of 1 gram of oxalic acid evolves 670 gram-degrees), and this is regarded by Marchand as a measure of the chemical power of the solar rays. The solution is most strongly decomposed by the blue rays between F and G, the action diminishing much more slowly towards the red than towards the violet end. When the liquid is in constant contact with a horizontally exposed surface of glass, the number of c.c. of carbon dioxide evolved per square centimeter is expressed, for a mean sun's altitude h , by the formula

$$m = 0.00092300 + 0.00000729 (h-1).$$

When the rays are reflected constantly at right angles to the surface by a heliostat, the expression becomes

$$m' = 0.001394 + 0.000002 (h-1).$$

These numbers are true for the sea-level at Fécamp on the Channel for a perfectly clear sky. The chemical irradiations are not altered by wind, but are affected by clouds, brightly illumined cirri and cumuli increasing the reaction. By this method

Marchand has drawn up tables representing the chemical climate of Fécamp. E. Becquerel, however, observes that these tables can have only a relative value, and cannot afford a true measure of the chemical energy of the rays, inasmuch as rays which have no action on the particular liquid employed might be capable of exerting a very powerful action on other liquids.

J. Dewar (*Phil. Mag.* [4], xliv. 307) has calculated, from Boussingault's measurements of the decomposition of carbon dioxide by the leaves of plants (*Ann. Chim. Phys.* [4], xiii. 415), the fraction of the total energy of the solar rays received on a unit of leaf-surface, which takes the form of chemical energy. Starting from the two formulæ,

and the thermal equivalents, $\text{CO}, \text{O} = 68000$; $\text{H}_2, \text{O} = 68000$; glucose, $\text{C}^6\text{H}^{12}\text{O}^6 = 642000$ (the last said to have been determined by Frankland), he calculates as follows: According to the first formula, the decomposition of 1 c.c. CO_2 requires 6.06 gram-degrees of heat. If, however, the products of decomposition become condensed, as represented by the second formula, the quantity of heat required will be only $6.06 \times \frac{642000}{6(68000 + 68000)} = 4.78$; and since, according to Boussingault, 1 square centimeter of leaf-surface assimilates in an hour 5.28 c.c. CO_2 , while on the other hand Pouillet estimated the amount of energy radiated by the sun in the latitude of Paris on 1 square centimeter of normally exposed surface at 6000 gram-degrees, it follows that the chemical energy of light is $\frac{4.78 \times 5.28}{6000} = \frac{1}{238}$ of the total energy.

LIGNITE. A lignite from Disco Island, on the west coast of Greenland, has been analysed by H. Wurtz (*Amer. Chemist*, iv. 401). The substance desiccated in dry winter air contained 14.00 per cent. water, 35.38 volatile matter, and 50.62 coke (= 41.79 carbon and 8.83 ash). When ignited even in a covered crucible, it emits a dull yellow, smokeless, feebly luminous flame. It gives off water at the heat of a sand-bath, and contracts strongly at higher temperatures, yielding an anthracitic coke, the volume of which is about 40 per cent. less than that of the original coal. The ash of the coke, which has a green colour, due to manganese, melts at high temperatures to a dark-coloured glass: it does not contain carbonic acid. The lignite has a very high specific gravity = 1.452–1.468; that of the coke is 1.836. The coke contains also a large quantity of occluded gas, which it does not give off completely till it has been boiled for half-an-hour.

On the composition of lignite from Toula in Russia, see p. 526.

On the gases enclosed in lignite from Bovey Heathfield, see p. 534.

LIMBACHITE. A hydrated silicate of aluminium and magnesium, occurring in clefts of the serpentine of Limbach. A and B. Analyses. C. Numbers calculated from the formula $3\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 3\text{H}_2\text{O}$:

	SiO_2	Al_2O_3	Fe_2O_3	MgO	H_2O	Sp. gr.
A.	41.42	22.09	undet.	23.67	12.47* = 99.65	} 2.395
B.	42.03	19.56	1.46	25.61	12.34 = 101.00	
C.	39.38	22.54	—	26.26	11.82 = 100	

(A. Frenzel, *Jahrb. f. Min.* 1873, 789).

LINARITE. This mineral occurs in the Ortiz mine, Sierra de las Capillitas, Argentine Republic, together with malachite, azurite, cerussite, brochantite, and anglesite (A. Stelzner, *Min. Mitt.* 1873, 249). An analysis by Frenzel (*Jahrb. f. Min.* 1875, 675) gave:

CuO	H_2O	PbSO_4	Sp. gr.
20.22	4.69	74.42 = 99.33	5.06 at 17°.

LINSEED MUCILAGE. See MUCILAGE.

LINSEED OIL. An adulteration of this oil with cod-liver oil may be detected by stirring up 10 grams of it with 3 grams of commercial nitric acid, and leaving the mixture at rest till the oil and acid have separated. Pure linseed oil thus treated exhibits first a sea-green, then a dirty yellow-green colour, while the acid acquires a light yellow colour. If, on the other hand, cod-liver oil is present, the oil becomes dark-brown to black, the acid orange-yellow to yellow-brown (*Dingl. pol. J.* cxv. 284).

On the preparation of Linseed-oil varnish and of Varnish-paper, see E. Thorcy (*Dingl. Pol. J.* cxv. 427; *Jahresb. f. Chem.* 1874, 1197).

* At 100° = 4.4 per cent.

† Stelzner found 5.23 at 16°.

LIQUIDAMBAR. W. L. Harrison (*Arch. Pharm.* [3], vi. 541) obtained from the balsam of *Liquidambar styraciflua*, cinnamene, cinnamic acid, styracine, and a dark-brown, nearly scentless and tasteless resin, easily soluble in alcohol, insoluble in carbon sulphide.

J. M. Maisch (*ibid.* 545) infers from the results of Harrison's investigations that the balsams of *Liquidambar styraciflua* and *L. orientale* are identical, and ascribes their difference of external aspect to the presence of water in the balsam from *L. orientale*. To obtain pure styracine (cinnyl cinnamate, $C^{11}H^{17}O^2.C^9H^9$) and cinnamic acid from the balsam, Maisch recommends extraction with petroleum-ether, whereby a solution is obtained, which deposits a mixture of the two substances, separable by ammonia.

LIQUIDS. *Absorption by Charcoal.*—The absorption of water, alcohol, ether, carbon sulphide, and bromine by charcoal is attended with considerable evolution of heat. 5 to 10 grams of charcoal in contact with a 7 to 9-fold quantity of bromine produced a rise of temperature exceeding 30° . The volatile liquids thus condensed in the pores of the charcoal are only partially expelled, or not at all, at 100° (Melsens, *Compt. rend.* lxxvii. 781).

On the Compressibility of Liquids, see Amagat (*Ann. Chim. Phys.* [5], xi. 520–549; *Jahresb. f. Chem.* 1877. 71).

Capillarity.—G. Quincke, in connection with his former observations on the phenomena of capillarity at the surface of contact of two liquids (vii. 240–243), has investigated the edge-angle at the contact of a liquid and a solid, and the spreading out of liquids on the surface of solid bodies (*Ann. Phys. Chem.* [2], ii. 145–191). The results are stated in the following propositions: (1). The known properties of the surface of contact of two liquids may be extended to that of a liquid and a solid. (2). The contact-surface of a solid 1 and a liquid 2 tends to become as small as possible, or there prevails in it a certain surface-tension, $\alpha_{1,2}$, independent of the geometrical form of the surface, and dependent only on the nature of the substances 1 and 2. (3). The magnitude of the edge-angle of a solid 1 and a liquid 2, both bounded by a liquid 3, is determined by the nature of the three substances, and is independent of the geometrical form of the surface. (4). The main proposition of the theory of capillarity, established by Thomas Young, respecting the constancy of the edge-angle of the free surface of a solid and a fluid is a particular case of the preceding theorem (3), the fluid 3 consisting of the air. (5). The edge-angle may be deduced by calculation from the measurement of the surface of flat drops and bubbles, or measured directly by reflected light. (6). The edge-angle of the free surface of different liquids such as water, alcohol, &c., and of aqueous or alcoholic salt-solutions towards clean surfaces of glass, quartz, or metal, appears to be equal to 0° , the liquids spreading freely on the clean surface of the solid. (7). If the edge-angle, as in most cases, has a greater value, the surface of the solid becomes coated with an imperceptibly thin layer of foreign substance, the edge-angle varying with the thickness of the layer. (8). The thickness of this layer cannot, however, exceed a certain maximum value D, which is equal to or greater than the radius of the sphere of action of the molecular forces. (9). This thin layer adhering to the surface of the solid body may consist either of solid, or of liquid, or of gaseous substance. (10). It may consist of the liquid itself, which is in contact with the solid, and may be recognised, not only by the edge-angle, but also by the so-called 'creeping' of salts, or by the rate of electric conduction on the surface of the solid,—in some cases also by the interference-colours of the light reflected from it. (11). These imperceptibly thin layers of liquid differ in properties according to the mode of their production, and the length of time occupied therein, or according to the nature of the bodies to which they adhere. Quickly formed drops of water spread out on freshly cleaned surfaces of glass more quickly than those which have been slowly formed. (12). These imperceptibly thin films of foreign substance appear also to afford an explanation of the differences between theory and experiment in the estimation of the surface-tension at the common boundary of liquids and solids. (13). If the edge-angle is equal to 0° , or impossible, the liquid spreads out on the surface of the solid body. (14). In liquids which mix together in all proportions, that which has the smaller surface-tension, $\alpha_{1,2}$, displaces that which has the greater surface-tension, $\alpha_{1,3}$. The surface-tension and the possible displacement vary, however, with the nature of the solid substance. (15). The presence of other fluids, and especially of air, may essentially modify the spreading of a liquid on the surface of a solid. (16). The dependence of the edge-angle on the thickness of the imperceptibly thin film on the surface of a solid explains the breath-pictures of Moser (*Pogg. Ann.* lvi. 177; lvii. 1) and Waidele (*ibid.* lix. 255) with water-vapour; the light-pictures of Daguerre with mercury-vapour (*Compt. rend.* ix. 257), and the

electric breath-pictures of G. Karsten (*Pogg. Ann.* lvii. 493) and Riess (*Reibungs-elektricität*, ii. 224), with the vapours of water, mercury, and iodine.

Quincke further observes that a glass surface can never be perfectly cleaned by rubbing it with a linen cloth and alcohol, or by prolonged immersion in alcohol. The best way of proceeding is to treat the glass with hot strong sulphuric acid, then rinse it with distilled water, leave it immersed in water for a long time to remove the last traces of acid, and dry it in the warm current of air over the colourless flame of a Bunsen lamp. It must then be left to cool on a clean clock-glass in a clean glass vessel covered with a glass plate. *Metals* are still more difficult to clean than glass. Noble metals may be ignited in a colourless Bunsen flame and left to cool in clean covered vessels.

The *creeping* or *efflorescence* of salts is commonly attributed to the rise of the solution between the salt already crystallised out and the side of the vessel. The formation of the first crystals, which often takes place on a part of the solid surface at a considerable distance from the liquid, is, however, determined by the imperceptibly thin film of salt-solution which covers the surface of all solid bodies, as metals, glass, quartz, &c. When a portion of the water evaporates, a fresh portion of the salt solution flows in beneath the thin film. The thickness of the film and the quantity of salt solution which thus flows out are greater in proportion to the degree of cleanliness of the solid body. Crystals of the salt form on that part of the surface where the water evaporates most quickly, that is to say at the outer edge of the liquid film. The surface of the solid body often exhibits different degrees of cleanliness on different parts, and then the crystals form first on the cleaner places, and at a greater distance from the flat drop of liquid, than on the less clean parts. If the surface of the solid body is covered with a thin layer of oil, no efflorescence takes place. Since glass surfaces, when exposed to the air, remain clean longer than metal surfaces, salts mostly effloresce on them more readily than on metal surfaces. For the rest, efflorescence or creeping will be most readily exhibited by those salts which, when sufficiently concentrated, still remain mobile—that is to say, the least viscid salts will, under otherwise similar conditions, effloresce with the greatest facility.

Tension and Capillary Constants of Liquid Films.—The following table exhibits the results obtained by Sondhauss (*Pogg. Ann. Ergänzbd.* viii. 266) respecting the tension and capillary constants of liquid films formed in rings of wire. The experiments on the first two liquids were made at the temperature of the air :

	Tension for the space of 1 mm.	Capillarity-con- stant thence deduced	Observed capillary height for 1 mm. radius	Capillarity-con- stant thence deduced
<i>Soap solution :</i>

Obermayer (*Pogg. Ann.* cli. 130) describes the radiate spreading out of strong solutions of aniline-dyes in commercial aniline on water, and finds therein a confirmation of the view advanced by Mensbrugge (*ibid.* cxxxviii. 323; *Jahresb. f. Chem.* 1869, 39) that the tension on the surface of a liquid is diminished by placing on it a

drop of another liquid of inferior surface-tension, which gives rise to a movement of the superficial particles in the direction of those portions where the original tension exists.

On the Forms of Equilibrium of Liquid Masses, see Plateau (*Compt. rend.* lxxviii. 38).

On the Surface-viscosity of Liquids (Plateau, *Institut.* 1873. 22; *Chem. News*, xxvii. 161; *Jahresb. f. Chem.* 1873, 25). On the Vibrations of Liquid Surfaces of Definite Form, &c., Barthélemy (*Ann. Chim. Phys.* [5], i. 100-122).

On the Movements of Camphor and of certain Liquids on the Surface of Water, see Tomlinson (*Pharm. J. Trans.* [3], iv. 654, 672).

On the Diffusion of Saline Solutions, see Johannisjanz (*Ann. Phys. Chem.* [2], ii. 24-47; *Jahresb. f. Chem.* 1877, 80).

Velocity of Efflux from Capillary Tubes.—A. Guerout (*Compt. rend.* lxxix. 1201) has determined the influence of temperature on the rate of capillary efflux. The values for water, given in the following table, show the number of cubic millimeters run out in a second:

Temperature of the water	Coefficient of efflux	Temperature of the water	Coefficient of efflux
10°	3045	16°	3525
11	3110	17	3615
12	3190	18	3703
13	3270	19	3795
14	3350	20	3890
15	3440		

These numbers form a geometric series with the common ratio 1.025; for a solution of potassium sulphate of 10° B. the ratio is 1.026; for potassium carbonate of 43° B. it is 1.046. Considering the rapid decrease of mobility in the molecules of a liquid as the temperature falls, the arrest of circulation in the capillary tissues of the organism in consequence of frost may be due, not to freezing, but to a partial annihilation of mobility.

Guerout (*Compt. rend.* lxxxiii. 1201) has also determined the following efflux coefficients.

Acids.

Formic acid, CH^2O^2	115.0
Acetic " $\text{C}^2\text{H}^3\text{O}^2$	160.5
Propionic " $\text{C}^3\text{H}^4\text{O}^2$	189
Butyric " $\text{C}^4\text{H}^5\text{O}^2$	129.5
Valeric " $\text{C}^5\text{H}^6\text{O}^2$	92.3
Caproic " $\text{C}^6\text{H}^7\text{O}^2$	64.0

Ethers.

Ethyl Formate, $\text{C}^3\text{H}^6\text{O}^2$ 542.0	Methyl Acetate, $\text{C}^3\text{H}^6\text{O}^2$ 534.5
" Acetate, $\text{C}^4\text{H}^8\text{O}^2$ 450.3	Ethyl " $\text{C}^4\text{H}^8\text{O}^2$ 450.3
" Propionate, $\text{C}^5\text{H}^{10}\text{O}^2$ 360.3	Propyl " $\text{C}^5\text{H}^{10}\text{O}^2$ 362.8
" Butyrate, $\text{C}^6\text{H}^{12}\text{O}^2$ 297.0	Butyl " $\text{C}^6\text{H}^{12}\text{O}^2$ 305.3
" Valerate, $\text{C}^7\text{H}^{14}\text{O}^2$ 241.3	Amyl " $\text{C}^7\text{H}^{14}\text{O}^2$ 230.2

For all ethers, the coefficient of capillarity efflux is much greater than for the alcohols and acids from which they are formed. Isomeric ethers exhibit among themselves the same state of fluidity, which however is different from that of the acids which are isomeric with them.

Expansion of Liquids consequent on the Absorption of Gases.—J. Mackenzie and E. Nichols (*Ann. Phys. Chem.* [2], iii. 134) have determined the expansion thus produced, by exactly filling a vessel with the liquid to be examined, connecting it with a second vessel, and passing in the gas till the liquid is completely saturated. The portion which overflows into the second vessel is then weighed, as also that which remains in the first vessel.

The following table gives the average coefficients of expansion for water and carbon dioxide thus determined:

Temperature	Coefficient	Temperature	Coefficient
2°	0·002144	17°	0·001240
6	0·001726	18	0·001280
8	0·001670	22	0·001210
12	0·001450	27	0·001190
14	0·001379	32	0·001010
16	0·001378		

On comparing these results with the coefficients of absorption, as given by Bunsen, it is seen that the expansion is directly proportional to the amount of gas absorbed. The density of the absorbed carbonic anhydride is found to approximate closely to the value given for the liquefied gas by Andrews (*Phil. Mag.* [5], i. 78).

The expansion by heat of water saturated with carbon dioxide was determined in a glass vessel having a narrow glass tube dipping into mercury. The vessel filled with the saturated aqueous solution of the gas was cooled about 2°, and the amount of mercury which passed into the narrow tube was determined. The following table was thus obtained:—

Temperature interval	Average temperature	Coefficient
4·0 — 1·90°	2·95°	0·0000604
5·8 — 3·40	4·6	0·0000610
7·4 — 4·80	6·1	0·0000679
12·15 — 9·85	11·0	0·0000999
12·85 — 11·21	12·03	0·0001130
16·50 — 12·75	14·62	0·0001252
20·60 — 16·4	19·0	0·0001710
23·43 — 20·33	21·88	0·0001811
25·3 — 23·46	22·88	0·0002170
27·55 — 25·0	26·27	0·0002526
29·15 — 26·32	27·73	0·0002923
31·7 — 28·73	30·21	0·0002680

On the Conducting Powers of Liquids for Electricity and Heat, see pp. 723–725 and 1018.

Experiments by Tollinger on the Electric Resistance of solutions of sulphuric acid and various salts to the passage of constant and varying voltaic currents, have yielded results agreeing very nearly with those of Kohlrausch (p. 723), and have shown further that the values obtained with constant and with induction currents do not exhibit any material differences (*Ann. Phys. Chem.* [2], ii. 510; *Chem. Soc. J.* xxxiv. 103).

On Liquids enclosed in Mineral Cavities, see FLUID CAVITIES (p. 793).

Separation of Mixed Liquids.—A homogeneous mixture of two liquids may often be separated into two layers by a slight change of condition, such as a fall of temperature. Whatever may have been the composition of the mixture, that of the two layers thus formed is constant, their relative volume alone varying. The same statement holds good in the case of three liquids where the third is uniformly distributed in both layers.

In certain cases a variation of 0·1° C. will cause separation. For example, a mixture of 15 c.c. of amyl alcohol, 20 c.c. of ethyl alcohol, and 32·9 c.c. of water remains homogeneous at 20°, but with the slightest fall of temperature it divides into two layers, which do not reunite unless shaken up. By varying the quantity of water, the temperature of separation may be varied. Such mixtures may be used for the construction of minimum thermometers. A mixture of 10 parts ether, 6 parts ordinary methyl alcohol, and water, is transparent at low temperatures, but when heated above a certain point, which varies with the quantity of water, it becomes turbid, and resolves itself into two layers. With this liquid, therefore, maximum thermometers may be constructed (Duclaux, *Compt. rend.* lxxxi. 815).

Ebullition of Superimposed Liquids.—According to Gernez (*ibid.* lxxxvi. 472), superimposed liquids having no chemical action upon one another, boil at the

same temperature as that at which the sum of the maximum tensions of their vapours is equal to the pressure. The following are examples :

	Boiling temperature	Sum of the maximum tensions of the two vapours at the boiling temperature	Excess of pressure	Pressure
Carbon bisulphide and water . . .	43·68°	766·64	1·29	765·35
Carbon chloride and water . . .	66·17	747·36	1·91	745·45
Benzene and water	69·43	765·92	1·48	764·44

On the Distillation of Liquids not miscible with Water in a Current of Steam, see Naumann, p. 948 of this Volume.

An Apparatus for Measuring the Heat of Vaporisation of Liquids is described by Berthelot (*Compt. rend.* lxxxv. 646); and an Apparatus for Measuring the Heat evolved in the Compression of Liquids, by Favre a. Laurent (*Ann. Chim. Phys.* [5], i. 433).

LITHIA-PSILOMELANE and **LITHIOPHORITE**. See MANGANESE OXIDES.

LITHIUM. *Occurrence.*—This element has been found in nearly all the members of the Upper and Lower Muschelkalk in the neighbourhood of Würzburg; also in the Loess of Geisnidda in Upper Hesse, a river-deposit 20 to 30 feet thick on the edge of the Nidda Valley. The portion of this deposit which is insoluble in hydrochloric acid contains 0·007 per cent. of lithia (Hilger, *Deut. Chem. Ges. Ber.* viii. 335; *Landw.-Versuchs-Stationen*, xviii. 166).

According to Truchot (*Compt. rend.* lxxviii. 1022), the soil of Limagne in Auvergne is very rich in lithium, 100 grams of it containing from 31 to 132 milligrams of lithium carbonate. The lithium passes into nearly all the plants growing on this soil, even rape and marigolds containing it. Contrary to the statement of Grandean (*Jahresb. f. Chem.* 1872, 234) 100 grams of the ashes of these plants were found by Truchot to contain 10 mgm. lithium chloride; 100 grams of tobacco ash yielded 440 mgm. of the same salt. Several mineral waters of Auvergne were also found to contain lithium, viz.—

Name of Water	Lith in 1 litre	Name of Water	Lith in 1 litre
Mont Dore	8 mg.	La Bourboule	18 mg.
Royat, source César	9	Sainte-Nectaire	22
Clermont:		Chatel-Guyon	28
Source des Salins	14	Saint-Alyre	31
Source de Jaude	15	Les Roches	33
Source de Loiselot	18	Chateaufort	35
Artesian Well	20	Royat, source de l'établissement	35

According to Fresenius (*J. pr. Chem.* [2], xvi. 278), the warm spring of Asmannshausen in Nassau contains 0·01746 pt. per thousand of normal lithium carbonate, Li²CO³.

S. de Luca (*Compt. rend.* lxxxvii. 171) has detected lithia in the trachytic earth and the water of the Solfatara at Pozzuoli.

L. Dieulafoy (*Ann. Chim. Phys.* [5], xvi. 377) has shown that lithium is much more widely diffused in nature than has hitherto been supposed. He has found it in sea-water from all parts of the globe, in quantity sufficient to be easily recognisable by the spectroscope in the residue obtained by evaporating less than a cubic centimeter of the water; in larger quantity in the water and the mud of salt marshes; in salt springs, and in mineral waters belonging to the primary rocks; further in these rocks themselves (granite, syenite, gneiss); and in gypsums both of the secondary and tertiary formations—not however in the crystals of pure calcium sulphate, but in the marls which accompany them. The general conclusion is that lithia is as widely diffused as potash and soda, and is found accompanying them in rocks of all ages, in sea water and in mineral waters.

Preparation.—The following method of preparing lithium-salts on the large scale from lepidolite, as practised at Schering's works in Berlin, is described by Pilsinger (*Dingl. pol. J.* cexix. 183; cexxii. 321, 385). The finely ground and sifted mineral is stirred up to a thin paste with strong sulphuric acid in a warm brick trough, and digested, with gentle stirring till it forms into lumps, which are then calcined in a

reverberatory furnace and thoroughly lixiviated with water while still warm. The lye thus obtained is mixed with a quantity of potassium carbonate sufficient to convert all the alumina into alum; the alum-meal which separates on boiling is removed; and the small remaining quantity of alumina is precipitated by milk of lime. All the lyes are then united; the salts are converted into chlorides by precipitation with barium chloride; the liquid is evaporated to dryness; the chlorides of lithium and calcium are extracted with absolute alcohol; the alcohol is distilled off; the calcium precipitated with ammonium oxalate; any heavy metals that may be present are precipitated by a small quantity of ammonium sulphide; and the lithium chloride, which is now quite pure, is evaporated in a large silver vessel. The solution of this salt, treated with ammonia and ammonium carbonate, yields lithium carbonate in the form of a very light precipitate which may be freed from chlorides by washing with alcohol of 60 per cent. (see also Petersen, *Dingl. pol. J.* cccxiv. 176; *Jahresb. f. Chem.* 1877, 1153; *Chem. Soc. J.* xxxii. 706).

On the Spectroscopic Estimation of Lithium, see Truchot (*Compt. rend.* lxxviii. 1022) and Ballmann (*Zeitsch. anal. Chem.* 1875, 297).

Borates. Filsinger (*Arch. Pharm.* [3], viii. 198) has examined the following borates of lithium: $\text{Li}_2\text{O} \cdot 2\text{B}^2\text{O}_3 + 5\text{H}^2\text{O}$, $\text{Li}_2\text{O} \cdot 3\text{B}^2\text{O}_3 + 6\text{H}^2\text{O}$, and $\text{Li}_2\text{O} \cdot 4\text{B}^2\text{O}_3 + 10\text{H}^2\text{O}$. The first two of these salts are formed on dissolving lithium carbonate in aqueous boric acid, the former with excess of the carbonate, the latter with excess of boric acid. The third salt is produced by boiling lithium acetate with boric acid for some time, and repeatedly evaporating the solution to a syrupy consistence till all excess of acetic acid is driven off. All three are easily soluble in water, but insoluble in alcohol. The first two do not crystallise, but dry up to gummy masses, which, however crumble to granular powders after prolonged treatment with alcohol. The third salt separates, after prolonged standing, in white hard crystalline crusts.

On Sulphate and Pyrophosphates of Lithium, see the respective Acids.

LITHOFRACTEUR. See EXPLOSIVES (p. 766).

LITHOSPERMUM. The ash of the seeds of gromwell (*Lithospermum officinale*) has been analysed by L. Hornberger (*Liebig's Annalen*, clxxvi. 85). The seeds yielded 41.47 per cent. ash, which, after deduction of charcoal and CO_2 , gave in 100 parts:

CaO	MgO	K ² O	Na ² O	Fe ² O ³	SO ³	P ² O ⁵	SiO ²
59.01	3.15	6.17	0.77	0.28	0.77	2.17	27.68 = 100

LIVER. On Chemical Changes in the Liver, see C. Flügge (*Zeitschr. f. Biologie*, xiii. 133–171; *Chem. Soc. J.* xxxiv. 160).

On the Formation of Glycogen in the Liver, and its Conversion into Glucose, see GLYCOGEN (p. 877); further, Cl. Bernhard (*Compt. rend.* lxxxii. 114, 173, 777, 1351, 1405; lxxxiii. 369, 407; lxxxiv. 1201; lxxxv. 519; *Ann. Chim. Phys.* [5], viii. 367; ix. 207; xi. 256; xii. 397; *Jahresb. f. Chem.* 1876, 922; 1877, 980; *Chem. Soc. J.* xxxiv. 82).

On the Estimation of Glycogen in the Liver, see G. Salomon (*Zeitschr. anal. Chem.* 1874, 470; *Jahresb. f. Chem.* 1874, 1051).

On Liver-ferment, see FERMENTS (p. 780).

LOLLINGITE. This mineral occurs at Mont Challanches in Dauphiné, massive, and in small crystals only $\frac{1}{2}$ mm. long, and of the form $\infty P \cdot \frac{1}{2}P \infty$. An analysis of the massive portion gave:

Fe	Co	As	Sb	S	Sp. gr.
21.22	6.44	63.66	5.61	3.66 = 100.59	6.34 at 16°

leading to the formula FeAs_2 . Measurements of the crystals by Schrauf gave, as mean values, $\infty P : \infty P = 113^\circ 40'$; $\frac{1}{2}P \infty : \frac{1}{2}P \infty = 133^\circ 50'$; $\frac{1}{2}P \infty : \infty P = 77^\circ 25'$, whence the axial ratio is $a : b : c = 1.535 : 1 : 1.970$, which agrees nearly with that given by Dana for mispickel, viz. 1.4793 : 1 : 1.7588.

LOPHINE, $\text{C}^{10}\text{H}^{16}\text{N}^2$. This compound is the chief product formed by the decomposition of nitroso-amarine at 149° – 150° (p. 70). Its formation by the dry distillation of hydrobenzamide in presence of air is accompanied by evolution of light (p. 1063).

LORANTHUS. K. Martins (*N. Rep. Pharm.* xxiv. 687) finds, from examination of several branches of *Acacia Verek*, on which gummy exudations had formed, that these exudations are produced by a parasite which he designates as *Loranthus senegalensis*.

LOTUR BARK (O. Hesse, *Deut. Chem. Ges. Ber.* xi. 1542–1546). This bark, from *Symplocos racemosa*, contains three alkaloids, viz.: *loturine*, 0.24 per cent.; *colloturine*,

0.02; and *loturidine*, 0.06 per cent. The alkaloids are extracted from the bark by hot alcohol, and are converted into acetates. Loturine and colloturine are precipitated from the neutral solution by the addition of potassium thiocyanate, leaving the loturidine in solution. The crystalline precipitate is decomposed by soda, and the alkaloids are extracted with ether and recrystallised from alcohol. The efflorescent crystals of loturine are separated mechanically from the non-efflorescent crystals of colloturine.

Loturine is soluble in alcohol, ether, chloroform, and acetone, but insoluble in water, ammonia, and caustic soda. It gives no coloration with ferric chlorido, with strong sulphuric or nitric acid, or on the addition of bleaching powder and ammonia to its alcoholic solution acidulated with hydrochloric acid. Loturine melts at 234° , and sublimes, forming colourless prisms. A solution of loturine in dilute acids exhibits a fluorescence brighter than that of quinine sulphate. Loturine forms well-crystallised salts. The hydrochloride, which crystallises in white prisms soluble in alcohol and in water, forms double salts with the chlorides of platinum, gold, and mercury. The hydriodide forms a crystalline double salt with mercuric iodide. The nitrate, thiocyanate, acetate, chromate, and picrate are crystalline compounds. The tannate and phosphotungstate are amorphous powders.

Colloturine is deposited from alcohol in prisms terminating in pyramids, which sublime at 234° . The solution of the alkaloid in dilute sulphuric or hydrochloric acid is fluorescent. Gold chloride produces a yellow amorphous precipitate in the solution of the hydrochloride.

Loturidine.—The filtrate from the thiocyanates of loturine and colloturine is rendered alkaline by ammonia, and the loturidine extracted with ether. Loturidine is a yellowish-brown amorphous body yielding amorphous salts. It dissolves in strong nitric and sulphuric acids, forming yellow solutions. The solution in dilute acids is fluorescent.

Winckler's *californine* (i. 722) was not a simple substance, but a mixture of the acetates of these three alkaloids.

LOXOCLASE. A soda-felspar with orthoclasic cleavage, and therefore resembling Breithaupt's loxoclase (iii. 735), has been examined by Ch. Vélain (*Compt. rend.* lxxix. 250). It occurs, with angite and epidote, in the slags and tufas of the island of Rachgouin, Algeria, and, like the angite, exhibits all the signs of derivation from the older rocks by whose decomposition the tufas have been formed. The mean of three analyses gave:

SiO ²	Al ² O ³	CaO	Na ² O	K ² O	MgO	Sp. gr.
66.72	19.73	2.20	7.63	3.71	0.10 = 100.09	2.58

LUDLAMITE. A hydrated basic ferrous phosphate, found in Cornwall, associated with quartz, chalybite, vivianite, iron pyrites, and mispickel. Hardness = 3.4; sp. gr. = 3.12. Colour, clear green, from pale to dark, transparent and brilliant. Streak very pale green, approaching to white. It tinges the flame of the blowpipe slightly green, and yields a semi-fused blackish residue. It is soluble in dilute mineral acids, and is readily decomposed by boiling with a solution of caustic alkali. Analysis gave as follows:—

Fe	P ² O ⁵	H ² O
52.76	30.11	16.98 = 99.85

These numbers correspond very closely with the formula $7\text{FeO} \cdot 2\text{P}^2\text{O}_5 \cdot 9\text{H}^2\text{O}$. The mineral differs from vivianite, $(3\text{FeO} \cdot \text{P}^2\text{O}_5 \cdot 8\text{H}^2\text{O})$, in the fact that it decrepitates violently when heated, and breaks up into brilliant crystalline plates of a deep bluish-green colour. Vivianite, on the contrary, does not decrepitate, but gradually exfoliates and turns white (F. Field, *Phil. Mag.* [5], iii. 52).

Ludlamite is monoclinic, with the axial ratio $a : b : c = 0.4439 : 1 : 0.8798$. Angle $a c = 79^{\circ} 27'$. Observed faces, $\pm P$, $-\frac{1}{2}P$, ∞P , $0P$, $\infty P \infty$, $+P \infty$, $+2P \infty$, $R \infty$. Cleavage distinct parallel to $0P$. The crystals are optically positive, the optic axes lying in the plane of symmetry. Acute bisectrix = $88^{\circ} 54'$. Dispersion inconceivable; $p > v$ (Maskelyne, *ibid.* iii. 54, 135, 525).

LUDWIGITE. This mineral, from the Banat, is parallel-fibred and mostly short-fibred. Sp. gr. = 3.907 to 4.016. Hardness = 2. Tough, difficult to split. Colour blackish-green to black. Lustre silky. Streak powder blackish-green. Thin splinters melt with difficulty to a black magnetic slag. Dilute hydrochloric acid dissolves the powder very quickly. Its composition, according to E. Ludwig, is:

B ² O ³	Fe ² O ³	FeO	MgO
16.09	39.92	12.46	31.69 = 100.16
15.06	39.29	17.67	26.91 = 98.93

whence may be deduced the formula $3\text{MgO} \cdot \text{B}^2\text{O}^3 + \text{FeO} \cdot \text{Fe}^2\text{O}^3$, representing it as a molecular compound of normal magnesium borate and ferroso-ferric oxide.

Ludwigite occurs in the southern part of the mining district of Morawitz, and on the western outcrop of the limestone, associated with a very compact magnetic iron-ore imbedded in the crystalline limestone, in the neighbourhood of a cleft traversing that formation. The ludwigite occurs only in isolated lumps in the magnetic iron ore, which often traverses it in thin threads (G. Tchernak, *Liebig's Annalen*, clxxiv. 112).

A decomposition-product of the blackish-green variety of this mineral has been examined by F. Berwerth (*Min. Mitth.* 1874, 247). Sp. gr. = 3.41. Mineralogical examination shows that it is a mixture of brown iron-ore, talc, brucite, magnesite, and calcite, and this result is confirmed by the direct chemical analysis of the product, as appears from the following comparison:

	Fe^2O^3	CaO	MgO	CO^2	SiO^2	H^2O	B^2O^3	
Brown iron-ore	75.44	—	—	—	—	12.73	—	= 88.17
Talc	—	—	1.44	—	2.88	0.22	—	= 4.54
Brucite	—	—	3.08	—	—	1.39	—	= 4.47
Magnesite	—	—	1.40	1.54	—	—	—	= 2.94
Calcite	—	0.09	—	0.07	—	—	—	= 0.16
Totals	75.44	0.09	5.92	1.61	2.88	14.34	—	= 100.28
Direct analysis	75.34	0.09	5.80	1.65	2.83	14.51	0.80	= 101.02

LUPINE. The transformations of substance which take place during the germination of lupine-seeds have been examined by Schulze, Umlauf, a. Ulrich (*Deut. Chem. Ges. Ber.* ix. 1314). Out of the 45 per cent. of albuminoids (conglutin and albumin) contained in the ungerminated seeds, there remained, after fifteen days' germination in the dark, only 8 per cent., the remaining 37 per cent. having been decomposed. The chief nitrogenous decomposition-product was asparagine, besides which there were formed small quantities of other amides not isolated, and a very small quantity of ammonia. The sulphur of the decomposed albuminoids appeared to be converted into sulphuric acid, as the proportion of sulphates in the sprouts increased considerably. No separation of non-nitrogenous substances in the decomposed albuminoids was observed to take place.

LUPULINE. This name is given by Griessmayer to a base obtained by distilling the aqueous extract of hops with lime or magnesia (p. 1040).

LUTECOBALT COMPOUNDS. See COBALT-BASES (p. 546). On the crystalline form of the Chloride, vii. 365.

LUTIDINE. See PICOLINE-BASES.

LUZONITE. See ENARGITE (p. 733).

LYCINE. The base from *Lycium barbarum*, to which this name was applied by Husemann a. Marmé (iii. 738), has been shown by later researches of Husemann to be identical with betaine (p. 323).

LYCOPERDON. The substance called 'Indian Bread,' sometimes used as food by the North American Indians, consists of a parasitic fungus (*Lycoperdon solidum*) found growing in tuberose masses, weighing from an ounce to several pounds, on the roots of coniferous trees. Its surface is ash-grey and wrinkled, while the inside is nearly white and has the appearance of starch. The same substance is found in China and Japan, where it is called respectively 'Fuhling' and 'Tucka-hoe.'

The following analyses made by Braun in 1871 and by Keller in 1876 (*Chem. News*, xxiv. 168, 881) show that the composition of this fungus is subject to great variations, due, according to W. Mallet, to the penetration of the roots of the tree by the mycelium of the fungus, which converts the woody fibre of the roots into its own substance. In the specimen analysed by Braun, this process appears to have been only in its incipient stage, whereas in that analysed by Keller, it must have been nearly complete:

	Braun	Keller
Water	14.16	10.70
Glucose	0.93	0.87
Gum	2.60	2.98
Pectose	17.34	77.27
Woody Fibre	64.45	3.76
Nitrogen in insoluble combination	0.36	—
Proteids	—	0.78
Mineral substances:		
Soluble in Water }		{ 0.08
Insoluble in Water }	0.16	{ 3.56

The ash analysed by Keller was found to contain:

K ₂ O	Na ₂ O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ²	Cl	SiO ²	
4.675	2.192	5.169	11.375	11.808	19.781	1.587	1.642	41.771	= 100.000
Deduct O for Cl								.	0.370
									99.63

LYCOPODIUM. The following analyses of club-mosses are by G. W. Hawes (*Sill. Am. J.* [3], vii. 585):

	C	H	O	N	Ash
<i>Lycopodium dendroideum</i>	47.11	6.39	41.85	1.40	3.25 p. c.
"	47.29	6.43	41.62	1.38	3.28 "
" <i>complanatum</i>	45.78	6.25	40.66	1.84	5.47 "
"	45.62	6.26	40.79	1.84	5.49 "

M

MACLURIN, MORIN, and MORINTANNIC ACID. These three constituents of fustic have been examined by J. Löwe (*Zeitschr. anal. Chem.* 1875, 117). They contain a common nucleus with 15 at. carbon. The amount of water in crystallised morin differs accordingly as it is crystallised from hot water or from alcohol. Löwe's analyses lead to the following formulæ:

Morin dried at 100°	C ¹⁵ H ¹⁰ O ⁷
" precipitated by water from alcoholic solution	C ¹⁵ H ¹⁰ (O) ⁷ + H ² O
" recrystallised from water	C ¹⁵ H ¹⁰ (O) ⁷ + 2H ² O
Egg-yellow Lead-compound of Morin	C ¹⁵ H ¹² O ⁸ + PbO
Orange-yellow "	C ¹⁵ H ¹⁰ (O) ⁷ .2PbO

Maclurin dried over sulphuric acid has the composition C¹⁵H¹²O⁸; it gives off water at 120°–130°, leaving C¹⁵H¹⁰O⁷. Its alcoholic solution yields with lead acetate a precipitate having the composition C¹⁵H¹⁰O⁷.3PbO. Aqueous solutions of maclurin are precipitated by alkaloids, gelatin-solution, and albumin.

Morintannic acid, C¹⁵H¹²O⁷, forms a lead compound having the composition 2C¹⁵H¹²O⁷.5PbO. It differs from maclurin by containing 1 at. oxygen less.

MACONITE. A mineral from Macon County, North Carolina, where it is found accompanying corundum (p. 570).

MACROCHORDION. See BROMELIACEÆ (p. 350).

MAGNESIA-MICA. See MICA.

MAGNESITE. The crystallised magnesites of the north-eastern Alps have been examined by J. Rumpf (*Jahrb. f. Min.* 1874, 540).

1. Beautiful small crystals of this mineral occur at Mariazell, in Styria. They exhibit the combination 0R.∞P2, have a length of 1.6 mm., and are sometimes transparent and colourless, more often yellowish-brown. Sp. gr. = 3.038. Analysed by Rumpf.

2. A second locality is an iron mine near Flachau, in Salzburg. Light grey crystals, likewise exhibiting the combination 0R.∞P2. Sp. gr. = 3.015. Analysed by K. Sommers.

3. Remarkable is the occurrence of lenticular magnesite crystals in the block-shaped masses of magnesite lying between clay-slates. These crystals are known in Styria by the name of pinestone (*Pinolistein*, probably from the resemblance of their section to that of the fruit of *Pinus pinca*). Rumpf proposes to designate the magnesite rock as *Pinolite*. It consists mainly of crystalline milk-white magnesite and clay-slate, which, however, is in some parts replaced by talc-slate. The magnesite crystals have the appearance of flat lentils abundantly disseminated through the clay-slate in variously shaped bundles and tufts. The principal localities are the mountain-gorge of the Sund (a) and Wald (b), in Styria, and the Semmering in Lower Austria. Analyses of magnesites from the two first-named localities have been made by Fr. Ullik.

	MgO	CaO	Fe ² O ³	FeO	MnO	CO ²	H ² O	Insoluble
(1)	45.32	1.58	—	2.12	—	50.90	0.36	0.34 = 100.62
(2)	44.53	0.65	3.62	—	0.28	49.67	0.61	0.58 = 99.94
(3, a)	45.60	1.01	—	1.74	—	51.87	—	0.25 = 100.47
(3, b)	45.55	0.86	—	1.62	—	51.62	—	0.47 = 100.12

MAGNESIUM. Experiments on the action of metallic magnesium on various metallic salts have been made by S. Kern (*Chem. News*, xxxii, 309; xxxii, 112, 236). Concentrated solutions were used and left in contact with magnesium ribbon for 30–40 hours. The experiments show that most metallic salts are converted by the action of magnesium into oxides or hydroxides.

Cobalt chloride is decomposed, with evolution of hydrogen and deposition of a green substance containing cobalt oxide. With *silver nitrate* a precipitate of silver oxide is obtained. In a solution of *lead nitrate*, the magnesium quickly becomes covered with metallic lead in the form of a very fine powder, which is soon converted into $\text{Pb}(\text{OH})_2$. *Strontium salts* require much more time to decompose them. Concentrated strontium chloride solution, in contact with magnesium for two days, gives a white precipitate of strontium hydroxide:

Mercuric chloride with magnesium gives a greyish precipitate, which turns red when ignited. This precipitate is a third form of mercuric oxide, which had hitherto been known only as a red or yellow precipitate. *Platinic chloride* with magnesium evolves hydrogen. After about 20–25 hours a black precipitate of metallic platinum is formed. On leaving it in contact with water, brown $\text{Pt}(\text{OH})_4$ is obtained. *Ferric chloride* is rapidly converted into ferric hydrate:

With *zinc salts* magnesium eliminates hydrogen very slowly; with zinc chloride after 48 hours a small amount of hydroxide was formed. In a solution of *sodium chloride* magnesium also eliminates hydrogen very slowly, sodium hydroxide being formed, which quickly turns red-litmus paper blue. *Manganous chloride* yields manganous oxide, rapidly oxidised to manganoso-manganic oxide, Mn^2O^4 . *Uranic nitrate* yields uranic oxide. *Potassium dichromate* is but slowly attacked, with formation of magnesium dichromate and potassium hydroxide. *Aluminium salts* are very slowly attacked, with formation of aluminium hydroxide. From a *palladium solution* magnesium eliminates hydrogen, forming palladium monoxide, together with a small quantity of metallic palladium which unites with the hydrogen, forming Pd^2H . In a solution of *copper*, the magnesium quickly becomes coated with metallic copper. A solution of *sal-ammoniac* is decomposed by magnesium, with rapid evolution of hydrogen.

Detection and Estimation.—A delicate spectroscopic reaction for magnesia and for alumina is afforded by the absorption-spectrum of a solution of purpurin mixed with one or other of these bodies. A dilute aqueous solution of pure purpurin shows a weak absorption in the yellow, and a stronger in the green, between F and b. This absorption becomes more intense when ammonia is added, and disappears on adding dilute acetic acid, a faint absorption in the blue alone remaining. But when to a very dilute aqueous solution of purpurin a dilute solution of alum is added, the liquid becomes red, and gives two strong absorption bands between D and E and b and F. This reaction, which is also produced by other aluminium salts, is best seen in a very weak alkaline solution; it is weakened but not destroyed by acetic acid.

Magnesium salts give the same bands, only that in the yellow is stronger than the other, but the least excess of acetic acid destroys the spectrum. The least traces of magnesium and aluminium can be detected by this reaction, which is not shown by the salts of iron, manganese, zinc, the alkali-metals, or those of the alkaline earths; it does not appear when salts of iron or zinc are present in excess (H. W. Vogel, *Deut. Chem. Ges. Ber.* ix. 1641).

For the precipitation of magnesia as ammonio-magnesium phosphate, F. Mohr (*Zeitschr. anal. Chem.* 1873, 36) recommends the use of ammonio-sodium phosphate, by which the magnesium is thrown down at once as crystalline ammonio-magnesium phosphate. The same method is recommended by W. Gibbs (*Chem. News*, xxviii. 51) with the addition that the precipitation with phosphorus-salt should be performed in a hot concentrated solution, and ammonia added only after cooling.

On the estimation of magnesia in a mixture of alkaline and earthy sulphates, see SULPHATES.

Separation from Calcium.—Sonstadt (*Chem. News*, xxix. 209) employs for this purpose a concentrated solution of *potassium iodate*, which throws down the calcium as iodate without perceptibly redissolving it, but does not precipitate magnesium salts, and has the further advantage of not interfering with the subsequent precipitation of the magnesium by ammonio-sodium phosphate, the resulting precipitate of ammonio-magnesium phosphate being, on the other hand, less soluble in the liquid containing the calcium iodate, than in dilute ammonia. Sonstadt regards this method of separation as much more effective than the ordinary method with ammonium

oxalate, inasmuch as when the latter is employed, not only is a small portion of magnesia thrown down with the lime, but the presence of the magnesium salts likewise interferes with the complete precipitation of the calcium as oxalate.

Magnesium chloride. A hydrated chloride of magnesium, $\text{MgCl}^2 \cdot 6\text{H}^2\text{O}$, named *Bischofite*, is found, together with carnallite, in cavities and as a crust on rock-salt in the Stassfurth mines. The crystals of bischofite often contain microscopic crystals of sodium chloride, and may be distinguished from carnallite by the fact that they are very deliquescent, harden on exposure to a temperature of $40^\circ\text{--}45^\circ$, but deliquesce when the temperature falls: this property is not possessed by carnallite. They are transparent or white and more or less opaque. Hardness 1.7. Sp. gr. 1.65. When heated, they give off water and hydrochloric acid, and leave a residue of oxychloride.

Oxychloride.—Bender, by mixing calcined magnesia with a strong solution of magnesium chloride, and leaving it exposed to the air for six months, obtained a pasty mass which he regarded as a mixture of the oxychloride, $\text{MgCl}^2 \cdot 5\text{MgO} \cdot 17\text{H}^2\text{O}$, with normal magnesium carbonate (vii. 759). It is, however, by no means certain that magnesia is completely converted into normal carbonate by exposure to the air, and moreover, an oxychloride differing in composition from Bender's salt is obtained by mixing freshly calcined magnesia (30 grams) with solution of magnesium chloride (1500 grams) in a flask well corked and nearly filled with the mixture, and heating it in a water-bath, with frequent agitation, till the liquid when examined under the microscope exhibits nothing but needle-shaped crystals. These crystals, when washed with water, and dried at 110° , were found to consist of $\text{MgCl}^2 \cdot 10\text{MgO} + 14\text{H}^2\text{O}$, and when dried over soda, of $\text{MgCl}^2 \cdot 10\text{MgO} + 18\text{H}^2\text{O}$. When dry they withstand the action of carbonic acid, but are completely decomposed by it when moist. The pasty mass obtained by kneading magnesia with solution of magnesium chloride, is a mixture of the 18 mol. hydrate with basic magnesium carbonate (O. Krause, *Liebigs Annalen*, clxv. 38).

Nitride, Mg^3N^2 . Briegleb and Geuther obtained this compound as a greenish-yellow amorphous mass by passing ammonia or nitrogen gas over strongly heated magnesium (iii. 754); and J. W. Mallet (*Chem. News*, xxxviii. 39) has lately observed the formation of the same substance in large quantity by the simple combustion of magnesium with limited access of air. The chief part of the metal burned is, of course, converted into oxide, and the temperature produced by the combustion is high enough to induce the remainder, when the supply of oxygen is limited, to unite with nitrogen.

The following three experiments show the largest absorption of nitrogen:

	Mg. used grms.	NH^3 obtained grms.	Equiv. Mg^3N^2 grms.	Equiv. Mg. grms.	Mg. converted into nitride per 100 pts. used
No. 1 . . .	2.635	0.292	0.859	0.618	23.5
No. 2 . . .	2.204	0.286	0.841	0.606	27.5
No. 3 . . .	3.117	0.365	0.773	0.773	24.8

Aluminate, $\text{MgO} \cdot \text{Al}^2\text{O}^3$. This compound may be obtained in the crystalline state by packing 25.5 grams of pure and freshly ignited magnesia in a crucible of hard carbon, imbedding in the centre a lump of aluminium containing 8 grams of the pure metal, and raising the whole to a very high temperature. After cooling, the whole of the aluminium, the magnesia, and the crucible were separately treated with moderately strong, hot, hydrochloric acid, and the solutions filtered. The greyish residue left on the filters from the first two solutions was dried, ignited in a stream of oxygen to burn off some specks of carbon, and on being examined with the microscope was found to consist of minute, colourless, transparent crystals of two kinds: the one being thin elongated scales, consisting of pure alumina; the other of regular octahedrons, which scratched glass readily, and on fusion with acid sodium sulphate yielded magnesia 28.99 per cent., and alumina 70.81 per cent., giving the ratio, $\text{MgO} : \text{Al}^2\text{O}^3 = 725 : 689$, and showing that these crystals consisted of artificial spinelle, MgAl^2O^4 .

Magnesium-alum, $\text{MgAl}^2(\text{SO}^4)^2 \cdot 24\text{H}^2\text{O}$ (v. 583), has been found in luminous crystalline masses, and occasionally in long-fibred bundles, on the island of Negros, Philippine group. When recrystallised it formed small crystals exhibiting the combination $\text{O} \cdot \infty \text{O} \cdot \infty$. Analysis gave:

SO^3	Al^2O^3	MgO	CaO	H^2O
37.76	32.60	3.52	0.91	45.21 = 100

(Frenzel, *Min. Mitth.* 1877, 303).

MAGNETIC IRON ORE. MAGNETITE. This mineral, occurring with amethyst veins in the trapp of Annapolis County, Nova Scotia, has been analysed by H. How (*Phil. Mag.* [5], i. 136).

Quartz	MgO ⁽¹⁾	O ⁽²⁾	Fe
5.46	1.27	24.94	68.33 = 100
4.94	4.84	25.19	65.03 = 100

⁽¹⁾ With traces of CaO.

⁽²⁾ Determined by difference.

J. Strüver (*Zeitschr. f. Kryst.* i. 230) has described the magnetite of the Alban mountains (ancient Latium), where it occurs, partly as a constituent of the lavas, partly in geodes, partly in loose crystals in ashes and tufas, and in the sands of streams and lakes. The forms observed were O, ∞ O ∞ , ∞ O, 2O2, 3O3, ∞ O3, 5O $\frac{5}{2}$, of which the fourth and sixth are new for magnetic iron oxide. Older authorities assign to the magnetic iron ore of this locality a very large amount of titanium; Struve however found only traces.

Fine crystals of magnetite are found at Mulatto, implanted on a solid mass of the mineral and exhibiting the faces ∞ O, 5O $\frac{5}{2}$, 3O3, O (Doelter, *Jahrb. f. Min.* 1877, 647).

A. Knop (*Zeitschr. f. Kryst.* i. 64) has analysed a titaniferous magnetic iron oxide from enclosures in the Sanidin-Hayn-Phonolite from Horberig near Oberbergen in the Kaiserstuhl range, with the following results:

Fe ² O ³	TiO ²	Al ² O ³	MgO	MnO
88.41	4.08	6.85	4.57	trace = 103.91

These values correspond with the following:

Fe ² O ³	Fe(Fe, Ti) ² O ³	MgAl ² O ³	MgFe ² O ³
69.84	11.42	9.54	9.40 = 100.20

J. R. Müller (*Zeitschr. f. Kryst.* i. 512) has analysed the magnetic iron ore from the Kaschberg in Bohemia, consisting of mixtures of augite and magnetite, which latter can be very accurately separated by the magnet:

Fe ² O ³	Al ² O ³	FeO	CaO	SiO ²
61.14	0.4815	32.2164	3.507	1.0655 = 98.4104

Magnetic iron sand has lately been found in a granite vein accompanied by an excess of mica, at Grotta d'Oggi, near San Piero, Elba. The upper part of the magnetic iron deposit is partially decomposed, and contains numerous black magnetite crystals some of which exhibit a bronze-like tarnish. The crystals, which are octahedrons or rhombic dodecahedrons, or combinations of the two, have a diameter of from $\frac{1}{2}$ to 1 centimeter, and are strongly polar-magnetic. Lower down in the vein-stone the magnetite crystals increase in size, but are less freely crystallised. Magnetite also occurs in the green diorite slate, at Caviere, near San Piero, but it is not so strongly magnetic as that found in the granite, and not crystallised (G. Roster, *Jahrb. f. Min.* 1877, 531).

Allotropic Varieties of Magnetic Iron Oxide.—This oxide, when obtained by heating ferric oxide for some hours in hydrogen gas or carbonic oxide at 350°–440°, or by heating the hydrate of the magnetic oxide at 300° in an indifferent gas, or by calcining pyrophoric ferrous oxide at a low red heat, passes into ferric oxide by calcination in the air, and is attacked by concentrated nitric acid. Its density is 4.86. Magnetic oxide obtained at a high temperature by burning iron in oxygen, or by decomposing the sesquioxide at a bright red heat, has a density of 5 to 5.09, and does not possess those properties. Pyrophoric ferrous oxide is transformed when heated in the air into ferric oxide, but if this substance be heated to dull redness in carbonic acid gas, magnetic oxide is obtained identical with the first variety mentioned above. If this variety be heated intensely in nitrogen, the second kind, namely, that which is incapable of taking up more oxygen, is obtained (H. Moissan, *Compt. rend.* lxxxvi. 600).

MAGNETIC PYRITES. The following are recent analyses of this mineral: (1). From Elizabeth Town, Canada, by J. Lawrence Smith (*Compt. rend.* lxxxi. 976). (2). From the same locality, by Lindström (*Deut. Chem. Ges. Ber.* ix. 858). (3). From Todtmoos in the Schwarzwald, by A. Hilger (*Liebig's Annalen*, clxxxv. 208):

Fe	Cu	Mn	Ni	Co	S	SiO ²	X	Sp. gr.
59.88	—	—	—	—	39.24	—	1.01 = 100.13	4.642
60.56	0.145	0.06	0.112	0.111	39.02	0.036	— = 100.044	4.622
50.58	0.54	—	1.82	0.48	40.46	—	— = 99.88	4.12–4.2

The proportions of iron and sulphur in these analyses agree most nearly with the

formula $\text{Fe}^{\frac{2}{3}}\text{S}$, which requires 60.5 Fe and 39.5 S. The formula FeS requires 63.6 Fe and 36.4 S.

The crystals from Elizabeth Town are composite, three individuals of the combination $\frac{2}{3}\text{P}$. 0P, being grown together in the direction of the faces of the pyramid P, whereby the axes of the individual crystals are set perpendicularly to each other (E. S. Dana, *Sill. Am. J.* [3], xi. 386). Crystallised magnetic pyrites from Bottino in Italy exhibits the faces P (?), 0P, ∞ P, 2P, 6P (Grattarola a. d'Achiardi, *Zeitschr. f. Krystallographie*, i. 526).

MAGNETISM. *Relationship of the Magnetic Metals.*—The following table, exhibiting the physical resemblances between the magnetic metals, iron, cobalt, and nickel, has been drawn up by W. F. Barrett (*Phil. Mag.* [4], xlvii. 478):

Substance	Density	Atomic weight	Specific heat	Atomic heat	Dilatation		Conductivity	
					By heat	By strain	For heat	For sound
Iron . .	7.8	56.0	0.1138	6.38	.0926	.0387	.168	15.3
Nickel .	8.3	58.5	0.1091	6.33	.0899	.0394	.131	14.9
Cobalt .	8.5	58.5	0.1070	6.26	.0981	.0456	.172	14.2

These metals likewise present a remarkable similarity in many of their chemical properties. Both iron and nickel become passive when immersed in strong nitric acid; the action of the concentrated acid upon cobalt may with great probability be attributed to the of iron which it invariably contains.

Ferrous salts are bluish-green; nickel-salts emerald-green; cobalt-salts (when warmed) bright green; the change of cobalt-salts by heat may perhaps be related to the increase in the magnetic power of the metal, which likewise takes place when it is heated. Cobalt and nickel, moreover, generally occur together, and all the three metals are associated in meteoric iron. The feebly magnetic metals, manganese and chromium, likewise participate to a certain extent in the chemical properties of iron, nickel, and cobalt.

Nickel and cobalt, when magnetised by an electric current, give out, on the closing of the circuit, a sound, which in the case of cobalt is louder than with nickel, and has the metallic ring of that produced by iron under similar circumstances. Bars of iron and cobalt appear to be somewhat elongated by magnetisation; nickel does not. The result obtained with cobalt is, however, scarcely decisive, as the metal used was not quite free from iron (Barrett, *Phil. Mag.* [4], xlvii. 51).

On the effect of Magnetisation in the Physical Properties of Iron, see further p. 1096.

W. Hankel (*Ann. Phys. Chem.* [2], i. 285) has determined the magnetism of very pure nickel and cobalt, under the influence of currents of various strength. In nickel, the magnetism excited by comparatively feeble currents is nearly equal to that of iron, and differs from that of the latter in increasing ratio as the currents become stronger. Cobalt, on the other hand, acquires under the influence of weak currents only about half the magnetism of iron, and with stronger currents a fraction of that of iron becoming continually smaller as the strength of the current is greater.

H. A. Rowland (*Phil. Mag.* [4], xlv. 10; xlviii. 321) has also made comparative experiments on the behaviour of iron, nickel, and cobalt under the influence of magnetising forces, from which he infers that the differences between the magnetic characters of the three metals are only quantitative, and may be summed up in the following propositions: (1). As the magnetising force increases, the resistance to magnetisation diminishes down to a certain minimum, after which it increases without limit. (2). In nickel and cobalt this resistance depends upon the temperature, and in cobalt it diminishes with rise of temperature; in nickel it diminishes or increases with rise of temperature accordingly as the magnetising force is weak or strong. (3). All the three metals have a maximum of magnetisability, which, however, is attainable only under the influence of magnetising forces not practically available (the limit would be first attained with nickel). (4). In iron and nickel, this maximum diminishes as the temperature rises, at least between 10° and 220° , slowly in iron, quickly in nickel.

The following conclusions are deduced by A. L. Holz (*Pogg. Ann.* cli. 69; cli. 67) from experiments on the effect of solvents on steel magnets: (1). The magnitude of the magnetic moment of a steel bar depends upon the structure of the iron and that of the iron carbide associated with it. (2). This moment (referred to 1 mg. as unit of weight) is diminished by removal of magnetised iron, but increased by removal of

magnetised iron carbide. (3). The particles of iron carbide which remain after the pure iron has been dissolved out, are magnetisable and become permanently magnetic. (4). The coercive power of steel magnets and of magnets formed of electrolytically deposited iron is dependent on the distances between the molecules, the magnetic moment being increased by every process which widens these distances (see further, *Ann. Phys. Ergänzb.* viii. 353; *Jahresb. f. Chem.* 1877, 171). L. Kalp (*Pogg. Ann.* clv. 320) concludes, from experiments on two iron bars of equal size and weight, the one having a fibrous, the other a granular texture, that the magnetic moments induced in the two by currents of equal strength are almost exactly equal, and hence infers that *texture has no influence on magnetism*.

From experiments by Trève a. Durassier (*Compt. rend.* lxxx. 799; lxxxi. 1123, 1246; remarks thereon by Jamin, *ibid.* lxxxi. 1126) it appears: (1). That the magnetism of very carefully prepared homogeneous steel bars penetrates them uniformly to the very centre (thickness 16 mm.), as shown by the fact that when the magnet is dissolved, its magnetism decreases proportionally to the weight. (2). That the magnetic moment decreases with the proportion of carbon, and is greater the higher the temperature of the water in which the steel has been hardened; at equal temperatures, on the other hand, it is greater with water than with oil as the refrigerating agent.

Electrolytically-prepared Magnets.—According to experiments by M. v. Jacobi (*N. Petersb. Acad. Buv.* xviii. 11), it appears that iron electrolytically precipitated under the influence of a strong electromagnetic spiral does not differ in its physical or chemical properties from iron similarly precipitated without such electromagnetic influence; and in particular it does not exhibit more decided magnetic properties. Electrolytically precipitated iron shows very little coercive force, which, moreover, cannot be imparted to it even when it has been brought, by ignition and slow cooling, to the degree of softness and tenacity of bar iron, or finally converted into steel having the hardness of glass. It is capable of acquiring strong temporary magnetism, which, however, disappears very quickly.

According to W. Beetz, on the other hand (*Pogg. Ann.* clii. 484), iron electrolytically precipitated from a solution containing sal-ammoniac is capable of acquiring very strong permanent magnetism; iron similarly precipitated from other solutions possesses this power only in a minor degree. If the precipitation takes place under the influence of strong magnetism, the solution containing sal-ammoniac yields strong magnets of uniform texture, whereas a solution not containing sal-ammoniac yields magnets of irregular structure and exhibiting consecutive points, whereby the already weak magnetism of the precipitate thrown down from such solutions is made to appear still less. Under no circumstances, however, does electrolytically precipitated iron possess much coercive power, unless its structure has been altered by ignition or other processes.

Influence of Hardening and Heating on Magnetisation.—According to Gauguin (*Compt. rend.* lxxxii. 144), the hardest steel bars acquire, under the influence of powerful magnetising forces, a stronger magnetism than those which have been tempered, whereas, under the influence of a weaker inducing force, the softer steels are more highly magnetised than those of greater hardness. The magnetism of any cross section of the bar consists of an inherent portion which remains in it even after separation from the bar, and another portion due to the action of the other sections. Hardening increases the coercive power, and, therefore, also the inherent magnetism, but diminishes the temporary magnetism or magnetism of reaction. The latter, therefore, plays a more conspicuous part in steel of inferior hardness.

Jamin (*Compt. rend.* lxxvii. 89) finds that different kinds of steel form weaker electromagnets in proportion as they are harder and richer in carbon. Steel of the hardness of glass is almost unmagnetisable, and therefore not well adapted for making permanent magnets; the best steels for this purpose are those of medium hardness. When steel is re-tempered, the power of acquiring temporary magnetism increases with the degree of heat at which the tempering takes place. In steels containing a small or a medium proportion of carbon the power of acquiring permanent magnetism is greatest when they are completely hardened, is diminished by tempering, and disappears altogether at a full red heat. In glass-hard, highly carbonised steel, the latter power is increased by tempering up to a certain temperature, higher as the hardness is greater, then again diminishes, but does not disappear completely even at a full red heat.

When a bar of highly carbonised steel was removed from a sand-bath in which it had been tempered to the dark-blue, and quickly introduced into an electric spiral, its temporary magnetism (that which it possessed while still within the spiral) was found to be slightly less than that which it would have acquired in the cooled state, but its

permanent magnetism was considerably greater. At the first moment the latter appeared to be equal to the temporary magnetism, but it quickly diminished and disappeared completely in a quarter of an hour, whether the original temperature were maintained or the bar left to cool gradually. The disappearance of magnetism is exactly analogous to cooling. If the bar be again heated, but to a lower temperature, the temporary magnetism rises to a higher degree than before, sinks for a moment much lower on the breaking of the current, and then decreases more slowly than before down to a certain limit, but does not disappear altogether. On repeating the experiment upon the cold bar, a still higher temporary magnetism is developed, and a permanent magnetism greater than the residual magnetism in the preceding case.

Experiments on the influence of heat on magnetisation have also been made by Favé (*Compt. rend.* lxxii. 276), who finds that when heated steel bars are magnetised by the electric current, the amount of permanent magnetism slowly diminishes as the temperature at which the magnetisation takes place is raised; it is still considerable at a dull red heat, but becomes imperceptible at cherry-redness. The magnetism, which disappears very quickly as the bar cools, may be retained for an indefinite time at any temperature, provided this temperature be kept constant, but every rise or fall of temperature is attended with loss of magnetic power. The quantity of magnetism retained at any particular temperature depends upon the nature of the steel, the temperature at which the magnetisation originally took place, and the changes of state which have occurred since the magnetisation. On heating the bars, the magnetism diminishes regularly according to a law depending on the composition of the steel. As the bar cools, the magnetism diminishes according to a law which (contrary to Jamin's statement) is very different from the law of cooling, the diminution being very slow at first, but afterwards taking place with increasing rapidity. The higher the temperature at which the bar was magnetised, the longer is the duration of the earlier stage of slow decrease. When a cooling bar is reheated, the magnetism again increases considerably under certain circumstances, but never regains its original value.

Daubrée (*Compt. rend.* lxxii. 279) suggests that the results of Favé's experiments may have been somewhat influenced by the inducing action of the earth, and refers to some experiments of his own (*ibid.* lxxx. 526), in which bars formed of an alloy of platinum with 14 to 16 per cent. iron, and cast with the axis of the mould in the direction of the magnetic dip, exhibited strong magnetic polarity, which was reversed by turning the bars upside down and again heating them strongly.

The influence of heat on magnetisation has also been studied by J. M. Gauguain (*Compt. rend.* lxxx. 297; lxxii. 685, 1422; lxxiii. 661, 896; lxxxv. 219), whose mode of operating is similar to that adopted by Favé, excepting that the inducing power was furnished by a permanent magnet, one pole of which was placed in contact with the steel bar under investigation, and that the inducing power was in most cases made to act constantly during all changes of temperature. These experiments showed that when a bar is moderately heated, the total magnetism (permanent + temporary) is considerably increased, but that when the heat is raised till the steel turns blue, its magnetism attains a maximum value at a certain temperature depending on the nature of the steel, and then diminishes to a certain extent. When the bar is left to cool in uninterrupted contact with the inducing magnetic pole, its magnetism increases, and remains, after complete cooling, considerably higher than it was before heating, and higher in proportion as the heat was greater. A short time after the removal of the inducing magnet, part of the excess of magnetism developed by heating disappears, and cannot be restored by renewed contact with the magnet. The ratio of the difference of the two values to the higher limiting value is called by Gauguain the *transient variation*. It is very different for different kinds of steel, and greater for the several transverse sections in proportion as they are farther removed from the inducing pole. The *permanent variation* is the ratio of the difference between the magnetism of a point after heating, and that of the same point before heating, referred to a certain temperature; this variation increases with the magnetising force. In iron these two variations are smaller than in steel. Determinations of the total magnetism at different high and constant temperatures, show that in bars of great transient variation the total magnetism is weaker at 300° than at ordinary temperatures, but that in bars which exhibit only a small transient variation, the total magnetism is strongest at 300°. Sheffield steel, magnetised at a red heat, not only lost its magnetism completely on cooling, but acquired opposite polarity. On reheating, this reversed magnetism disappeared and the original polarity was restored.

New Method of Magnetisation.—When steam of 5 or 6 atm. pressure is passed through a copper tube 2 or 3 mm. thick coiled round an iron cylinder, the iron becomes magnetic, and remains so as long as the stream of vapour is kept up (D. Tommasi, *Compt. rend.* lxxx. 1007). Maumené (*ibid.* 1138) attributes this result to a thermoelectric current due to the difference of temperature between the heated inner surface and the cold outer surface of the tube.

Influence of Traction on Magnetisation.—Experiments on the effect of traction forces on the magnetisability of wires have been made by Sir William Thomson (*Proc. Roy. Soc.* xxiii. 445, 473). Pianoforte-wire suspended vertically within an induction-spiral, and stretched by weights, acquires weaker magnetism both temporary and permanent, than when it is not stretched, the difference being more considerable for the permanent than for the temporarily induced magnetism. The variation in the magnetism consequent on repeated closing and opening of the inducing-current is greater with stretched than with unstretched wire. In wires of perfectly soft iron, the result depends on the strength of the magnetising force. When this force has attained a certain magnitude, the induced magnetism is increased by tension; but beyond that critical point it is diminished by tension. The alteration produced by repeated opening and closing of the circuit in soft iron wires is always diminished by tension, contrary to that which takes place in steel wires.

Magnetism of Chemical Compounds. Elaborate experiments on the magnetic behaviour of the salts of iron, cobalt, nickel, manganese, chromium, cerium, and didymium, have been made by G. Wiedemann (*Pogg. Ann.* cxxvi. 1; cxxxv. 177; *J. pr. Chem.* [2], ix. 145; *Phil. Mag.* [4], xxx. 366; xxxvii. 314; [5], iv. 161, 276). The apparatus used consisted of a brass bar suspended by a torsion wire of German silver, and carrying—besides a horizontal mirror for reading off the angle of rotation—a brass arm directed from north to south, on which was fixed a small glass flask filled with the substance under examination; in front of this flask was placed an electromagnet having its axis directed from east to west. This apparatus affords the means of determining the magnitude of the temporary magnetic moment of the salt under the influence of the electromagnet, previous observation having shown that the magnetic attraction is proportional to the square of the magnetic moment of the attracting electromagnet, and consequently that the temporary magnetic moment of the glass vessel filled with the solid or dissolved salt is directly proportional to the magnetic force. By subtracting from the magnetic moment which the glass vessel filled with solutions of a salt in various solvents and of various degrees of concentration exhibits under the influence of the *unit* of magnetic force, the magnetic moment of the same vessel filled with the pure solvent and under the influence of the same force,—and applying this method to various salts, and at various temperatures, the following results were obtained: (1). The magnetic moment of any salt dissolved in various solvents is directly proportional to the weight of that salt contained in a unit-volume of the solution, and independent of the nature of the solvent. (2). It decreases with rise of temperature, and in the same ratio for all the salts examined.

Denoting the temperature by t , the temporary magnetic moment at 0° by m_0 , and the same at t° by m_t , we have:

$$m_t = m_0(1 - 0.00395 t).$$

It is remarkable that the decrease of the magnetic moment does not differ much from the decrease of the electric conductivity of the metal for the same changes of temperature.

In the following tables, m denotes the specific magnetism of the salts according to Wiedemann's definition, that is to say the quotient of the magnetic moment developed in them by the *unit* of magnetising force, divided by the weight of the salt contained in a unit of volume; μ the values obtained by multiplying m into the molecular weight of the salt.

A. *Estimations with Solutions.*—(All data, with exception of ammonioferrous sulphate, relate to the anhydrous salt. For the mean values deduced from the results of several experiments, the number of the experiments is given in brackets).

	m	μ		m	μ
NiSO ⁴	18.40	1426	MnSO ⁴	62.18	4695
NiN ² O ⁶	15.67	1433	MnN ² O ⁶	52.46	4693
NiCl ²	21.54	1400	MnC ² H ⁶ O ⁴	53.03	4586
			MnCl ² [2]	74.74	4706
CoSO ⁴	41.52	3218			
CoN ² O ⁶	33.98	3109	Cr ² (SO ⁴) ³ [2]	19.40	3812
CoCl ²	47.08	3058	Cr ² (N ² O ⁶) ³ [3]	15.46	3705
			Cr ² Cl ⁶	25.15	3988
FeSO ⁴ [3]	51.35	3904			
FeN ² O ⁶ [2]	42.91	3861	Fe ² (SO ⁴) ³	46.48	9296
FeCl ²	60.78	3858	Fe ² (N ² O ⁶) ³	38.89	9410
FeSO ⁴ .(NH ⁴) ² SO ⁴ + 6H ² O	19.35	3795	Fe ² Cl ⁶	59.34	9633

B. *Estimations with Solid Salts.*—(These were introduced into the flask in the state of fine powder, and intimately mixed with ignited silica or dry potassium chloride. Here also the numbers—except in the case of ammonioferrous sulphate, refer to the anhydrous salt):

	<i>m</i>	<i>μ</i>		<i>m</i>	<i>μ</i>
FeSO ⁴ + 7H ² O . . .	46.87	3683	MnSO ⁴ cryst. . .	60.92	4600
FeCl ² . . .	57.71	3660	CoSO ⁴ . . .	38.09	2950
FeSO ⁴ .(NH ⁴) ² SO ⁴ + 6H ² O	20.81	4078	CoSO ⁴ [2] . . .	38.66	2996
			Fe ² Cl ⁶ . . .	55.41	9000

These numbers show (3): that in analogously constituted salts of the same metal the product of the specific magnetism of the salt into its molecular weight is constant; or, in other words, the molecular magnetism of analogously constituted salts, including the haloid salts, of the same metal, is a constant quantity. The mean magnetic moments of a molecule of the nickel, cobalt, ferrous, and manganous salts are to one another as 142 : 313 : 387 : 468. The magnetism of a molecule of the cobalt-salts is nearly the mean of the magnetisms of the nickel and manganous salts; that of the ferrous salts is intermediate between those of the cobaltous and manganous salts. The several oxides of the same metal, FeO and Fe²O³ for example, possess different magnetic powers, and for the same oxide the magnetism varies with the form: thus it is smaller in the soluble form of ferric oxide obtained by dialysis, and in that which exists in basic salts, than in the crystalline oxide, or in that which exists in the acid salts. (4). The magnetism of salts in the solid state is nearly the same as that of their solutions; moreover the magnetism of anhydrous salts is not essentially altered by the entrance of water of crystallisation. The insoluble salts of the metals above mentioned—so far as they are not decomposed by washing with hot water—agree with the soluble salts in respect of the value of *μ*. From the preceding results, Wiedemann considers it probable that in all similarly constituted salts of a metal the atom of the metal, when subjected to the action of equal magnetising forces, acquires the same degree of temporary magnetism.

In a second series of experiments (*Pogg. Ann.* cxxxv. 177; *Phil. Mag.* [4], xxxvii. 314) Wiedemann shows: (5). That equality of molecular magnetism exists also in the salts of cerium, didymium, and copper. (6). The hydroxides of the magnetic metals above mentioned likewise possess nearly equal magnetism. (7). The molecular magnetism of the magnetic metals and of the atomic groups containing them, remains constant in the passage of a binary compound into another similarly constituted compound by double decomposition, so that the molecular magnetism of binary compounds may be calculated from that of their constituents in their existing state by simple addition. (8). In the double cyanides of the magnetic metals the magnetism of the atom of metal united with the cyaniferous groups (e.g. Cy + $\frac{1}{2}$ MeCy and Cy + Me $\frac{2}{3}$ Cy) is the same as in the simple salts, whereas the cyaniferous groups, although they contain a magnetic metal, possess a much smaller degree of magnetism, or even exhibit diamagnetism. The molecular magnetism of *potassium ferricyanide* is intermediate between those of the corresponding manganic- and cobaltic-cyanides, just as in the lower oxyalts of the same metals. The magnetic powers of the three groups of cyanides just mentioned are smaller by equal amounts than those of the corresponding oxyalts. (9). The magnetic deportment of the *ferrous* and *ferric double oxalates* shows that these salts have, in the solid state as well as in solution, a constitution exactly similar to that of other ferrous and ferric salts. (10). On the other hand, the molecular magnetism of colloidal ferric oxide is only 0.22 times as great as that of ferric salts and ferric hydroxide, so that in this form of ferric oxide the magnetic group of atoms possesses properties essentially different from those which it exhibits in other forms. (11). The magnetic behaviour of *ammoniacal copper* and *nickel compounds*, as affected by alterations of density, appears to be nearly the same as that of the other oxyalts and haloid salts of the same metals—so that the magnetic groups of atoms in these two salts must be essentially the same. On the other hand, the very feeble magnetism of the *purpurco-* and *lateo-cobaltic compounds* shows that their atomic grouping is essentially different from that of the simpler salts. (12). When considerable alterations of density take place, the magnetism of compounds in the solid state may be essentially different from that of the same compounds in solution, as in the case of cupric bromide, cobaltous chloride, &c. (13). The higher oxides of the magnetic metals (Fe²O³, &c.) are much less magnetic than the corresponding hydroxides and salts; but it is not yet determined with certainty how far this difference is due to

alterations of density or differences of atomic grouping. (14). The sulphides of the magnetic metals are for the most part much less magnetic than the corresponding salts. (15). Two diamagnetic elements (bromine and copper) may form a magnetic compound, whereas a magnetic element in combining with a nearly indifferent or slightly diamagnetic radicle (*e.g.* sulphur, cyanogen in the double cyanides) may lose its magnetism.

Wiedemann has also applied his observations on the magnetism of solutions to the study of the affinity of ferric oxide for acids, and the dissociation of ferric salts. It has been already stated that the molecular magnetism of colloid ferric oxide prepared by diffusion of basic ferric salts, is only about 0.22 of that of ferric oxide in strongly acidulated solutions. Further observations on solutions of recently precipitated ferric hydroxide in solutions of crystallised ferric chloride, gave for the magnetism of colloid ferric oxide a value equal to 0.2198 of that of an equal quantity of ordinary ferric oxide dissolved in ferric chloride. The observations show further that the magnetism of ferric chloride solutions containing ferric oxide is equal to the sum of the magnetisms of the iron in the chloride and in the colloid oxide; this, however, no longer holds good when basic salts are formed in the solution, the iron in these salts probably possessing an atomic magnetism peculiar to itself. If therefore in a neutral or a slightly acid solution of a ferric salt, part of the salt be resolved into free acid and dissolved colloid oxide, observations of the magnetism of the solutions will afford the means of calculating the ratio of the ferric oxide combined with the acid in the form of a salt to that of the dissolved free colloid oxide, $1-x : x$. The experiments with this object were made in the manner above described (p. 1251), excepting that the torsion-balance was made more sensitive by the use of a longer suspending wire and a stronger electromagnet. The observations made on solutions of ferric chloride of different degrees of dilution gave the following results:

Solutions of Ferric Chloride.

Iron in 10 c.c.	x	$1-x$
1.606	—	100
1.207	—	100
0.806	1.6	98.4
0.404	2.4	97.6
0.202	6.6	93.4
0.138	8.9	91.1
0.071	11.7	88.4

These numbers show that the dissociation of ferric chloride solutions increases slowly with increasing dilution. By similar observations it is found that in solutions of *neutral ferric sulphate* one-fourth of the salt is resolved into colloid dissolved ferric oxide and sulphuric acid, independently of the degree of dilution. In *ammonia-iron-alum*, one-fourth of the ferric sulphate is dissociated, independently of the ammonium sulphate. In a basic solution of *ferric nitrate*, 32 to 36 per cent. of the iron was found to be present as colloid dissolved ferric oxide. In a neutral solution of *ferric acetate* containing 0.182 gram of iron in 10 c.c., 70 per cent. of the ferric oxide was found to be dissolved in the colloid state; in neutral solution of *ferric tartrate*, 57 per cent. of the salt was dissociated (Wiedemann, *J. pr. Chem.* [2], ix. 145-171; *Phil. Mag.* [5], iv. 276).

The *hydrated peroxides of manganese, cobalt, and nickel* have but a very feeble magnetism; *chromium dioxide*, CrO_2 , on the contrary, by its very strong magnetic power, shows that it is a saline compound of chromic anhydride with chromic oxide, $\text{Cr}^{\text{O}_3}\text{CrO}_2$. Solution of *chrome-alum* exhibits the same degree of magnetism in the violet state and in the green state produced by heat; the alteration in the colour cannot therefore be due to separation of colloid chromium sesquioxide, as this latter would be much less magnetic. In *ammonio-chromic chloride* the chromium exhibits the same magnetic behaviour as in the chromic salts: hence its constitution must be that represented by the formula $\text{Cr}^{\text{O}_3}\text{Cl}^{\text{O}_3}\cdot 8\text{NH}_3\cdot 2\text{H}_2\text{O}$ (*Phil. Mag.* [5], iv. 161).

Magnetism of Ilmenite (Titaniferous Iron).—This mineral may be magnetised by friction with a steel magnet, and is intermediate in its magnetic properties between iron and steel. Fine specimens from Norway of sp. gr. 4.8, containing 24.60 per cent. TiO_2 , 72.10 FeO , 2.06 FeS_2 , 1.24 SiO_2 , and a trace of manganese, were found to act on the magnetic needle, and appeared to consist of a mixture of differently oriented magnets, probably the individual crystals. A piece broken off, $1\frac{1}{2}$ inch long and $\frac{1}{4}$ inch broad, became permanently magnetised by an hour's friction with a good magnet, and when freely suspended, remained in the magnetic meridian for a month, when it suddenly lost all its polarity (T. L. Phipson, *Bull. Soc. Chim.* [2], vii 322; *Chem. News*, xxxii. 162).

On the Magnetic Anomaly of Ferric Oxide prepared from Meteoric Iron, see IRON (p. 1097).

MAGNOCHROMITE and **GROCHAUTE**. The name magnochromite was given by von Bock in 1868 to a chrome-ore rich in magnesia, occurring in the serpentine of Grochau, near Frankenstein in Silesia. It is black, without metallic lustre, and has a brown streak. Hardness below 6. Sp. gr. = 1–4.110. It forms nodules imbedded in a mountain-green matrix, which ramifies into the lumps of chrome-ore in such a manner as to render mechanical separation of the chrome-ore impossible. Perfectly pure portions of the matrix may, however, be detached from the chrome-ore. This matrix gave by analysis:

SiO ²	Al ² O ³	FeO	MgO	H ² O
28.20	24.56	5.27	30.94	12.15 = 101.12

Websky deduces from this analysis the formula $H^{90}Fe^5Mg^{64}Al^{16}Si^{21}O^{214}$. If the isomeric admixture of aluminium-hemisilicate be deducted as unimportant, the formula of the mineral will be—

It is, therefore, a new species, and Websky proposes to call it grochauite, from the locality in which it occurs. The thicker scales of the mineral contain small druses, in which the grochauite appears in six-sided tables, but its behaviour to polarised light shows that it belongs, not to the hexagonal, but to an optically biaxial system.

Deducting the composition of grochauite from that of the inseparable mixture of grochauite and magnochromite, as given by v. Bock's analysis, the remainder gives the composition of magnochromite, and shows it to be a compound belonging to the spinel group—

	SiO ²	Al ² O ³	Cr ² O ³	FeO	MgO	H ² O	
Mixture	5.71	29.61	33.25	13.61	18.28	2.19	= 102.65
Grochauite	5.72	5.22	—	1.14	6.87	2.57	= 21.52
Magnochromite	—	24.39	33.24	12.47	11.41	—	= 81.51

(Websky, *Zeitschr. geol. Ges.* xxv. 394; *Jahrb. f. Min.* 1874, 300).

MAGNOFERRITE. Intergrowths of this mineral with iron-glance, from Vesuvius, are described by G. vom Rath (*Jahrb. f. Min.* 1876, 388).

MAHONIA. The fruit of this plant yields by fermentation a very astringent wine containing 6.25 per cent. alcohol (Is. Pierre, *Compt. rend.* lxxxi. 1086).

MAIROGALLOL, $C^{18}H^7Cl^{11}O^{10}$. A compound obtained, together with leucogallol, by the action of chlorine on pyrogallol dissolved in glacial acetic acid (see PYROGALLOL).

MAIZE. For the saccharification of maize and other cereals, and of lichens, &c., Colami a. Krüger make use of dilute hydrochloric acid instead of malt, the material being stirred up with water and dilute hydrochloric acid in a cylindrical copper vessel, by a current of steam under high pressure and at a temperature above the boiling point of water, but not high enough to induce the formation of caramel. The saccharification of maize requires a pressure of 3 atmospheres, under which 360 kg. of the ground grain are converted into sugar by the action of 16 kg. hydrochloric acid and 600 litres of water in 65 minutes (*Dingl. pol. J.* cccxiv. 302).

Mouldy maize-bread, treated by the Stas-Otto method (i. 125–127), yields a white non-crystalline alkaloid, which is very liable to change, and becomes coloured on exposure to the air: it is insoluble in water, but dissolves, with alkaline reaction, in alcohol and ether. Heated with sodium carbonate, it yields an alkaline distillate. Its tartrate is also easily decomposable. With sulphuric acid and oxidising agents it yields a sky-blue coloration, which disappears spontaneously after some time, but quickly and with transient violet coloration on addition of excess of water, oxidising agents, &c. With the ordinary tests for alkaloids it yields precipitates, some of which are crystalline. It resembles strychnine in its physiological action, but is not identical therewith (Lombroso, *Compt. rend.* lxxxi. 1041; *Gazz. chim. ital.* 1876, 538; Brugnatelli a. Zenoni, *ibid.* 240).

MALACHITE-GREEN (O. Doebner, *Deut. Chem. Ges. Ber.* xi. 1236). A green dye-stuff, consisting of the double zinc salt of a base having the composition $C^{23}H^{21}N^2$. It is produced on the large scale by heating 2 mols. dimethylaniline, mixed with half its weight of zinc chloride, with 1 mol. benzoyl trichloride; a deep green mass is thus produced, which may be freed from excess of the original substances by

steam. The zinc salt thus produced is soluble in water and alcohol. The free base is a red-brown uncrystallisable oil, whose salts are changed by an excess of mineral acid from green to yellow. Its formation is represented by the equation :

This base is reduced by zinc and hydrochloric acid, yielding a colourless base, $\text{C}^{23}\text{H}^{26}\text{N}^2$, identical with O. Fischer's tetramethyldiamidotriphenyl-methane, $\text{C}^6\text{H}^5\cdot\text{CH}[\text{C}^6\text{H}^4\text{N}(\text{CH}_3)^2]^2$, obtained by the action of benzaldehyde or benzal chloride on dimethylaniline (*Deut. Chem. Ges. Ber.* x. 1624; xi. 950): it melts, according to Doebner, at 97° – 98° , according to Fischer at 92° – 93° .

The base $\text{C}^{23}\text{H}^{24}\text{N}^2$ produced from benzonitrile and dimethylaniline is evidently related to Fischer's base in the same manner as rosaniline to leucaniline, and may probably be represented by the constitutional formula :

Malachite-green is said to possess many advantages over methyl-green, being much cheaper and less affected by soap and acids (*Chem. Centr.* 1878, 587).

acid as an unsaturated compound, founded on its behaviour with hydrobromic acid, have already been given under FUMARIC ACID (p. 831).

Maleic acid is formed by the cautious dry distillation of silver succinate, mixed with three times its weight of sand, ($\text{C}^4\text{H}^4\text{Ag}^2\text{O}^4 = \text{Ag}^2 + \text{C}^4\text{H}^4\text{O}^4$), and passes over, partly as a highly concentrated aqueous solution which collects in the receiver, partly in crystals melting at 130° , which collect in the neck of the retort (Bourgoin, *Bull. Soc. Chim.* [2], xx. 70).

Action of Hydrobromic acid.—Maleic acid or its anhydride dissolves easily in hydrobromic acid, and the solution, even before the last particles of acid or anhydride have disappeared, deposits slender colourless needles, the quantity of which increases so rapidly that the entire liquid is soon converted into a thick crystalline pulp. The product consists of a mixture of fumaric and monobromosuccinic acids in equal numbers of molecules, whatever may have been the proportion of maleic acid and hydrobromic acid employed in the reaction. The bromosuccinic acid may be extracted from this mixture by water, which leaves it on evaporation in well-defined colourless crystals, melting at 159° , and identical in every respect with the bromosuccinic acid obtained in like manner from fumaric acid (Fittig a. Dorn, *Deut. Chem. Ges. Ber.* ix. 1191).

Bromomaleic Anhydride, $\text{C}^4\text{H}^2\text{BrO}^3$, formed by heating dibromosuccinic acid in a sealed tube to 120° – 150° with acetic anhydride, melts at 125° – 126° , and boils at 215° (Anschütz, *ibid.* x. 1881).

Dibromomaleic acid, $\text{C}^4\text{H}^2\text{Br}^2\text{O}^4$, is formed by heating tribromosuccinic acid with water to a temperature above 100° : $\text{C}^4\text{H}^2\text{Br}^3\text{O}^4 = \text{HBr} + \text{C}^4\text{H}^2\text{Br}^2\text{O}^4$. It is a very stable compound, not being decomposed by distillation or by prolonged boiling with moist silver oxide; its silver salt also is not altered by heating with water to 120° . When, however, the acid or its silver salt is heated with water to 150° in sealed tubes, it is converted into dihydroxymaleic acid, $\text{C}^4\text{H}^2\text{Br}^2\text{O}^4 + 2\text{H}^2\text{O} = 2\text{HBr} + \text{C}^4\text{H}^4\text{O}^6$. Heated with bromine it yields carbon dioxide and tetrabromomethane: $\text{C}^4\text{H}^2\text{Br}^2\text{O}^4 + \text{Br}^2 = 2\text{CO}^2 + \text{C}^2\text{H}^2\text{Br}^4$.

Maleic Ethers.—When either maleate or fumarate of silver is left in contact at ordinary temperatures with ethyl iodide, a considerable rise of temperature takes place, and a diethyl ether, $\text{C}^4\text{H}^2(\text{C}^2\text{H}_5)^2\text{O}^3$, is formed, which boils at 218.5° (mercury-column wholly in the vapour), and is converted by saponification with alcoholic potash into fumaric acid. This result renders it doubtful whether the ether obtained from fumaric acid is really a fumarate or a maleate, and moreover throws doubt on the conclusions drawn by Hübner a. Schreiber (vii. 765) from the vapour-densities of ethyl fumarate and maleic anhydride, as to the relative molecular weights of fumaric and maleic ethers (Anschütz, *Ber.* xi. 1644).

When ethyl chloromaleate (1 mol.) is mixed with a solution of potassium cyanide (3 mols.) in twice its weight of water, and sufficient alcohol to form a clear solution, the liquid becomes very hot, and potassium chloride separates out, but no cyanised compound is formed, the product when boiled with potash yielding succinic acid. Hence it appears that a reduction has taken place, a dicyanosuccinic acid being first

formed, which then gives off carbon dioxide and retains 2 atoms of hydrogen instead of the cyanogen-residue (A. Cluses, *Ber.* xi. 928).

Hydroxymaleic acid, $C^4H^1O^5 = COOH-CHOH-\overset{\parallel}{C}-COOH$, is obtained by agitating a cold solution of potassium bromomaleate with recently precipitated silver oxide: $C^4HBrK^2O^4 + AgOH = AgBr + C^4H^2K^2O^5$. Separated from its lead salt by hydrogen sulphide, and crystallised from water, it forms long slender needles, and is easily soluble in water, alcohol, and ether. It is bibasic, and forms soluble salts with the alkalis and with baryta. The *silver salt*, $C^4H^2Ag^2O^5$, is insoluble in water, soluble in acids and in ammonia; it is decomposed by boiling with water, and detonates when heated. The *lead salt* is insoluble in water, even at the boiling heat, also in ammonia and the fixed alkalis, but dissolves readily in nitric acid (Bourgoin, *Bull. Soc. Chim.* [2], xix. 482).

Dihydroxymaleic acid, $C^4H^1O^6 = COOH-C(OH)^2-\overset{\parallel}{C}-COOH$.—This acid, related to tartaric acid in the same manner as hydroxymaleic to maleic acid, and maleic to succinic acid, is formed by heating dibromomaleic acid or its silver salt with water to 150° in a sealed tube for several hours: $C^4H^2Br^2O^4 + 2H^2O = 2HBr + C^4H^1O^6$. When the silver salt is used, and the liquid filtered from the precipitated silver bromide is neutralised with ammonia and mixed with silver nitrate, a white precipitate of *silver dihydroxymaleate*, $C^4H^2Ag^2O^6$, is formed, soluble in ammonia, nitric acid, and a large quantity of acetic acid, and decomposing without detonation when heated. The acid separated from this salt by hydrogen sulphide forms colourless crystals, having a strongly acid taste like that of tartaric acid, soluble in water and in alcohol, nearly insoluble in ether. The dihydroxymaleates of the alkalis and alkaline earths are soluble in water (Bourgoin, *Bull. Soc. Chim.* [2], xxii. 443).

MALIC ACID, $C^4H^1O^5 = \begin{array}{c} CHO\dot{H}-COOH \\ | \\ CH^2-COOH \end{array}$. 1. *Optically Active Modi-*

fications.—The malic acid which Dessaignes obtained by the action of phosphorus iodide and water on tartaric acid (v. 675) is dextrogyrate, and has a rotatory power = $+3.157$, which is nearly equal, but opposite, to that of maleic acid from mountain-ash berries (-3.299). The *acid ammonium salt* of dextromalic acid has a rotatory power = $+7.912$; that of the corresponding salt of ordinary maleic acid, on the other hand, is -5.939 . If, however, the acid calcium salt of the latter acid be neutralised with ammonia, and the lime exactly precipitated by oxalic acid, an acid ammonium salt is obtained having a lævo-rotation = -7.816 . These facts point to the existence of two isomeric acid ammonium malates:

(G. W. Brewer, *Bull. Soc. Chim.* [2], xxv. 6; *Deut. Chem. Ges. Ber.* viii. 861; v. 1594).

Ordinary malic acid is decomposed by sulphuric acid into CO^2 , CO, H^2O , and aldehyde, C^2H^1O . As ethylidene-lactic acid is resolved by similar treatment into CO, H^2O , and aldehyde, it is probable that the malic acid is first converted into lactic acid, $C^3H^4O^3 = CO^2 + C^2H^2O^3$, and that the latter is then decomposed in the manner just mentioned (Weith, *Deut. Chem. Ges. Ber.* x. 1744).

Lead malate dissolves to a considerable amount in dilute acetic acid at 50° – 60° , and crystallises therefrom on slow cooling to 30° – 40° in slender needles. This reaction may be utilised for the separation of malic acid from oxalic, citric, and tartaric acid, the lead salts of which are insoluble in dilute acetic acid (F. A. Hartsen, *Arch. Pharm.* [3], vi. 110).

2. *Inactive Malic acid*.—This modification, which Pasteur obtained by the action of nitrous acid on inactive aspartic acid (iii. 789), is also produced: *a.* together with fumaric acid, by treating ethyl dichloropropionate with a weak alcoholic solution of potassium cyanide, and boiling the product with potash (Werigo a. Tantar, *Liebigs Annalen*, clxxiv. 367). *B.* By heating fumaric acid with soda-ley to 100° for six hours, the reaction being apparently analogous to that which takes place in the conversion of acrylic acid into hydracrylic and ethylenelactic acids (p. 43). The *calcium salt* is precipitated by boiling from a solution prepared in the cold, in microscopic six-sided tablets, and when dried over sulphuric acid has the composition $C^4H^4CaO^5$ (Linneman a. Loidl, *Deut. Chem. Ges. Ber.* ix. 925). The *alkali-salts* of inactive malic acid are easily soluble, crystallise with difficulty, and are thrown down by alcohol as amorphous flocculent precipitates; so likewise are the *copper* and *zinc* salts. The

aqueous solution of the zinc salt becomes turbid when heated, but clear again on cooling. The *lead, silver, and mercury salts* are nearly insoluble in water, and the two latter are easily decomposed by water (Werigo a. Tantar).

3. **Isomalic** or **Isohydroxysuccinic Acid**, $\text{CO}^2\text{H}.\text{CHOH}.\text{CH}^2.\text{CO}^2\text{H}$, is obtained by adding recently precipitated silver oxide to aqueous bromisuccinic acid (see Succinic Acids) previously freed as completely as possible from adhering hydrobromic acid by heating in a stream of carbon dioxide, then gently heating the liquid, and separating the silver bromide by filtration. The solution freed from dissolved silver by hydrogen sulphide contains isomalic acid still contaminated with a greasy substance. For purification the acid is converted into the lead salt, which separates on adding a solution of neutral lead acetate to the aqueous or alcoholic solution of the acid, as a white, bulky, sparingly soluble precipitate. This salt, $\text{C}^4\text{H}^4\text{PbO}^2$ (dried at 120°), is distinguished from ordinary malate of lead by not melting under water. On decomposing it with hydrogen sulphide and concentrating the filtrate, isomalic acid separates in crystals, apparently monoclinic. It is easily soluble in water, alcohol, and ether, and begins to melt and give off gas at about 100° . All its salts hitherto prepared—even the acid calcium salt—are amorphous.

Isomalic acid does not react with calcium chloride and ammonia in the same manner as isosuccinic acid. When heated to 160° it is resolved into carbon dioxide and ordinary lactic acid, and has therefore the constitution of isohydroxysuccinic acid (Schmöger, *J. pr. Chem.* [2], xiv. 77).

MALIC CHLORALIDE, $\text{C}^4\text{H}^2\text{Cl}^2\text{O}^3$. See CHLORALIDE (p. 445).

MALONAMIDE, $\text{C}^3\text{H}^4\text{N}^2\text{O}^2 = \dot{\text{C}}\text{H}^2(\text{CONH}^2)^2$, is formed by digesting methyl malonate (p. 1259) in aqueous ammonia. On evaporating the solution, dissolving the residue in hot dilute alcohol, and leaving the liquid to cool, the malonamide separates in needles having a silky lustre. It is insoluble in absolute alcohol and in ether, and when boiled for some time in water, with repeated addition of ammonia, is converted into ammonium malonamate, $\text{CONH}^2.\text{CH}^2.\text{COO}(\text{NH}^4)$ (Osterland, *Deut. Chem. Ges. Ber.* vii. 1286). According to van't Hoff (*Arch. néerland.* x. 274) malonamide melts at 170° .

MALONIC ACID, $\text{C}^3\text{H}^4\text{O}^4 = \text{CO}^2\text{H}.\text{CH}^2.\text{CO}^2\text{H}$. *Formation*.—1. From Ethyl Chloracrylate, $\text{C}^2\text{H}^2\text{ClO}^2.\text{C}^2\text{H}^3$. This ether is converted by prolonged boiling with baryta-water into barium acryl-lactate or hydroxyacrylate, which remains dissolved, and barium malonate which separates out; and on decomposing the mixture of barium salts thus obtained with the requisite quantity of sulphuric acid and evaporating the filtrate to a syrup on the water-bath, malonic acid crystallises out in flat prisms. Its formation from hydroxyacrylic acid, $\text{CHOH}=\text{CH}.\text{CO}^2\text{H}$, produced in the first instance, may perhaps be represented by the following equations:

The oxygen may be supposed to be derived from the air. Malonic acid is also said to be contained, together with a second acid, in the water which passes over on distilling crude ethyl chloracrylate in a current of steam.

2. Malonic acid is formed in small quantity, together with much carbon dioxide and oxalic acid, by the oxidation of ethylene-lactic acid with chromic acid (Wislicenus, *Liebig's Annalen*, clxvii. 346).

3. From Mucobromic acid, $\text{C}^4\text{H}^2\text{Br}^2\text{O}^3$. The acid which Schmelz a. Beilstein obtained by the action of bromine and water on pyromucic acid (iii. 763) was supposed by them to be resolved by boiling with excess of baryta-water into carbon dioxide, hydrogen bromide, bromacetylene, and an acid, $\text{C}^4\text{H}^2\text{O}^4$, which they designated as *muconic acid*. Jackson a. Hill, however, find that the lead salt of the acid thus obtained has the composition $\text{C}^3\text{H}^2\text{PbO}^4$, and that the acid separated from it is identical in every respect with malonic acid prepared from cyanacetic acid. They find also that mucobromic acid treated with baryta-water yields bromide and formate of barium, as well as malonate, so that the reaction may be represented by the equation:

Preparation.—The ethyl cyanacetate required for the preparation of malonic acid (iii. 799) is best obtained, according to Franchimont (*Deut. Chem. Ges. Ber.* vii. 216), from ethyl bromacetate. This latter, obtained by boiling bromacetic acid for an hour in the water-bath with absolute alcohol, is washed several times with water, dissolved in about ten times its volume of alcohol, and pure pulverised potassium cyanide is then added to it in excess. The liquid soon boils, and the odour of the ethyl brom-

acetate disappears after a short time. It is then filtered to separate potassium bromide, caustic potash is added, the alcohol is distilled off, and the aqueous solution boiled as long as it continues to give off ammonia. The malonic acid is best extracted from the residue by acidulation and agitation with ether. A small quantity of succinic acid is formed at the same time.

Conrad (*Ber.* xi. 749) dissolves monochloroacetic acid in a small quantity of alcohol and neutralises it with dilute soda-ley, keeping the liquid cool; then adds an equivalent quantity of potassium cyanide dissolved in water, whereupon cyanacetate of alkali-metal is formed with great rise of temperature; and heats the liquid for several hours to complete the reaction. On subsequent addition of a quantity of soda-ley equal to that which was used for the neutralisation of the chloroacetic acid, a copious evolution of ammonia takes place after some minutes, attended with sudden ebullition. After all the ammonia has been driven off by prolonged boiling, the solution may be neutralised with hydrochloric acid, and the malonic acid precipitated by calcium chloride.

On the preparation of malonic acid, see also Petrieff (*Ber.* vii. 400); van't Hoff (*ibid.* 1571); Osterland (*ibid.* 1286); H. v. Miller (*J. pr. Chem.* [2], *ix.* 326).

Electrolysis.—A solution of 100 grams malonic acid in 200 c.c. water, neutralised with potassium carbonate and subjected to the action of a battery of six Bunsen's cells, yields nothing but carbon dioxide and hydrogen, the methylene liberated in the first instance (succinic acid similarly treated yields ethylene) being probably oxidised by nascent oxygen (v. Miller).

Malonic Ethers. When *ethyl malonate*, $\text{CO}^2\text{C}^2\text{H}^5\cdot\text{CH}^2\cdot\text{CO}^2\text{C}^2\text{H}^5$, is treated with 1 mol. potassium hydroxide, both dissolved in alcoholic potash, the whole solidifies to a crystalline pulp of potassium ethylmalonate, which is decomposed by phosphorus pentachloride, yielding ethyl chloromalonate, according to the equation:

Ethyl chloromalonate boils between 170° and 180° , and is decomposed by water, like an acid chloride, the resulting liquid, when heated with potash, yielding ethyl alcohol (*J. van't Hoff, Deut. Chem. Ges. Ber.* vii. 1571).

Ethyl malonate, like ethyl acetate, is capable of taking up 1 or 2 atoms of sodium. The reaction begins, with evolution of hydrogen, at ordinary temperatures, but is much retarded by the crust of sodium-compound which forms on the surface of the metal. This, however, may be prevented by adding absolute alcohol (2 vol. to 1 vol. of the ethyl malonate) which holds the sodium in solution. As the liquid cools, the sodium-compound of the malonic ether separates as a crystalline mass. If required to be free from alcohol, it must be heated to 150° on an oil-bath in a flask through which a brisk current of dry hydrogen is passed; if, however, it is wanted merely for synthetical purposes the presence of alcohol is for the most part not injurious, and the sodium compound may be subjected to the action of an organic halogen-compound as soon as the sodium is dissolved. The action is usually very energetic, but prolonged heating on the water-bath is necessary for its completion, which may be recognised by the fact that a drop of the mixture no longer blues moistened red litmus paper. Water is then added to dissolve the haloïd sodium-compound, and the oil which then separates is submitted to fractional distillation. The yield of the organic substituted malonic ether thus obtained is very nearly equal to that required by the following equation, in which X denotes an organic residue, and J the substituted halogen:

From this primary substitution-product, a secondary substitution-product may be obtained as in the case of the aceto-acetic ethers (p. 13), by replacing the remaining hydrogen-atom in the group CHX by sodium, and treating the product with another organic halogen, JY:

Ethylic Ethylmalonate, $\text{CH}(\text{C}^2\text{H}^5)(\text{CO}^2\text{C}^2\text{H}^5)^2$, thus prepared (with 15 grams of absolute alcohol, 2·3 sodium, and 16 $\text{C}^2\text{H}^5\text{J}$) distilled over between 208° and 210° . On saponifying this ether with potash, acidulating, and agitating with ether, ethylmalonic acid, $\text{C}^2\text{H}^5\text{O}^4$, separates in the form of a crystalline mass (Conrad, *Deut. Chem. Ges. Ber.* xi. 750).

ETHYLMALONIC ACID, $\text{C}^2\text{H}^5\text{O}^4 = \text{CH}(\text{C}^2\text{H}^5)(\text{CO}^2\text{H})^2$, metameric with pyrotartaric acid, and likewise called *α -isopyrotartaric acid*, was first obtained by Wislicenus in 1869 (*Liebigs Annalen*, cxlix. 220), who prepared it by treating ethyl bromobutyrate with potassium cyanide, and decomposing the resulting nitril with potash:

The acid thus obtained was a syrupy liquid. Subsequent experiments by Wislicenus a. Urech (*ibid.* clxv. 93) showed, however, that this syrup was a mixture of ethylmalonic acid with a small quantity of oxybutyric acid, and that the former may be separated in the crystalline state by leaving the syrupy acid at rest for some time, or better by converting it into a copper salt, purifying this salt by repeated crystallisation, and decomposing it with hydrogen sulphide.

Ethylmalonic acid is also produced from ethyl cyanobutyrate by the action of hydrochloric acid, or better of potash, since it is decomposed by hydrochloric acid in the subsequent evaporation. Its aqueous solution likewise decomposes when evaporated at too high a temperature, giving off carbon dioxide and butyric acid vapour. By slow crystallisation it is obtained in rhombic prisms, sometimes a centimeter long. From warm solutions, or by rapid crystallisation, it separates in feathery groups resembling sal-ammoniac. It dissolves easily in water, alcohol, and ether, melts at 111.5° , and decomposes without sublimation at 160° (or more quickly at 170°) into carbon dioxide and butyric acid.

Potassium ethylmalonate separates on mixing the alcoholic solutions of the acid and potassium hydroxide in small crystals, easily soluble in water, insoluble in alcohol. The sodium salt separates from concentrated solutions in granular masses, effloresces in contact with the air, and dissolves easily in water, more freely however in cold than in hot water (Markownikoff, *Liebig's Annalen*, clxxxii. 324). The barium salt is anhydrous, and crystallises in small needles. The calcium salt, $C^5H^5O^4Ca + H^2O$, crystallises in prisms, and is more soluble in cold than in hot water (Tupoleff, *Deut. Chem. Ges. Ber.* vi. 1440).

The zinc salt, $C^5H^5O^4Zn + 2\frac{1}{2}H^2O$, is especially characteristic; it dissolves but sparingly in water, whether hot or cold, and separates on evaporation as a crystalline powder made up of hexagonal or quadratic (rhombic?) plates. At the moment of its formation it dissolves more readily, and then separates on cooling (also by slow evaporation of cold solutions) as a crystalline crust (Markownikoff, *loc. cit.* According to Wislicenus a. Urech (*ibid.* clxv. 93) this salt, prepared by saturation or by precipitation, contains 3 mols. H^2O , and gives off only $2\frac{1}{2}$ mols. at 150° . The copper salt, $C^5H^5O^4Cu + 3H^2O$, forms blue-green tablets, which give off only $2\frac{1}{2}$ mols. H^2O at 150° . The lead salt, $C^5H^5O^4Pb$, is formed on precipitating a solution of the ammonium salt with lead acetate (W. and U.). The ethylic ether, $C^5H^5O^4(C^2H^5)^2$, already mentioned (p. 1258) may also be prepared by decomposing the silver salt with ethyl iodide, and forms a colourless liquid having a faint aromatic odour and boiling, after repeated rectification, at 199° – 201° (uncorr.) At a higher temperature (250° – 300°) it is partially decomposed with formation of ethyl butyrate (Markownikoff).

DIMETHYL-MALONIC ACID, $C^6H^6O^4 = CO^2H.C(CH^3)^2.CO^2H$. β -Isopyrotartaric acid (Markownikoff, *Deut. Chem. Ges. Ber.* vi. 1440; *Liebig's Annalen*, clxxxii. 324). This acid is formed by heating bromisobutyric acid with potassium cyanide, and decomposing the resulting nitril with potash:

It crystallises in transparent four-sided prisms, sparingly soluble in alcohol, moderately soluble in water, though less so than its isomerides, pyrotartaric and α -isopyrotartaric or ethyl-malonic acid. At about 120° it sublimes in white needles resembling sal-ammoniac, and at about 170° it begins to melt, and split up into isobutyric acid and carbon dioxide. It is not attacked by boiling dilute nitric acid, and scarcely at all by boiling chromic acid mixture. The mother-liquors obtained in its preparation appear to contain oxyisobutyric acid.

Sodium dimethylmalonate forms small efflorescent needles, slightly soluble in water. The barium salt is less easily soluble, and crystallises in stellate groups of thin needles. The calcium salt, like that of the α -acid, is moderately soluble in cold water, and is deposited from the solution on warming. It crystallises in nodules. The magnesium salt is crystalline, and easily soluble in water. The zinc salt, $C^6H^6O^4Zn.3H^2O$, obtained by saturating the acid with zinc carbonate, dissolves in 106 parts of water. It resembles the zinc salt of the α -acid, and decomposes in the same manner. The lead salt, produced on adding lead acetate to a hot solution of the sodium salt, forms white scales, insoluble in hot and cold water. The silver salt crystallises in small needles, insoluble in water and not affected by boiling.

METHYL MALONATE, $C^5H^5(CH^3)^2O^4$, obtained by the action of methyl iodide on silver malonate, is a mobile liquid having an ethereal odour, a specific gravity of 1.135 at 22° , boiling at 175° – 180° , and remaining fluid at -14° . Its vapour-density ($H=1$) is 66.79 (calc. 66). It is insoluble in water, by which, however, it is gradually decomposed; soluble in alcohol and ether. Ammonia converts it into malonamide (Osterland, *Deut. Chem. Ges. Ber.* vii. 1286).

Bromomalonic acids. The *monobrominated acid*, $\text{CHBr}(\text{COOH})^2$, obtained by the action of sodium-amalgam on an aqueous solution of the dibrominated acid, crystallises in large square plates, which dissolve easily in alcohol, forming acid ethyl bromomalonate, $\text{CO}^2\text{H}.\text{CHBr}.\text{CO}^2\text{C}^2\text{H}^5$, which may also be formed directly by the action of sodium-amalgam on an alcoholic solution of dibromomalonic acid (W. Petrieff, *Deut. Chem. Ges. Ber.* xi. 414).

Dibromomalonic acid, $\text{CBr}^2(\text{CO}^2\text{H})^2$, is formed in small quantity by the action of bromine, aided by heat, on an aqueous solution of malonic acid. The action is attended with evolution of hydrobromic acid, together with a large quantity of a colourless gas, and the principal product is a heavy neutral oil (Petrieff, *Ber.* vii. 400). According to van 't Hoff (*ibid.* viii. 355), the colourless gas is carbon dioxide, and the oily liquid consists of bromoform, which, however, is not a constant product of the reaction. A concentrated solution of malonic acid is attacked by bromine, even at ordinary temperatures, with considerable evolution of heat. At the end of the reaction, tribromoacetic acid separates as a white crystalline mass, and the mother-liquor contains dibromoacetic acid together with a very small quantity of dibromomalonic acid.

Hydroxymalonic or Tartronic acid, $\text{C}^3\text{H}^4\text{O}^6 = \text{CH}(\text{OH})(\text{CO}^2\text{H})^2$. This acid was discovered by Dessaignes, who obtained it by the spontaneous decomposition of nitrotartaric acid, and by the action of sodium on mesoxalic acid (v. 698). Demole (*Deut. Chem. Ges. Ber.* x. 1788) prepares it by gradually adding 20 grams of nitrotartaric acid to 60 c.c. alcohol of sp. gr. 0.925 in a porcelain basin on the water-bath, and leaving the liquid to cool after the evolution of gas has ceased. The crystals which separate are pressed between filter-paper and dissolved in water, the solution evaporated to dryness, and the residue treated with ether to separate oxalic acid. The acid thus obtained melts at $150^\circ\text{--}151^\circ$; Grimaux (*Ber.* x. 903), who prepared it by treating dibromopyruvic acid with baryta-water, found that it melted at $145^\circ\text{--}147^\circ$.

Tartronic acid is also produced by the action of silver oxide on monobromomalonic acid, and by heating the product of the action of potassium cyanide on dibromoacetic acid with potassium hydroxide (Petrieff, *Ber.* x. 414).

Dihydroxymalonic acid, $\text{C}^3\text{H}^4\text{O}^6 = \text{C}(\text{OH})^2(\text{CO}^2\text{H})^2$. The *barium salt* of this acid, $\text{C}(\text{OH})^2(\text{CO}^2)^2\text{Ba}$, is formed by boiling the solution of the dibromomalonate, and keeping it neutral by repeated addition of baryta-water. It then separates as a white crystalline salt, and crystallises from solution in a small quantity of hot water, in short white needles easily soluble in acids. The *calcium salt* is a white amorphous precipitate. The *silver salt* is a flocculent precipitate which dissolves in nitric acid and in ammonia, and decomposes with explosion when heated. The acid prepared from the barium salt by evaporation with hydrochloric acid and extraction with ether, crystallises, though at first with some difficulty, from its aqueous solution acidulated with hydrochloric acid. By recrystallisation from ether it is obtained in radiate groups of needles which melt at 96° , and dissolve readily in water, alcohol, and ether.

Mesoxalic acid, which is produced by oxidation of amidomalonic acid (iv. 115), has hitherto been regarded as $\text{C}^3\text{H}^2\text{O}^5$, its salts in the anhydrous state being represented by the formula $\text{C}^3\text{M}^2\text{O}^5$. According to Deichsel's analyses, however (vi. 825), all these salts, except the ammonium salt, contain at least 1 mol. H^2O , and might therefore be equally well represented by the formula $\text{C}^3\text{H}^2\text{M}^2\text{O}^6$, according to which the acid would be $\text{C}^3\text{H}^4\text{O}^6$, that is to say dihydroxymalonic acid. The ammonium salt, however, appeared to contain 1 mol. H^2O less than the other mesoxalates, a fact which if established would be inconsistent with this view of the composition of the acid; but Petrieff, by saturating an aqueous solution of mesoxalic acid with ammonium carbonate, and evaporating the solution in a vacuum, has obtained ammonium mesoxalate in colourless needles analogous in composition to the other mesoxalates, that is to say, represented by the formula $\text{C}^3(\text{NH}^4)^2\text{O}^6.\text{H}^2\text{O}$ or $\text{C}^3.\text{H}^2(\text{NH}^4)^2\text{O}^6$. Deichsel's salt, which formed granular crystals turning red in the air, was probably the corresponding monamide, $\text{C}^3\text{N}^2\text{H}^3\text{O}^5 = \text{C}^3\text{H}^2(\text{NH}^4)^2\text{O}^6 - \text{H}^2\text{O}$; and this view is in accordance with the manner in which it was prepared, namely, by the action of ammonia on an alcoholic solution of mesoxalic acid, as such a solution would probably contain ethyl mesoxalate, which with ammonia would yield the amide. The property which Deichsel's compound exhibits, both in the solid state and in solution, of turning red in the air, affords another argument in favour of this view of its constitution, the same property being exhibited by the diamide which Petrieff obtained by the action of ammonia on ethyl mesoxalate.

That mesoxalic acid really contains two hydroxyl-groups attached to the same carbon-atom is shown by the formation of diethylic diacetomesoxalate, $\text{C}(\text{OC}^2\text{H}^5\text{O})^2(\text{COOC}^2\text{H}^5)^2$. This ether, prepared by heating 2 mols. acetyl chloride

with 1 mol. ethylmesoxalate for an hour in the water-bath, crystallises in long white needle-shaped crystals, melting, with partial decomposition, at 145° , partly decomposed by solution in water, completely by agitation with a weak alcoholic alkaline ley. The diacetomesoxalic acid thereby produced crystallises in needles, melts at -130° , and decomposes at a higher temperature. Its alkali-salts are crystallisable and easily soluble in water; the silver and lead-salts are insoluble pulverulent precipitates. Finally, mesoxalic acid agrees in all its properties with the dihydroxymalonic acid which Petrieff obtained by the action of baryta-water on barium dibromomalonate (Petrieff, *loc. cit.*)*

MALT. On the preparation of Malt extract, see Jassey (*N. Jahrb. Pharm.* xxxix. 150; *Jahresb. f. Chem.* 1873, 1076).

On the Malt-test and Mash-process, see Lintner (*Dingl. pol. J.* cxxviii. 182; *Jahresb. f. Chem.* 1875, 1131); also W. Schultze (*Dingl. pol. J.* cxxxi. 53; *Chem. Soc. J.* xxxiv. 569).

MALTOSE. See SUGARS.

MALYLURAMIDE and **MALYLUREIDIC ACID.** See URIMIDOSUCCIN-AMIDE and URIMIDOSUCCINIC ACID, under SUCCINIC ACID.

MANDELIC ACID, $C^6H^5O^3 = C^6H^5.CH(OH).CO^2H$. This acid is formed by reduction of phenylglyoxylic acid, $C^6H^5.CO.CO^2H$, with sodium amalgam (Schwebel, *Deut. Chem. Ges. Ber.* x. 2045). On its preparation from benzoic aldehyde, acid sodium sulphite, and potassium cyanide, see O. Müller (*vi.* 767). It melts at 115° (Müller, *Arch. Pharm.* [3], ii. 385).

On *Mandelic Chloralide*, see CHLORALIDE (p. 445).

MANGANESE. Ores. The lithia psilomelane of Salm-Chateau in Belgium has been analysed by H. Laspeyres (*J. pr. Chem.* [2], xiii. 1) with the following results:

1. Mean of two analyses. 2. Reduced to 100, the excess being distributed nearly in proportion to the values of the several constituents:

	SiO ²	CuO	CoO	CaO	MgO	Al ² O ³	Fe ² O ³	MnO
(1.)	0.132	0.080	0.119	0.262	0.078	2.525	0.173	75.741
(2.)	0.129	0.078	0.116	0.255	0.026	2.458	0.168	73.728
	K ² O	Na ² O	Li ² O	O	H ² O			Sp. gr.
(1.)	3.379	0.835	0.481	14.658	3.764 =	102.227	4.328	at 18.2°
(2.)	3.289	0.813	0.468	14.658	3.764 =	100	4.277	at 16.8°

From this analysis, Laspeyres infers that psilomelane is a manganate of the bases $3R'O$, $3R''O$ and $R'''O^3$, in which $R' = Mn, Cu, Co, Ca, Sr, Mg$; $R'' = H, K, Na, Li$; $R''' = Al$ and Fe , the corresponding manganic acid being H^4MnO^5 or $2H^2O.MnO^3$. The older analyses of psilomelane (iii. 813) exhibit considerable divergence from this formula, but the differences range themselves about equally on both sides of it, so that it may be regarded as representing the average composition of the mineral.

Laspeyres (*ibid.* 176) has further extended this mode of representation to all varieties of manganese peroxide, natural and artificial, and classifies them as in the following table, the manganese of the base (bivalent) being denoted by mn , and that of the acid (sexvalent) by Mn :

Pyrolusite and Polianite, $mnMnO^4$	type H^2MnO^4
Psilomelane, H^2mnMnO^5	" H^1MnO^5
Grorollite, H^1mnMnO^6	}	" H^6MnO^6
Varvicite, $H^2mn^2MnO^6$		
Braunite (Marcelin), mn^2MnO^6		
Cupreous Manganese, $H^1R''mnMnO^7$, where $R'' = mn, Cu, \&c.$	" H^5MnO^7
Manganite, $H^4mn^3MnO^8$	}	" $H^{10}MnO^8$
Wad, $H^6mn^2MnO^8$		
Hausmannite, mn^3MnO^8		
Earthy Cobalt, $H^3R'''mnMnO^9$	}	" $H^{12}MnO^9$
$R''' = Co, Cu, \&c.$		
Crednerite, $Cu^3mn^3MnO^9$		
Pyrochroite, H^2mnO^2	" $x(H^2O)$

Laspeyres (*ibid.* 215) has also discussed the constitution of aluminiferous manganese ores, basing his calculations on an exact analysis of psilomelane with hæmatitic struc

* The discussion respecting the composition of mesoxalic acid is exactly analogous to that which has taken place respecting glyoxylic acid, $C^2H^2O^3$ or $C^2H^1O^4$ (p. 891).

ture from Kaltebsen near Eisenfeld. This mineral occurs on lepidocrocite, limonite, or quartz, especially on the former, with which it is very intimately interstratified:

SiO ²	CuO	CoO	CaO	BaO	MgO	Al ² O ³	Fe ² O ³	MnO
0.365	1.150	0.467	0.096	0.193	0.197	6.322	3.769	67.870
K ² O	Na ² O	Li ² O	O	H ² O	Sp. gr.			
0.384	0.389	0.210	13.662	6.420	= 101.499		4.361 at 14°.	

Also traces of strontium, but no nickel or vanadium.

The ferric oxide may be deducted as lepidocrocite, also the silica. The alumina, on the other hand, must be regarded as an essential constituent of the mineral, inasmuch as the quantity of silica present is not sufficient to justify the supposition of its existence in the form of admixed silicate, and, on the other hand, its solubility in dilute hydrochloric acid is inconsistent with its presence as corundum, diaspore, &c. Admitting that there is an excess in the estimation of the bases (from admixed silicate) and of the water (partly hygroscopic, as the mineral left in the exsiccator for sixteen days lost 0.358 per cent.), the analyses lead to the supposition that the mineral is a manganate derived from the acid $H^{10}Mn^2O^{11}$, and intermediate between those of the type H^4MnO^5 (psilomelane) and those of the type H^6MnO^6 (braunite, &c.) Laspeyres proposes to designate it as *Calvonigrite*.

Among former analyses of aluminiferous manganese ores, only that by Winkler (vii. 766) of a *lithiophorite* from Schneeberg appears to belong to a definite manganate of the type $H^{10}MnO^{11}$.

A *cupreous manganese* from Chile, occurring intergrown with chrysocola, and possibly identical with Richter's pelocnite (iii. 814), has been analysed by Frenzel (*Jahrb. f. Min.* 1873, 801). Sp. gr. 2.95 at 20°. a. Analysis. b. Composition after deduction of the residue.

A considerable number of manganese ores from the Arschitzaberg in the Bukowina, which have lately acquired great industrial importance, have been analysed by Morawski a. Stingl (*J. pr. Chem.* [2], xv. 228):

1. Soft, friable, fissured, strongly staining bluish-black masses. 2. Botryoidal, compact scaly masses having a strong lustre. 3. Stalactitic crust on a massive ore. 4. Micro-botryoidal, with irregularly conchoidal, highly lustrous fracture. 5. Principal mass of the commercial ore, compact, massive, bluish-black. 6. Porous mass, made up of quartz-veins and a yellow earthy substance consisting of iron phosphate and manganese dioxide. 7. Shaly masses, the layers of which alternate with the variety described under No. 4. 8. Transformation-product of No. 9. 9. Crystalline rose-red siliceous manganese often coated with an amorphous black-brown product of transformation (No. 8). 10–12. Silicates from Nos. 4, 5, and 7, obtained by decomposing considerable quantities of these ores with hydrochloric acid:

(¹) MnO².

(²) Alkalis.

	SiO ^a	MnO	FeO	CaO	MgO	Na ^a O	P ^a O ^s	Sp. gr.
9.	48.11	43.17	4.31	3.00	1.73	0.13 (1)	trace =	100.45
10.	85.40	5.82	6.67	1.87	0.75	0.30	— =	100.51
11.	85.93	7.80	3.16	1.83	0.29	0.81	— =	99.82
12.	99.15	0.11	1.02	trace	trace	—	— =	100.28

(1) Alkalis.

In the following calculation of the numbers 1 to 5, the silicate, soluble silicic acid, and phosphoric acid are deducted, whilst the dioxide and monoxide of manganese, together with the ferric oxide, lime, magnesia, alkalis, and water are regarded as essential constituents of the ores. Calculating in this way and reducing all the metal-atoms to bivalence, the following proportions are obtained :

	(1)	(2)	(3)	(4)	(5)	
R''	1	1	1	1	1	
O.	1.79	1.71	1.68	1.71	1.60	
or:						Mean
R''	3	3	3	3	3	3
O.	5.37	5.15	5.05	5.15	4.80	5.10

The first series of numbers shows that these ores must be regarded as psilomelanes, a conclusion which agrees with their other constituents and with their properties; and the second series shows that they may be included in the formula H^4MnO^5 laid down by Laspeyres (p. 1261), if this formula be generalised in the form R^3O^5 , by writing $R'' = H^2$. The silicates mixed with the samples 4 and 5 consist, as shown by analyses 10 and 11 compared with 9, of altered rhodonite (v. 106), which, as manganous carbonate is not found in the neighbourhood of these ores, may be regarded as the original mineral from which the psilomelanes have been formed. The residue No. 12 from No. 7, consists essentially of quartz.

Reactions. 1. *Precipitation as Dioxide.*—From a solution of manganous chloride mixed with a certain amount of ferric chloride, the whole of the manganese may be precipitated as dioxide by a sufficient excess of solution of *calcium hypochlorite* or *bromine-water*, the solution being heated to 140°–160° F. (60°–71° C.), an excess of calcium carbonate added, and the mixture well stirred. Without the ferric salt, the precipitation of the manganese as dioxide is incomplete. Zinc chloride may be substituted for ferric chloride, but neither aluminium chloride nor barium chloride has the same effect (J. Pattinson, *Chem. Soc. J.* xxxv. 365).

Manganese may also be precipitated as dioxide from acetic acid solution by *hydrogen dioxide*. In applying this method to analytical purposes, the solution should be warm and carefully neutralised, if necessary, with ammonia. Iron if present must be previously removed by precipitation with sodium acetate (Rosenthal, *Dingl. pol. J.* ccxxv. 154).

2. Manganous oxide, either precipitated or crystalline, and precipitated manganese dioxide, are converted by yellow *ammonium sulphide* into sulphides (Prioznik, *Deut. Chem. Ges. Ber.* 1873, 1291).

3. By fusing any manganese compound (free from iron) with silica and baryta or a mixture of soda and lime, a blue compound is obtained, the intensity of the colour of which depends on the quantity of manganese used, but it may be changed to green or violet by adding different quantities of alkali or silica. The blue compound, which appears to be a silico-manganate of the alkaline earths, is destroyed by reducing agents, by acids, and after some time by water, but resists a temperature of 1100°. This reaction is proposed as a means of detecting traces of manganese in minerals (G. Bong, *Bull. Soc. Chim.* [2], xxix. 199).

4. *Detection in Plant-ashes.*—According to G. Campani (*Gazz. chim. ital.* 1876, 464) manganese occurs in plant-ashes chiefly in the form of phosphate. On treating the ashes with water and then with nitric acid free from phosphoric acid, there remains after evaporation of the latter solution, a residue which is amethyst or violet coloured according to the quantity of this metal present. This reaction will serve to detect 1 pt. of manganese in 1000 pts. of ash.

Estimation. 1. *By Electrolysis.*—The manganese solution is placed in a platinum crucible, which serves as positive electrode, the negative being formed of a spiral of platinum wire. The manganese is deposited on the crucible in the form of dioxide. The accuracy of the result is not impaired by the presence of copper, cobalt, nickel, zinc, magnesium, aluminium, or of alkalis or alkaline earths, but iron-salts must be previously removed. By this method 0.0005 grm. of Mn^2O^4 can be easily estimated and 0.000025 grm. detected by the rose coloration which it exhibits (A. Riche, *Compt. rend.* lxxxv. 226; *Chem. Soc. J.* xxxiv. 750).

2. *By precipitation as Oxalate.*—The solution is mixed with a strong solution of potassium oxalate (1 : 6), and then with strong alcohol or acetic acid, whereupon the whole of the manganese is precipitated as manganous oxalate, mixed, however, with potassium oxalate, which must be removed by washing. The best mode of proceeding is to add to the concentrated solution of the manganese salt, first potassium oxalate and then strong acetic acid, as long as a precipitate continues to form. The presence of hydrochloric acid, ammonium chloride, or potassium chloride, in considerable quantity, renders the results inexact (Classen, *Zeitschr. anal. Chem.* 1877, 315, 470).

If the solution, after addition of the potassium oxalate, be rendered ammoniacal and then mixed with ammonium sulphide, the precipitated manganous oxalate will be converted into anhydrous manganous sulphide. The presence of ammonium chloride does not interfere with the reaction (Classen, *ibid.* 319).

3. The following volumetric method, founded on the precipitation of manganese as dioxide in presence of ferric chloride (p. 1263), is recommended by J. Pattinson (*Chem. Soc. J.* xxxv. 368). The reagents employed are: (1). The clear liquid obtained by decantation from a 1·5 per cent. solution of bleaching powder; (2) light granular calcium carbonate obtained by precipitating an excess of calcium chloride with sodium carbonate at 180° F.; (3) a 1 per cent. solution of ferrous sulphate in dilute (1 in 4) sulphuric acid; (4) a standard solution of potassium dichromate equivalent to 1 part of iron in 100 of solution. The application of the process to manganiferous iron ores is as follows: 10 grains of the ore, dried at 212° F., are dissolved in a 20-oz. beaker in about 100 fluid grains of hydrochloric acid (sp. gr. 1·18). Calcium carbonate is then added until the free acid is neutralised and the liquid turns slightly reddish. 6 or 7 drops of hydrochloric acid are now added, and 1000 grains of the bleaching-powder solution, or 500 grains of saturated bromine-water, and boiling water is run in until the temperature is raised to 140° to 160° F.; 25 grains of calcium carbonate are added, and the whole is well stirred. If the supernatant solution has a pink colour, the permanganate is reduced by a few drops of alcohol. The precipitated oxides of iron and manganese are filtered off and washed; 1000 grains of the acidified ferrous sulphate solution are carefully measured into the 20-oz. beaker already used; and the filter with its washed contents is added. A certain quantity of the ferrous sulphate is oxidised by the MnO_2 ; this quantity is estimated with the standard dichromate solution, and the quantity of MnO_2 can then easily be calculated. The iron present must be at least equal in weight to the manganese during the precipitation, in order to ensure the absence of lower oxides. The method is applicable to the analysis of spiegeleisen, ferro-manganese steel, and manganese slags.

For other volumetric methods, see Morrell (*Amer. Chem.* vi. 45); Morawski a. Stingl (*J. pr. Chem.* [2], xviii. 96; *Chem. Soc. J.* xxxvi. 277); Kessler (*Zeitschr. anal. Chem.* 1879, 1; *Chem. Soc. J.* xxxvi. 342); and for the estimation of manganese in Iron and Steel, see pp. 1103 and 1104 of this volume.

Alloys. Terrell (*Bull. Soc. Chim.* [2], xxi. 289) has obtained alloys of manganese by the action of certain metals on anhydrous manganous chloride (prepared by igniting the well-dried hydrated chloride in a stream of hydrochloric acid gas). The *aluminium alloy* Mn^3Al scratches glass, and has a fracture like that of amalgamated zinc. The *magnesium alloy* is less hard. The action of zinc on manganous chloride is attended with explosion.

Manganese-bronze.—An alloy thus named, and said to be a compound or mixture of ordinary bronze with manganese, is manufactured by the White Brass Company in Southwark. Its fracture resembles that of fine-grained steel; it is capable of acquiring considerable hardness, and in colour and lustre it resembles good gun-metal. At a red heat, it can be forged, rolled, and drawn into wire and tubes. Experiments on the tenacity of several bars of this metal gave for the cast material an absolute tenacity and extensibility equal to that of bar-iron of medium quality, while its limit of elasticity was higher. Forged samples excelled the best bar-iron in tenacity and extensibility, and were in these respects equal to soft steel (*Dingl. pol. J.* cccxi. 384).

Alloys of Manganese and Iron.—Numerous analyses of spiegeleisen (with less than 26 per cent. Mn) and ferromanganese (with more than 26 per cent. Mn) are given under Iron (pp. 1109–1111).

Rosenthal (*Dingl. pol. J.* cccxiv. 654) has analysed two specimens of English manganiferous iron prepared by a new process, with the following results:

	Fe	Mn	Si	C	S	P
I.	58·54	30·14	9·775	1·739	—	0·051
II.	60·10	28·89	8·812	2·131	0·009	0·048

On fusing the first of these alloys in the cupola-furnace, nearly all the silicon and half the manganese were eliminated, and the proportion of carbon was increased by 5 per

cent. The mass, which was at first white and brittle, then exhibited the ordinary properties of spiegeleisen.

According to P. Ward (*ibid.* cccxvi. 53), the blast-furnace of Rechitza, in Austria, produces from 1400 kg. of manganese ore only 50 kg. ferromanganese containing 35 per cent. manganese, so that of the manganese introduced into the furnace-charge only 4.5 per cent. is obtained in the metallic state. According to Blake (*ibid.* 54), the combination of the manganese with the iron is facilitated by a large addition of limestone (43 per cent. limestone to 57 per cent. manganese ore), whereby a slag is produced containing 25 per cent. manganous oxide and 33.5 per cent. lime. Ward, on the other hand, obtained in a charcoal blast-furnace 10.5 meters high, and having a tuyere 76 mm. wide, a ferromanganese containing 67.2 per cent. manganese, so that 58.1 per cent. of the manganese employed was obtained in the metallic state. The fuel used was a mixture of 1 pt. coke and 3 pts. charcoal, and the pressure of the blast was 0.28 on 1 c.c.

With regard to the use of manganese in iron metallurgy, Gautier is of opinion that the manganese acts as a reducing agent, removing iron oxide from the metallic iron, and preventing it from becoming 'hot short.' Henderson's process (vii. 699) yields a manganese-iron containing 25 to 75 per cent. of manganese. The amount of manganese required for reduction is usually 1 per cent., if added as manganese-iron. The resulting iron is extremely soft; its coefficient of elasticity is 22 to 25 kilos.; its resistance to strain, 45 kilos.; and its expansion, for 200 mm., 20 to 25 kilos. It does not become hard by tempering. The product of the resistance to strain multiplied by end-expansion is nearly 7 times that of ordinary iron, and more than twice that of hard steel. This iron is used in plating ships. Addition of $1\frac{1}{2}$ per cent. of manganese to inferior iron counteracts the influence of phosphorus. Addition of 1 per cent. of manganese to cast steel gives it great resisting power (*Chem. Centralbl.* 1877, 204).

See also Troost a. Hautefeuille (p. 1111).

Boride. A compound of manganese and boron in equivalent proportions (Mn^3B^2) is obtained by heating boric oxide with manganese carbide, Mn^3C . It forms small grey-violet crystals, which dissolve in acids, with evolution of hydrogen, and are but slowly attacked by gaseous hydrogen chloride at a low red heat. It decomposes water at 100°, alkaline liquids at a lower temperature. Moist mercuric chloride decomposes it in a few minutes, forming manganous chloride, boric oxide, and hydrochloric acid. It is also decomposed by moist mercuric cyanide (Troost a. Hautefeuille, *Compt. rend.* lxxxi. 1263).

Chlorides. Nicklès in 1864, by passing gaseous hydrogen chloride into a well-cooled mixture of manganese dioxide with ethyl oxide, obtained a green, very unstable liquid to which he assigned the composition $\text{MnCl}^{4.12}(\text{C}^2\text{H}^5)^2\text{O} \cdot 2\text{H}^2\text{O}$ (vi. 804), and, according to W. W. Fisher (*Chem. Soc. J.* xxxiii. 409), the tetrachloride of manganese contained in this compound is also produced when either of the higher oxides of manganese, Mn^2O^3 , Mn^3O^4 , or MnO^2 , is dissolved in strong hydrochloric acid. The brown liquids thereby formed decompose spontaneously at ordinary temperatures, with evolution of chlorine and formation of manganous chloride, MnCl^2 , and each of them, when diluted with water, yields a precipitate of hydrated manganese dioxide. The analysis of the precipitate thus formed, combined with estimations by the iodometric method of the quantity of loosely combined chlorine (*i.e.* chlorine in excess of that required to form MnCl^2), led to the conclusion that the ratio of the manganese precipitated from the solution by water to the loosely combined chlorine is 1 : 2, and consequently that the formula of the higher chloride is MnCl^4 .

Pickering, on the other hand (*Chem. Soc. J.* xxxv. 661), infers from experiments made in a similar manner:

1. That when a solution of manganese dioxide in strong hydrochloric acid is diluted with water, a mixture of oxide is precipitated, which is not of definite composition, and that it may generally be represented by formulæ intermediate between $16\text{MnO}^2 \cdot 5\text{MnO}$ and $36\text{MnO}^2 \cdot 5\text{MnO}$.

2. That the manganese contained in this precipitate as dioxide bears to the loosely combined chlorine of the higher chloride from which it is precipitated the ratio of 1 : 2 atoms, and consequently that the total manganese precipitated bears to this chlorine the ratio of about 1 : 1.64 atoms.

3. That when the dioxide is dissolved in weaker acids, the amount of the higher chloride formed is not appreciably diminished.

4. That an increase in the actual amount of the aqueous acid employed for the solution is prejudicial to the stability of the higher chloride formed,

5. That the higher chloride formed in this reaction is Mn^2Cl^6 , and not MnCl^4 , the solution of the dioxide and sesquioxide by hydrochloric acid, and the subsequent decomposition of the sesquichloride formed, being represented by the following equations:

the reactions thereby represented taking place simultaneously, but in various proportions, and the average values for x and y being about 4 and 1 respectively.

Oxides. *Manganous Oxide*, MnO , occurs native in a manganiferous dolomite at Langbanshyttan, Wermland, in small shining irregular lumps, green by reflected, red by transmitted light; they contain 98 per cent. MnO , the remainder being converted into manganite (Blomstrand, *Deut. Chem. Ges. Ber.* viii. 120).

Manganic Hydroxide occurs mixed with franklinite in pseudomorphs after calcite (locality not stated):

H ² O	Mn ² O ³	Fe ² O ³ (?)	ZnO	CaO	MgO	K ² O, Na ² O	CO ²	SiO ²
11.293	58.387	14.627	5.285	4.739	1.253	traces	3.438	0.170 = 99.242.

(?) Other determinations gave 12.777 and 16.129 per cent.

Dioxide, MnO^2 .—This oxide in the anhydrous state is usually regarded as an indifferent oxide. Frémy, however (*Compt. rend.* lxxxii. 1231), from an examination of its behaviour with acids and bases, infers that it behaves sometimes like a saline oxide, sometimes as an acid, sometimes as a base. Its resemblance to a saline oxide is seen in its reaction with melting potash, by which it is converted into potassium manganate and manganous hydroxide:

This formation of potassium manganate, without addition of oxygen from without or evolution of hydrogen, is characteristic of the dioxide, and serves to distinguish it from the other oxides of manganese, which yield manganates only under the influence of oxidising agents. The acid character of the dioxide is shown by its uniting with bases, forming compounds like those obtained by Weldon, viz. CaMnO^3 or $\text{CaO} \cdot \text{MnO}^2$, and $\text{CaH}^2 \cdot 2\text{MnO}^3$ or $\text{CaO} \cdot \text{H}^2\text{O} \cdot 2\text{MnO}^2$ (*Jahresb. f. Chem.* 1874, 1098). Its *basic* character has been especially studied by Frémy, who has succeeded, though with difficulty, in converting it into a *sulphate*, $\text{MnO}^2 \cdot 2\text{SO}^3$, by acting on its hydrate with strong sulphuric acid. A better mode of preparing this salt consists in decomposing potassium permanganate with a considerable excess of sulphuric acid. 100 grams of permanganate are treated with a cold mixture of 500 grams of sulphuric acid and 150 grams of water, whereupon an oily layer of permanganic acid separates, which gradually decomposing, forms, at the end of a few days, a deep yellow liquid from which crystals can be obtained.

This salt, which Frémy at first regarded as a sulphate of the sesquioxide, is deliquescent, soluble in sulphuric acid, and decomposed by water, forming at the same time a hydrate of the dioxide, $\text{MnO}^2 \cdot 2\text{H}^2\text{O}$. The liquor resulting from this decomposition contains no manganese. The yellow solution, exposed to the air or saturated with potassium sulphate, deposits a black basic sulphate, $\text{MnO}^2 \cdot \text{SO}^3$, which when redissolved in sulphuric acid reproduces the yellow sulphate. Certain salts, such as manganous sulphate, potassium sulphate, &c., combine with the yellow sulphate, forming well-crystallised double salts. The salt $\text{MnO}^2 \cdot \text{MnO}^3 \cdot (\text{SO}^3)^3 + 9\text{H}^2\text{O}$ separates in hexagonal plates on adding a strong solution of manganous sulphate to a solution of the salt $\text{MnO}^2 \cdot 2\text{SO}^3$ in a large excess of sulphuric acid. It dissolves in dilute sulphuric acid, forming a rose-coloured solution. The same compound is formed by the action of strong sulphuric acid on manganese dioxide, as shown by the red colour of the resulting solution; also by the cautious addition of reducing agents, such as alcohol, to the solution of the yellow sulphate. The double salt might of course be regarded as containing manganese sesquioxide; but the existence of a corresponding potassium salt, and the fact that when decomposed by an alkali it gives a precipitate from which ammonia dissolves manganous oxide, leaving a residue of dioxide, are sufficient to show that the manganese exists in the salt in two different states of oxidation. Manganese sesquioxide is not broken up by the action of ammonia.

Regeneration.—A description of Weldon's process for the recovery of the dioxide from the residue of the chlorine manufacture is given in *Dingl. pol. J.* cccxix. 54; *Chem. Soc. J.* xxxiv. 938).

On the precipitation of Manganese as Dioxide, see pp. 1265, 1266.

A black *hydrated dioxide*, $3\text{MnO}_2 \cdot 2\text{H}_2\text{O}$, which appears to have been previously observed by Berthier and Dingler, separates on gradually adding water to a mixture of potassium permanganate with strong sulphuric acid (Rammelsberg, *Deut. Chem. Ges. Ber.* viii. 232).

Manganates.—The preparation of barium manganate of fine green colour for use as a pigment is described by Böttger (*N. Rep. Pharm.* xxv. 115). See BARYTAGREEN, p. 151 of this Supplement.

Potassium Permanganate.—According to Brücke (*Zeitschr. anal. Chem.* 1877, 231), the absorption-spectrum of this salt in dilute solutions exhibits five distinct bands, the first near D, the last near F, and the middle ones between E and b.

Potassium permanganate, when heated to redness, gives off oxygen and is converted into a salt having the composition $\text{K}^2\text{Mn}^2\text{O}^5$:

This compound is a brown-black powder, which is resolved by water into free potash and an acid salt:

(Rammelsberg, *loc. cit.*)

On the use of Potassium Permanganate as a disinfectant, see Schröter (*Dingt. pol. J.* ccix. 375; *Jahresb. f. Chem.* 1876, 1128).

On *Manganese Phosphates*, see PHOSPHATES.

Silicate. Rhodonite from a vein of crystalline limestone at Belec near Husinec in the Bohemian Forest is described by Helmhacker (*Min. Mitth.* 1873, 278).

On *Bustamite*, from Rezbanya in Hungary, see p. 354 of this volume; on *Jeffersonite* from Franklin, New Jersey, see vii. 709.

Sulphide. Anhydrous manganous sulphide, MnS , may be prepared by boiling a solution of a manganous salt with potassium oxalate, then adding ammonia and ammonium sulphide. The presence of sal-ammoniac does not interfere with the reaction (*Zeitschr. anal. Chem.* 1877, 319).

MANGANESE-GARNET. This mineral occurs, together with ottrelite, at Salm-Château, near Ottrez in Belgium, in dodecahedrons $\infty \bar{O}$, a millimeter in size, containing, together with manganese and aluminium, only 4.49 per cent. FeO , and 1.9 per cent. Fe^2O^3 (L. de Koninck, *Jahrb. f. Min.* 1873, 163, 219).

MANGANESE-TANTALITE. See TANTALATES.

MANNITOL, $\text{C}^6\text{H}^{14}\text{O}^6$. *Mannite*.—According to Müntz (*Compt. rend.* lxxvi. 649; lxxxii. 210), this substance occurs, together with glucose and trehalose, in the higher kinds of fungi; some species, as *Agaricus muscarius*, contain only trehalose; in others, again, as *Agaricus campestris*, mannitol is the only kind of sugar present. Mannitol is also found in the alcoholic extract of the sugar-cane, and appears to be formed in the plant, together with a reducing, optically inactive sugar, by the action of vegetable organisms on cane-sugar.

On the relations of Mannitol to Polarised Light, see LIGHT (pp. 1216, 1221).

On the Schizomycetic Fermentation of Mannitol, see FERMENTATION (p. 777).

On the Heat of Formation of Nitromannitol, see HEAT (p. 973).

Mannitan, $\text{C}^6\text{H}^{10}\text{O}^4$, may be prepared by heating mannitol for an hour or two in an oil-bath to 295° with half its weight of water, the conversion being complete; also by heating mannitol to 120° with half its weight of strong sulphuric acid, saturating with barium carbonate, exhausting with alcohol, and evaporating. Its production in this manner depends on simple dehydration, and not on the decomposition of previously formed mannito-sulphonic acid. The decomposition of barium mannito-sulphonate by water is, indeed, never complete, a fact which may be due to the occurrence of an isomeric compound. Mannitan, heated for a considerable time with dilute sulphuric acid or baryta-water, does not yield any perceptible quantity of mannitol. The specific rotatory power of mannitan for the transition-tint is $[\alpha]_D = +36.5^\circ$.

Nitromannitan, $\text{C}^6\text{H}^9(\text{NO}^2)\text{O}^4$, is obtained by adding 1 pt. mannitan to a mixture of 10 pts. sulphuric acid (of 60° Bm.) and $4\frac{1}{2}$ pts. nitric acid (sp. gr. 1.5), leaving the mixture at rest, and keeping it cool; then throwing it into a large quantity of water, dissolving the deposit in ether, and leaving the ether to evaporate. In ether-alcoholic solution it exhibits a rotatory power $[\alpha]_D = +53.26^\circ$. By boiling alkalis it is converted into a blackish, gummy, non-explosive mass; by ammonium sulphhydrate into mannitan (Vignon, *Ann. Chim. Phys.* [5], ii. 433).

* The termination 'ol' is now applied to all compounds of alcoholic character (see NOMENCLATURE).

Mannitone, $C^6H^{12}O^5$, is produced by heating mannitol with water for three hours to 180° , whereby there is obtained, together with brownish products of decomposition, a viscid mass which may be easily separated from undecomposed mannitol by solution in alcohol. By purifying this solution with animal charcoal, evaporating, drying the remaining liquid at 120° , and leaving the resulting syrup to itself, small crystals are obtained, which must from time to time be separated from the soluble mother-liquor by means of alcohol, and finally purified by dissolving them in water, decolorising the solution with animal charcoal, and evaporating to the crystallising point. Mannitone does not reduce copper-solution; it has a sweet taste, and a rotatory power $[\alpha]_D = -25^\circ$. By heating to 295° it is converted into mannitan.

The syrupy mother-liquor, which no longer deposits crystals, yields, by repeated solution in alcohol, filtration through animal charcoal, evaporation, and finally heating to 120° , a light brownish viscid mass which does not yield either mannitol or mannitan when boiled with sulphuric acid or baryta-water. It forms a sulphonic acid whose barium salt is easily soluble; with nitric acid, a product resembling nitromannitan; and when heated to 295° is converted into mannitan. It tastes bitter-sweet, does not exert a reducing action, is not fermentable, is levogyrate: $[\alpha]_D = -5.59$. It has the composition $C^{12}H^{28}O^{21} = 2C^6H^{14}O^6 - H^2O$, and is, therefore, the ether of mannitol (Vignon, *loc. cit.*)

Mannitic Ethers containing Acid Radicles. It has already been mentioned (p. 1223) that the several mannitic ethers prepared from glucose and from invert-sugar have the same rotatory powers as the corresponding derivatives of mannitol from the ash-tree. The hexaceto-derivative of glucose-mannitol has, moreover, the same crystalline form as the corresponding ether of ash-mannitol, being orthorhombic, with a prismatic angle of $75^\circ 40'$, while that of the ash-mannitol ether is $73^\circ 45'$; the angle between the dome-faces (012) is $78^\circ 40'$ in the former, $78^\circ 30'$ in the latter; and the angle between prism and dome is $112^\circ 2'$ in the former, $112^\circ 10'$ in the latter. The mannitol obtained from the β -glucose of milk-sugar appears also to be identical with that from the ash (Bouchardat, *Compt. rend.* lxxiv. 34).

MARGAROLIC ACID, syn. with ELÆOMARGARIC ACID (p. 706).

MARMATITE, Zn^3FeS^4 , is found in quartz in the iron mines of Rio and Tarre della Marina, Elba, crystallised in cubes in combination with the tetrahedron, the cubic faces being rough, and the tetrahedral faces smooth. The exterior of the crystals has a dull brown to black colour, whilst the interior is reddish-brown with a metallic lustre. Streak reddish. Hardness = 4. Sp. gr. = 3.92 (G. Roster, *Jahrb. f. Min.* 1877, 531).

MATECERIC ACID. An acid obtained from the wax of the Yerba Maté (*Plex paraguayensis*). When the solution obtained by exhausting the leaves of this plant with ether, or better with ether-alcohol, is treated with lime, then filtered and evaporated, a waxy residue is left, which may be freed from chlorophyll by treating its ethereal solution with animal charcoal. This solution, agitated with water to remove caffeine and other substances, and evaporated, leaves the pure waxy matter, which, when boiled with aqueous potash, partly dissolves, leaving a residue soluble in ether, much more butyraceous than the original substance, and separable by treatment with alcohol into an insoluble yellow transparent substance, and a soluble portion which is white and melts at 55° . On neutralising with hydrochloric acid the alkaline solution obtained by saponification of the wax, mateceric acid is obtained as a white precipitate which has acid properties, and is soluble in ether and in boiling alcohol. It melts at 105° – 110° , and has a density of 0.8151 at 26° . From the results of its analysis, it does not appear to belong to the acetic series, but its molecular weight is very high (Arata, *Gazz. chim. ital.* 1877, 366).

MATICO-STEAROPTENE. This substance separates from the volatile oil of matico when cooled to a few degrees below 0° , in crystals 2 cm. long and 5 mm. thick, belonging to the trapezo-tetartohedral division of the hexagonal system, and having the axial ratio $a : c = 1 : 0.31605$. It melts at 103° . The crystals exhibit a weak negative double refraction. Indices of refraction:

for the Lithium line:	extraordinary ray	=	1.5404,	ordinary ray	=	1.5415
" Sodium "	" "	=	1.5436	" "	=	1.5447
" Thallium "	" "	=	1.5476	" "	=	1.5488

Respecting the optical rotatory power, see p. 1218.

MAXITE. To decide the question as to the identity or non-identity of this mineral from Sardinia with the Scotch leadhillite (p. 1171), Laspeyres (*J. p. Chem.* [2], xiii. 370; xv. 317) has made fresh analyses of both these minerals. The result of these analyses is to establish for leadhillite (A) and maxite (B) the same

chemical composition, represented by the formula $\text{H}^{10}\text{Pb}^{18}\text{C}^8\text{S}^5\text{O}^{56}$, or $5\text{PbSO}_4 \cdot 9\text{PbCO}_3 \cdot 4\text{PbO} \cdot 5\text{H}_2\text{O}$, so that the name *maxite* may be abandoned, but at the same time the received formula for leadhillite (vii. 732) must be considerably altered. The whole of the water is given off at once between 250° and 290° :

	H_2O	CO^2	SO^2	PbO	
A (found) . . .	1.818	7.981	8.424	81.777	= 100
B (found) . . .	1.866	8.032	8.123	81.979	= 100
C (calc.) . . .	1.838	8.083	8.171	81.908	= 100

Laspeyres (*Zeitschr. f. Kryst.* i. 194) has further established, by exact measurements, the crystallographic identity of the Scotch and Sardinian minerals, but refers them, not to the rhombic system, as Descloizeaux does, but to the monoclinic system, with the following fundamental angles and ratios:

$$\text{Angle } \frac{1}{2}\text{R}\infty : \infty\text{R}\infty = 42^\circ 4' 26''; \frac{1}{2}\text{R}\infty : -\text{P} = -69^\circ 15' 27'';$$

$$-\text{P} : \infty\text{R}\infty = 36^\circ 7' 54''$$

$$\begin{array}{ccc} a & : & b & : & c \\ 1.7464 & : & 1 & : & 2.21545 \\ 1 & : & 0.57220 & : & 1.26768 \end{array}$$

or

The following faces were observed, and, for the sake of comparison with former statements, are given both as rhombic and as monoclinic forms:

rhomb.: $\infty\text{P}\infty$, $\infty\text{P}\infty$ (new), ∞P , $\infty\text{P}2$ (new), $\frac{1}{2}\text{P}\infty$, $\frac{1}{2}\text{P}\infty$, 0P
monocl.: $\infty\text{P}\infty$, $\infty\text{R}\infty$ (new), ∞P , $\infty\text{P}2$ (new), $\frac{1}{2}\text{R}\infty$, $\frac{1}{2}\text{R}\infty$, 0P .
rhomb.: P , $\frac{1}{2}\text{P}$, $\frac{1}{2}\text{P}2$ (new), $\text{P}2$, $\text{P}4$, $\frac{1}{2}\text{P}\infty$ (new)
monocl.: $-\text{P}$, $+\frac{1}{2}\text{P}$, $+\frac{1}{2}\text{R}2$ (new), $+\text{P}2$ (new), $+\text{P}2$, $+\text{P}4$, $-\frac{1}{2}\text{P}\infty$ (new).

The results of the optical investigation are as follows: Plane of optic axes normal to the plane of symmetry; the first (negative) median line is in the plane of symmetry in the obtuse axial angle, and forms with the vertical axis an angle of $0^\circ 12' 22''$. Dispersion of the axes rather large; $v > \rho$; a horizontal dispersion of the median lines was either non-existent or but very indistinctly observed (comp. Hinze, p. 1171).

MECONIC ACID, CHO. This acid is found in small quantity, together with morphine and narcotine, in officinal poppy-heads (G. Krause, *Arch. Pharm.* [3], v. 507).

The crystalline form of meconic acid is very much like that of α -pimelic acid (*q.v.*), both crystallising in transparent plates belonging to the orthorhombic system, and produced by predominant development of 0P . The crystals of meconic acid exhibit also the faces $\text{P}\infty$, $\text{P}\infty$, and ∞P ; those of pimelic acid the faces $\infty\text{P}\infty$ and $\infty\text{P}\infty$. Pimelic acid is easily distinguished from meconic acid by the absence of the domes (C. A. Burghardt, *Chem. Soc. J.* [2], xii. 937).

Meconic acid, treated with phosphorus oxychloride, gives off carbon dioxide, and forms a derivative of comenic acid not yet investigated (H. Schiff, *Liebig's Annalen*, clxxii. 359).

The blood-red colour which meconic acid produces with ferric salts is much weakened by oxalic acid, ordinary phosphoric acid, and still more by metaphosphoric acid—a point which may be of importance in chemico-legal investigations (A. Dupré, *Chem. News*, xxxii. 15).

MECONIN. See NARCOTINE-DERIVATIVES.

MEDULLOSE. See PARENCHYMA.

MEERSCHAUM. A fibrous meerschaum (*sepiolite*) occurring in a silver mine of Utah, in veins 5 cm. thick, partly white, partly bluish-green, has been analysed by A. Chester (*Sill. Am. J.* [3], xiii. 296), who assigns to it the formula $\text{Mg}^2\text{Si}^2\text{O}^6 + 2\text{H}_2\text{O}$ or $2\text{MgO} \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$.

1. Mean of four analyses of the white variety. 2. Blue-green variety:

	SiO^2	Al^2O^3	Fe^2O^3	Mn^2O^3	CuO	MgO	H_2O (?)	H_2O (?)
1.	52.97	0.86	9.70	3.14	0.87	22.50	9.90	8.80
2.	50.15	2.06	1.02	2.09	6.82 (?)	18.29	9.30	10.32

(?) At 100° . (°) A small quantity at 200° , the rest at a strong red heat. (°) This large amount of copper is probably the cause of the blue coloration.

MEGARRHIZA. The root of *Megarrhiza californica* contains an organic acid, megarrhizic acid, a crystallisable resin, megarrhizitin, and a glucoside, megarrhizin, which may be split up by acids or by baryta-water into sugar and megarrhiziretin. The ash of the root contains magnesia, lime, iron oxide, potash, soda, chlorine, sulphuric, phosphoric, and silicic acid (J. P. Heaney, *Pharm. J. Trans.* [3], vii. 393).

MEJONITE. G. vom Rath (*Pogg. Ann. Ergänzbd.* vi. 381) describes, as analogous to the leucites which are encrusted with sanidin, a crystal of mejonite 5 cm. long and 2 cm. thick, imbedded in a block ejected from Vesuvius, the surface of which appears roughened and rounded by a mixture of sanidin and sodalite.

A carefully selected specimen of mejonite (sp. gr. 2.716 at 16°) from Vesuvius, analysed by E. F. Newman (*Jahrb. f. Min.* 1875, 747; 1877, 942), yielded the following numbers:

SiO ²	Al ² O ³	CaO	MgO	Na ² O	K ² O	H ² O	Cl	CO ²
13.36	32.09	21.45	0.31	1.35	0.76	0.27	0.14	0.72 = 100.45.

Regarding the water, chlorine, and carbon dioxide as unessential, this analysis may be represented by the formula Na²O, 14CaO, 11Al²O³, 26SiO², 2H²O, which may, perhaps, also be written in the form 2(7CaO, 5Al²O³, 10SiO²) + (Na²O, Al²O³, 6SiO², 2H²O).

MELAM. Volhard (*J. pr. Chem.* [2], ix. 28) regards Liebig's melam (iii. 865) as probably a decomposition-product of guanidine thiocyanate, having the composition C²N⁴H⁴ = CNS.CN²H² — H²S, that is to say, as a polymeric cyanamide, with which, in fact, the formula generally assigned to melam agrees very nearly.

When the residue left after prolonged calcination of melam at a high temperature, till gas is no longer given off, is fused with potassium carbonate, it yields nearly pure potassium mellonide, which may easily be obtained quite pure by treatment with a small quantity of acetic acid. A solution of the same residue in hot strong potassium soda-ley immediately yields very fine crystals of cyameluric acid (Volhard).

When crude melam is dissolved in hot concentrated sulphuric acid, and alcohol is added to the solution, a snow-white chalky precipitate is formed, having the composition C³H⁴N⁴O², and identical with ammelide obtained from urea. The nitrate of this base crystallises in scales, the hydrochloride in microscopic needles (S. Gabriel, *Deut. Chem. Ges. Ber.* viii. 1165).

Melam treated with strong sulphuric acid at ordinary temperatures yields melamine sulphate containing a quantity of melamine equal to 17 per cent. of the melam; ammeline is formed at the same time; at higher temperatures, the product consists of ammelide in nearly theoretical quantity, as found by Gabriel (*J. Jäger, Deut. Chem. Ges. Ber.* ix. 1554).

MELAMINE or **CYANURAMIDE**, C³H⁴N⁴ = C³N³(NH²)³. The following methods of preparing this base are recommended by Claus a. Henn (*Liebig's Annalen*, clxxix. 120). A mixture of 25 grams melam, 100 grams potassium hydroxide, and 2½ litres of water, boiled together for twenty hours, yields nearly 50 per cent. of melamine; and a mixture of 35–36 per cent. melam, 100 KHO and 1 litre of water boiled for six or seven hours yields 35–36 per cent. melamine. *Melamine hydriodide* crystallises in needles having a silky lustre (Claus a. Henn). *Melamine thiocyanate* is formed, together with melam, when ammonium thiocyanate is quickly heated to 250°, and this temperature is kept up till the mass solidifies. It dissolves in water and in alcohol, crystallises in prisms, and sublimates when cautiously heated.

Benzoyl-melamine, C³N⁴H⁵(C⁷H⁵O) = (CN)³ $\left\{ \begin{array}{l} \text{NH}^2 \\ \text{NH}^2 \\ \text{NH}(\text{C}^7\text{H}^5\text{O}) \end{array} \right.$, appears to be

formed, together with benzonitril, by the action of benzoyl chloride on cyanamide; it is a white substance easily soluble in water, and in acetic, nitric, and hydrochloric acids (C. Gerlich, *J. pr. Chem.* [2], xiii. 270).

A *polymeric benzoyl-melamine*, (CN.NH.C⁷H⁵O)ⁿ, called by Gerlich tribenzoyl-melamine, is formed, together with benzoyl-cyanamide, cyanamide, benzonitril, and carbon dioxide, by the action of an ethereal solution of benzoyl chloride on sodium cyanamide suspended in ether. The mass must at first be kept cool, afterwards heated for several days on the water-bath, or better, for some hours in a sealed tube at 100°, and the ethereal solution finally separated from a yellow mass containing sodium chloride. The solution heated for eight hours to 150° in a sealed tube and then quickly cooled, deposits small round crystalline groups of benzoyl-cyanamide and a white amorphous substance. The ethereal solution saturated with hydrochloric acid yields a precipitate having the composition C³H⁴N⁴OCl².

The yellow mass insoluble in ether contains sodium chloride and tribenzoyl-melamine in the form of a yellow powder insoluble in water and in alcohol, soluble in phenol and in sulphuric acid, melting with decomposition at 275°. When heated with water it takes up the elements of the latter, and is resolved into ammonia and benzoic acid. By distillation in a stream of hydrogen it is resolved into carbon dioxide, hydrogen cyanide, benzonitril, dibenzoyl-dicyanamide (m. p. 112°; easily soluble in alcohol, less easily in ether and in water), and pseudotriphenylmelamine.

This last compound, isomeric with Hofmann's triphenylmelamine (p. 1271) does not melt at 360°. It forms shining yellow prisms, which are most readily purified

by dissolving them in phenol, and mixing the solution with alcohol (Gerlich, *loc. cit.*)

Trimethyl-melamine, $C^3H^3(CH^3)^3N^6 = (CN)^3N^3H^3(CH^3)^3$ (A. W. Hofmann, *Deut. Chem. Ges. Ber.* iii. 264). This base is prepared, similarly to triethyl-melamine (vi. 808, 1050), by desulphuration of methyl-thiocarbamide, the first product of this reaction being probably methyl-cyanamide, $N^2(CS)H^3(CH^3) - H^2S = N(CN)H(CH^3)$, which is then converted by polymerisation into trimethyl-cyanuramide or trimethyl-melamine.

Trimethyl-melamine crystallises from water or alcohol in small colourless prisms having a strong alkaline reaction; volatilises when heated, without previous fusion; and is decomposed by hydrochloric acid, with separation of ammonia. Its *platinochloride*, $C^3H^3(CH^3)^3N^6 \cdot 2HCl.PtCl_4$, crystallises in laminae sparingly soluble in water and in alcohol.

Triamyl-melamine, $C^3H^3(C^5H^{11})^3N^6$, prepared in like manner, forms a strongly alkaline syrup, insoluble in water and in aqueous hydrochloric acid. Its *platinochloride*, $C^3H^3(C^5H^{11})^3N^6 \cdot 2HCl.PtCl_4$, forms a network of yellow crystals, soluble in water, slightly soluble in alcohol, and is decomposed by boiling with hydrochloric acid, with separation of ammonia.

These trisubstituted melamines, as already observed, are not the direct products of the desulphuration of thiocarbamides, their formation being preceded by that of substituted cyanamides: in fact, the direct product of the desulphuration of ethyl-thiocarbamide does not crystallise, has no alkaline reaction, and does not yield a crystallisable platinum-salt; and it is only after repeated evaporation that complete polymerisation is effected. Moreover, Hofmann has given direct proof of the correctness of this view, by converting ethyl-cyanamide, prepared by the action of gaseous cyanogen chloride on ethylamine (ii. 190), into triethyl-melamine. He likewise explains the resolution of ethylecyanamide by heat into diethylecyanamide and a crystalline base, $C^2H^3(C^2H^5)^2N^4$ (*loc. cit.*) by a decomposition of triethylamine represented by the equation:

By brisk ebullition with *hydrochloric acid*, triethyl-melamine is resolved into ammonia and triethylammeline:

but by digestion for several hours with hydrochloric acid in sealed tubes it is converted into ammonia and methyl-cyanurate:

Similar reactions take place in the phenyl series.

Triphenyl-melamine, $C^3H^3(C^6H^5)^3N^6$ (Hofmann, *loc. cit.*). Monophenylthiocarbamide is converted by desulphuration into phenyl-cyanamide or cyananilide, agreeing in properties with that which Cahours & Cloez obtained by the action of gaseous cyanogen chloride on aniline (iv. 442). The product has at first the consistence of colophony, but may be crystallised by solution in alcohol and heating, or by leaving the alcoholic solution at rest for some time at ordinary temperatures. It is very soluble in alcohol and ether, melts at $36^\circ-37^\circ$, and when once fused takes a long time to solidify; it changes into triphenyl-melamine, slowly at ordinary temperatures, quickly when fused at the heat of the water-bath.

Triphenyl-melamine, when recrystallised from alcohol, forms pyramidal groups of prisms, melting at $162^\circ-163^\circ$. It is insoluble in cold, very slightly soluble in boiling water, easily soluble in alcohol and ether, especially when warm, and crystallises from the hot solution in capillary needles. Its *platinochloride*, $C^3H^3(C^6H^5)^3N^6 \cdot 2HCl.PtCl_4$, is a yellow precipitate which crystallises well. The base is decomposed by boiling hydrochloric acid, with separation of ammonia; and its alcoholic solution heated to boiling for a short time with hydrochloric acid, deposits on cooling crystals of phenyl-cyanurate:

MELANGLANCE. This mineral, from Freiberg, was found by Frenzel (*Jahrb. f. Min.* 1874, 188) to contain 68.64 per cent. silver, 15.76 antimony, and 16.49 sulphur, agreeing with the formula $5Ag^2S.Sb^2S^3$, which requires 68.36 Ag, 15.44 Sb, and 16.49 S. Sp. gr. = 6.28 at 18° .

MELANILINE. This compound crystallises in elongated monoclinic prisms exhibiting the faces $\infty P\infty$, $\infty R\infty$, $-P\infty$, $+R\infty$, ∞P . No distinct cleavage (Arzruni, *Pogg. Ann.* clii 284).

MELANOPHLOGITE. A mineral occurring on sulphur at Girgenti, in small light-brown cubes and cubic twins, closely intergrown with a crust of quartz, and mixed with sulphur, calcite, and cœlestin. The cubes when heated turn green, blue, and finally black-blue: hence the name of the mineral. Sp. gr. = 2.03–2.04; after ignition, 1.95. An analysis made with a very small quantity of material gave:

SiO ²	Fe ² O ³ , Al ² O ³	SrO	SO ²	H ² O
86.29	0.7	2.8	7.2	2.86 = 99.85

Deducting the iron and strontia, the latter combined with 1.3 per cent. SO² as cœlestin, there remains, as essential constituents, only water, sulphuric acid, and silica. The mode of combination of the silicon and sulphur has not been made out (A. v. Lasaulx, *Jahrb. f. Min.* 1876, 250, 627). Further notices on this mineral have been published by v. Zephanovich (*ibid.* 627). A. Brezina (*Min. Mitth.* 1876, 243) calls attention to a Grecian mineral described by A. Guyard (*Bull. Soc. Chim.* [2], xxii. 61) under the name of *sulphuricin* or *silex sulphuricin*, which is impregnated with sulphur and free sulphuric acid, and was found to contain:

SO ²	S	H ² O	SiO ²	CaO	Al ² O ³	Fe ² O ³	MgO
6.80	4.10	6.10	80.38	1.25	0.43	8.57	0.37 = 100

Assuming that in this analysis, in which there is an excess of 8 per cent., the 8.57 Fe²O³ should be 0.57, the numbers will agree nearly with those in the analysis by v. Lasaulx.

MELANOSIDERITE is the name given by J. P. Cooke (*Jahrb. f. Min.* 1875, 651) to a black amorphous mineral from West Chester, Pennsylvania. The analysis by W. H. Melville indicates a highly basic silicate having the composition 4Fe²O³.SiO² + 6H²O. It might be regarded as an impure brown hæmatite, were it not for the gelatinising reaction which it exhibits. Sp. gr. = 3.390–3.392.

	SiO ²	Fe ² O ³	Al ² O ³	H ² O
Analysis	7.42	75.13	4.34	13.83 = 100.72
Calculation	7.42	79.21		13.37 = 100

MELAPHYRE. A microscopic examination of melaphyres has been published by G. Haarmann (*Zeitschr. geol. Ges.* xxv. 436; *Jahrb. f. Min.* 1874, 313). The greater number of specimens exhibited, together with a vitreous ground-mass, plagioclase, less abundantly orthoclase, magnetic iron oxide, olivine (hitherto regarded as the most regular constituent of the melaphyres), augite (occurring less frequently than is commonly supposed), and apatite. Schillerspar, nephelin, and quartz were found in individual specimens, hornblende never. Among the varieties of structure exhibited, special mention must be made of a very distinct micro-fluctuation structure, inasmuch as it affords distinct evidence as to the genesis of the rock, pointing to its metamorphic formation from sedimentary material.

C. Doelter (*Jahrb. f. Min.* 1876, 563) has examined the mineralogical constitution of the melaphyres and augite-porphyrries of South Tyrol, which he divides into: 1. *Augite-melaphyres* (a. Augite-porphyr; b. Augite-melaphyres poor in augite, and augite-hornblende melaphyres). 2. *Hornblende melaphyres*. 3. *Melaphyres free from augite and hornblende*. The chief constituents of these melaphyres are plagioclase, orthoclase, augite (sometimes replaced by uralite), hornblende, and magnetic iron oxide; subordinate: olivine and apatite; as secondary products: epidote, calcite, clelesite, chalcedony, and iron pyrites, as well as pseudomorphs after augite and olivine.

Metamelaphyre, Metadiabase, and Metadolerite. These terms are applied by J. D. Dana (*Sill. Am. J.* [3], xi. 119) to the rocks which constitute the heights forming the western boundary of the plain of New Haven. They are metamorphic formations probably of old silurian age, but petrographically very nearly allied to eruptive dolerite, diabase, and melaphyre. The term *dolerite* is in this nomenclature not restricted, as usual, to eruptive rocks of the tertiary age, but denotes a rock free from chlorite, in opposition to the chloritic dialases. G. W. Hawes (*ibid.* 122) has supplemented Dana's memoir by a series of analyses in which the composition of these metamorphic rocks is compared with that of the corresponding formations of eruptive material, in order to show the petrographico-chemical identity of the two classes.

1. *Metadolerite* from Stoeckel's farm; crystallo-granular. The mineral constituents were found by calculation to consist of 55 per cent. augite, 41 labradorite, and 3 titanic iron.

2. *Dolerite* from West Rock, New Haven, an eruptive rock, added for comparison.

3. *Metadiabase* from the cutting of the Derby railway; light green, fine-grained variety, consisting, according to microscopical examination, of augite, chlorite, labra-

dorite, and titanite iron. From the absence of calcium carbonate it is inferred that the chlorite has been formed simultaneously with the other constituents, not at the expense of the augite.

4. *Metadiabase*, to the south of Maltby Park; porphyritic from the presence of felspar, otherwise formed of the same constituents as the preceding. Whether anorthite likewise occurs cannot be decided, on account of the impurity of the felspar which was separated for analysis, but its occurrence is not improbable.

5. *Diabase, eruptive*, from Lake Saltonstall.

6. *Metamelaphyre*, from Stoeckel's farm; crypto-crystalline. Calculation gave, as the component mineral species, 44 per cent. augite, 53 oligoclase, and 3 titanite iron.

	SiO ²	Al ² O ³	Fe ² O ³	FeO	MnO	CaO	MgO	Na ² O	K ² O	TiO ²	H ² O

The rocks of New Hampshire have also been discussed in the same manner by G. W. Hawes (*Sill. Am. J.* [3], xii. 129).

1. *Hornblende* from the *metadiorite* of North Lisbon. The rocks may be regarded, according to their amount of silica, as *Oligoclase-* and *Labrador-metadiorite*.

2. *Metadiabase* from Littleton.

3. *Metadiabase* containing hornblende, together with augite and chlorite. Nos. 2 and 3 exhibit structures which are regarded by Hawes as organisms.

4. *Metadiabase slate* from Hanover, analysed by Pease.

5. *Metadolerite* from Littleton, containing hornblende, apparently formed from augite.

6. *Clay-slate* from Woodrill; wrinkled and exhibiting only traces of crystalline constituents: 'nevertheless it has a composition which would have afforded a good granite if circumstances had been favourable to the formation of that rock.'

Peculiarly formed conglomerates from South African melaphyres are described by E. Cohen (*Jahrb. f. Min.* 1875, 113). One of these rocks from the Malati mountains exhibits conglomerates consisting of heulandite (p. 1030), in peculiar ramifications resembling certain precious corals. In the second rock, from Backhause on the left bank of the Vaal, are imbedded tubes more than 10 cm. long, and having a maximum diameter of 1 cm., which gradually renew themselves, and are filled with chalcedony coated with delessite. The loose cylinders of chalcedony (so-called 'pipe-stones'), which are of frequent occurrence in the diamond-washings, are attributed by Cohen to conglomerates of this kind which have fallen out of the rock.

MELEZITOSE. See SUGARS.

MELILOT. The yellow melilot (*Melilotus officinalis*), at flowering time, yields by distillation with steam 0.2 per cent. of melilotol, an acid oil, to which the odour of the flowering plant is due. This oil is slightly soluble in water, easily in alcohol and ether, and is easily converted into mellilotic acid (T. L. Phipson, *Chem. News*, xxxii. 25).

MELINOPHANE. Crystals of this mineral have been measured by E. Bertrand (*Compt. rend.* lxxxiii. 711), who refers them to the quadratic system, indicating the faces P and P ∞ , whereas hitherto rhombic forms have been assumed with $\infty P = 91^\circ$. The faces hitherto regarded as produced by cleavage parallel to OP are,

according to Bertrand, not cleavage-faces at all, inasmuch as the crystals exhibit no indication of cleavability.

MELISSIC ACID, $C^{30}H^{40}O^2$. This acid and its salts have recently been investigated by L. v. Pieverling (*Liebig's Annalen*, clxxxiii. 344). The acid is prepared by heating myricyl alcohol, $C^{30}H^{52}O$, to 220° , with three times its weight of potash-lime in a tube open at one end, the process being continued as long as hydrogen is given off, and the contents of the tube finally treated with hydrochloric acid. The crude melissic acid thereby separated is dissolved in alcohol and precipitated with lead acetate; the precipitate is washed with hot alcohol; and the melissic acid separated from it by digestion with alcohol containing hydrochloric acid, is purified by recrystallisation from alcohol.

Melissic acid thus prepared forms shining silky scales appearing under the microscope to be made up of slender needles, and melting at 88.5° . It is slightly soluble in ether, easily in boiling alcohol.

Lead melissate, $(C^{30}H^{50}O^2)_2Pb$, is insoluble in alcohol and in ether, but dissolves in boiling chloroform and toluene, and crystallises from the latter in yellowish needles.

Silver melissate, $C^{30}H^{50}O^2Ag$, forms white masses which quickly turn brown when exposed to light, melt to a black mass between 94° and 95° , and behave towards solvents like the lead salt. The *copper salt* is a green powder. The *potassium salt* dissolves in 20 parts water, and crystallises from alcohol in white needles, from ether in scales.

Ethyl melissate, $C^{30}H^{50}O^2.C^2H^5$, prepared from the silver salt with ethyl iodide, is a white waxy mass, melting at 73° . *Amyl melissate*, $C^{30}H^{50}O^2.C^5H^{11}$, may be prepared by passing hydrogen chloride into a solution of the acid in amyl alcohol, and when purified by crystallisation from ether, forms white shining needles, melting at 69° , resolidifying at 67° , soluble in alcohol, ether, benzene, and chloroform.

MELISSYL ALCOHOL. See MYRICYL ALCOHOL.

MELITOSE. See SUGARS.

MELLITIC ACID, $C^{12}H^6O^{12} = C^6(COOH)^6$. Claus a. Poppe (*Deut. Chem. Ges. Ber.* 1877, p. 559) find that pure mellitic acid may be prepared from very impure, earthy, nearly black honeystone, by evaporating the ammoniacal extract to dryness and heating the residue for some hours to 120° – 130° . The ammoniacal salts of the humus-acids are thereby decomposed and rendered insoluble, so that, on subsequently boiling the residue with water, a nearly colourless solution of mellitic acid is obtained.

Acid mellitates are obtained both by evaporating the solutions of the neutral salts, and by heating mellitic acid with metallic chlorides. With an ammoniacal magnesium-solution, moderately dilute solutions of mellitic acid yield a heavy crystalline precipitate of the salt $(NH^4)_2Mg_2C^{12}O^{12} + 15H^2O$, which crystallises from hot water in large prisms having a vitreous lustre. A *magnesium-potassium* salt, which likewise crystallises well, is obtained in a similar manner. *Zinc-ethyl* acts on mellitic acid in the same manner as on oxalic acid.

Mellitic Hexachloride, $C^{12}O^6Cl^6$, is formed by the action of phosphorus pentachloride on mellitic acid, together with a number of secondary products, from which it may be freed by recrystallisation from ether. From this solvent and from benzene it crystallises very readily in hard vitreous prisms which melt at 290° , and sublime in laminae at about 240° . An *oxychloride*, $C^{12}O^5Cl^5$, has also been obtained (Claus a. Poppe).

Mellitic Ethers.—According to Busse a. Kraut (*Liebig's Annalen*, clxxvii. 272), the melting point of ethyl mellitate (73°) is lowered to 51.5° by admixture of small quantities of methyl mellitate. That of the latter is also lowered by the presence of small quantities of impurities.

The results of Baeyer's investigations on mellitic acid and its derivatives have already been given (vi. 808–814; vii. 784–785).

Trimellitic acid, $C^6H^3(CO^2H)^3$, is obtained by the oxidising action of potassium permanganate on xylidic acid prepared from pseudocumene. This shows that trimellitic acid (as formerly suggested by Baeyer) has the same constitution as pseudocumene, viz. (1 : 2 : 4); and since trimesic acid has the position 1 : 3 : 5, there remains for hemimellitic acid only the position 1 : 2 : 3. The above reaction yields isophthalic as well as trimellitic acid (G. Krinos. *Deut. Chem. Ges. Ber.* x. 1491).

MELLONE. On the formation of potassium mellonide from the residue left after the calcination of melam, see p. 1270.

MELONITE. See TELLURIUM MINERALS.

MENTHENE, $C^{10}H^{18}$. This hydrocarbon, obtained by distilling solid peppermint-camphor with zinc-chloride, is converted by the action of bromine into cymene, $C^{10}H^{18} + Br^4 \rightarrow C^{10}H^{14} + 4HBr$, the hydrocarbon being first treated with a solution of

bromine in potassium bromide and the resulting addition-product distilled. A liquid compound having the same composition as solid peppermint camphor, likewise yielded menthene by distillation with zinc chloride (Beckett & Wright, *Chem. Soc. J.* xxix. 1).

MERCAPTAN and MERCAPTIDES (P. Claesson, *Bull. Soc. Chim.* [2], xxv. 183; *J. pr. Chem.* [2], xv. 193). Mercaptan, C^2H^5SH , may be advantageously prepared by neutralising a mixture of sulphuric acid and alcohol with sodium carbonate; evaporating; and after the sodium sulphate has crystallised out, mixing the mother-liquor with potassium sulphhydrate and gently heating the mixture for twelve hours in a retort, the vapours which escape condensation in the receiver being passed into a solution of caustic potash. By this process, 1 litre of alcohol and 350 grams of potassium hydrate yield 280–300 grams of crude mercaptan containing about 70–80 per cent. ethyl sulphhydrate, and 20–30 per cent. ethyl monosulphide. The product may be freed from hydrogen sulphide by repeated agitation with potash-ley, and the mercaptan separated from the ethyl sulphide by fractional distillation, or, better, by converting it into the sodium salt (*infra*), evaporating the alcoholic solution of this salt to dryness, adding water, and either filtering the solution, or agitating it with benzene or other hydrocarbons which dissolve the ethyl sulphide. The alkaline solution thus purified yields, on neutralisation with dilute sulphuric acid, perfectly pure mercaptan.

Mercaptan is a powerful reducing agent, converting, for example, nitrobenzene into azobenzene; the alkaline mercaptides exert a still more powerful reducing action.

A hydrate of mercaptan, $C^2H^5S \cdot 18H^2O$, first obtained by H. Müller (*Arch. Pharm.* [2], cl. 147), is formed when the vapours evolved in the preparation of mercaptan are passed through a condensing tube containing water cooled to 8° or a lower temperature, and solidifies to a crystalline mass of small needles which may be kept undecomposed for several days in a closed vessel at a temperature of 12° – 14° .

Mercaptides. The sodium and potassium compounds may be prepared either by dissolving the metal in mercaptan, whereupon the compound separates out in white snowy masses, or better, by dissolving potassium or sodium in absolute alcohol and adding mercaptan, drop by drop, or by passing mercaptan-vapour into the alcoholate. Sodium mercaptide, C^2H^5SNa , is decomposed by water into sodium hydrate and mercaptan, and by excess of alcohol into sodium alcoholate and mercaptan. The latter reaction, however, is by no means so complete. An aqueous solution of potash or soda dissolves mercaptan, partially converting it into mercaptide, and great contraction of the solution ensues. Sodium mercaptide absorbs oxygen when the gas is passed through its alcoholic solution, ethyl disulphide being formed. The action is different, however, when dry oxygen is passed over dry sodium mercaptide, oxidation then taking place, slowly at ordinary temperatures, more quickly at 100° – 120° , the change being complete when a solution of a small portion of the product in water gives with lead acetate, no longer a yellow, but a white precipitate. If the mass, which is not altered in appearance, be then dissolved in water, a small quantity of ethyl bisulphide separates out; and on removing this by filtration, mixing the filtrate with barium chloride, removing the small precipitate thereby produced (chiefly barium sulphate) by filtration, passing carbon dioxide into the filtrate, evaporating to dryness and exhausting with alcohol, a solution is obtained which, on evaporation, yields a neutral very deliquescent and indistinctly crystalline salt, exhibiting the composition and reactions of sodium ethylsulphinat, $C^2H^5SO \cdot ONa$. With solutions of metallic salts, mercaptan and sodium-mercaptide act exactly like hydrogen sulphide and the sulphhydrates of the alkali-metals.

Thallium mercaptide, C^2H^5STl , prepared by agitating thallious carbonate with mercaptan, is a yellow curdy precipitate slightly soluble in water.

Ferrous mercaptide, $(C^2H^5S)^2Fe$ (?), is obtained by mixing an alcoholic solution of ferric chloride with mercaptan and ammonia, as a black slimy mass resolved by heating with water into mercaptan and ferrous hydrate.

Nickel mercaptide, $(C^2H^5S)^2Ni$, prepared in like manner, is a chocolate-brown powder not decomposed by hot water.

Cobalt mercaptide, $(C^2H^5S)^2Co$, is obtained by agitating mercaptan with cobalt acetate, as a gummy precipitate, which, unlike all other mercaptides, is not attacked even by fuming nitric acid.

The mercaptides of Zinc and Cadmium, $ZnS^2(C^2H^5)^2$ and $CdS^2(C^2H^5)^2$, are precipitated on adding mercaptan to their compounds with weak acids; they dissolve in dilute acids without decomposition, and are reprecipitated on neutralising the acid. They are white, indistinctly crystalline bodies, and are best prepared from the acetates. They dissolve in ammonia, and are reprecipitated on neutralisation.

Mercuric mercaptide is best prepared by shaking mercuric cyanide with mercaptan, and separates out in long very thin crystals. On application of heat it melts to an oil, devoid of smell and taste. On treating it with warm nitric acid, a basic mercuric ethylsulphonate is formed, according to the equation :

Mercaptides of the Platinum Metals.—Of the metals of this group, only platinum, palladium, and rhodium appear to be capable of forming mercaptides. The platinum salt has been already mentioned (ii. 549). *Palladium mercaptide* is a powder of a fine yellow colour, which decomposes, when heated, with a glimmering light, and evolution of heat sufficient to melt the palladium. *Rhodium mercaptide*, $\text{Rh}^2(\text{SC}^2\text{H}^5)^6$, obtained from salts of rhodium sesquioxide, is a yellow precipitate.

The lower oxides of *iridium*, *ruthenium*, and *osmium* are not acted on by mercaptan ; the higher oxides are merely reduced. Claesson suggests that this difference of reaction might be utilised as a method of separating the platinum metals one from the other, especially for obtaining platinum absolutely free from iridium, and for separating small quantities of platinum from the osmium and iridium metals.

Tin mercaptides.—The *stannic salt*, $\text{Sn}(\text{SC}^2\text{H}^5)^4$, is formed by the action of stannic chloride on mercaptan, both dissolved in carbon sulphide, and remains as a thick oil after the solvent has been removed by distillation ; it is also formed on adding mercaptan to a strong aqueous solution of stannic chloride. It remains liquid at -40° , and may be distilled in a vacuum without decomposition, but is decomposed by distillation under the ordinary pressure, with formation of ethyl sulphide and separation of metallic tin. *Stannous mercaptide*, $\text{Sn}(\text{SC}^2\text{H}^5)^2$, is formed on adding mercaptan to a solution of stannous acetate, as a yellow precipitate, which oxidises very quickly on exposure to the air.

Bismuth mercaptide, $\text{Bi}(\text{SC}^2\text{H}^5)^3$, one of the most characteristic salts of the group, is obtained by mixing a solution of a salt of bismuth with mercaptan, and crystallises in long flexible yellow needles, moderately soluble in alcohol and in ether. It melts at 79° , oxidises easily in air, and when strongly heated decomposes into the sulphides of bismuth and ethyl.

Arsenious mercaptides.—Arsenious chloride acts on mercaptan at ordinary temperatures, forming arsenious chlorodimercaptide, $\text{As}(\text{SC}^2\text{H}^5)^2\text{Cl}$, the substitution of SC^2H^5 for Cl not going any further even at 100° . The trimercaptide, $\text{As}(\text{SC}^2\text{H}^5)^3$, is best obtained by adding sodium mercaptide to an ethereal solution of arsenious chloride, keeping the latter in excess, and afterwards removing this excess by a stream of ammonia-gas. The product, after filtration and removal of the ether by distillation, is quite free from chlorine. Both these products are colourless fetid oils. The former when heated gives metallic arsenic, arsenic chloride, and ethyl disulphide ; the latter metallic arsenic and ethyl disulphide. The former reacts with water, giving arsenious acid, hydrochloric acid, and mercaptan, but is not oxidised by air ; while the latter is not acted on by water, but decomposes in air, with formation of arsenious acid.

Phosphorus trichloride and mercaptan do not react at low temperatures, but on heating the mixture, the three chlorine-atoms are successively replaced by the group SC^2H^5 , the replacement of the third chlorine-atom being, however, not completely effected till the substances are heated together at 100° in sealed tubes. The trimercaptide, $\text{P}(\text{SC}^2\text{H}^5)^3$, is a colourless fetid oil, resolved by distillation into phosphorus and ethyl disulphide, and slowly decomposed by water at ordinary temperatures.

Antimony trichloride unites directly with mercaptan, forming the compound $\text{SbCl}^3.\text{C}^2\text{H}^5\text{S}$, which remains, on evaporating over the water-bath, as an oil, which does not oxidise in the air, but is decomposed by water like antimonious chloride itself, the mercaptan being set free.

Carbon mercaptides are obtained by the action of sodium mercaptide on the carbon chlorides CCl^4 , C^2Cl^6 , and C^3Cl^8 . *Carbon tetramercaptide*, $\text{C}(\text{SC}^2\text{H}^5)^4$, is a light yellow oil having a peculiar odour, a sp. gr. = 1.01, and decomposing when distilled. *Dicarbon-hexamercaptide*, $\text{C}^2(\text{SC}^2\text{H}^5)^6$, is a heavy, nearly colourless, fetid oil, solidifying at very low temperatures. *Dicarbon-tetramercaptide*, obtained by heating carbon dichloride, C^2Cl^4 , with sodium mercaptide at 100° , crystallises in very fine rhombohedrons having a faint odour and melting at 54° . All these compounds are oxidised by nitric acid to carbonic and ethylsulphonic acids.

Sulphur Mercaptides or *Ethyl Polysulphides*.—The *tetrasulphide*, $(\text{C}^2\text{H}^5)^2\text{S}^4$, is formed by mixing the solutions of sulphur chloride and mercaptan in carbon sulphide :

After removal of carbon sulphide and excess of mercaptan by distillation, the tetra-sulphide remains as a light-coloured, very fetid oil, heavier than water, soluble in carbon sulphide and in ether, very sparingly in alcohol. It converts most metals into sulphides, potassium cyanide into the thiocyanate, potassium hydroxide into thio-sulphate. It is resolved by distillation into sulphur and the disulphide, $(C^2H^5)_2S_2$, by contact with water into sulphur and $(C^2H^5)_2S_3$. It dissolves sulphur at 150° , possibly forming the pentasulphide.

MERCAPTOIC ACIDS. This name has been given to the sulphuretted dyes which Croissant and Bretonnière obtain by action of metallic sulphides, or of sulphur and an alkali, on carbohydrates, gum-resins, &c. (p. 698).

MERCURIALINE. According to E. Schmidt (*Deut. Chem. Ges. Ber.* x. 2226), this base, obtained from *Mercurialis perennis*, is identical with methylamine.

MERCURIPHENYLAMMONIUM CHLORIDE, $NH(C^6H^5)HgCl$, is formed, together with mercuridiphenylammonium chloride, on mixing the boiling solutions of aniline and mercuric chloride. The latter remains in solution, while the former separates as a yellowish precipitate. After repeated boiling with alcohol, it forms an amorphous insoluble 'phenylated white precipitate' (Carl Forster, *Deut. Chem. Ges. Ber.* vii. 294).

MERCURY. According to J. W. Mallet (*Proc. Roy. Soc.* xxvi. 71), the sp. gr. of solid mercury at its freezing point, -38.85° , is 14.1992, compared with water at 4° .

On the Specific Heat of Liquid Mercury, see HEAT (p. 928); of Mercury-vapour, p. 934.

On the Expansion of Mercury by Heat, see p. 935.

Heat-conductivity.—According to H. Herwig (*Pogg. Ann.* cli. 177), the heat-conductivity of pure mercury between the temperatures of 40° and 160° is perfectly constant, whereas its conducting power for electricity is known to vary with the temperature. Mercury, therefore, presents an exception to the law laid down by Wiedemann and Franz (*Pogg. Ann.* lxxxix. 497; *Jahresb. f. Chem.* 1853, 92), according to which the conduction of heat in metals is as variable as their power of conducting electricity. On the other hand, the result above mentioned relating to mercury agrees with Lorenz's law (*Pogg. Ann.* cxlvii. 429; *Jahresb.* 1872, 52), according to which the heat-conducting power is the same at all temperatures.

Electric Conductivity of Mercury-vapour.—Herwig (*Pogg. Ann.* cli. 350) finds that this vapour conducts electricity, not like a metal, but rather like a voltaic arc: moreover, it exhibits, like other gases, as shown by Hittorf (p. 726), a certain resistance to the transference of electricity at the cathode. Mercury-vapour at 400° in a tube 4 mm. in diameter, and between columns of liquid mercury as electrodes, exerts a resistance of about 50,000 Siemens' mercury-units.

Electric Impulsion.—Du Moncel's observations on the movement of a drop of mercury at the bottom of a layer of water through which an electric current is passed, have already been noticed (p. 714). R. Sabine (*Phil. Mag.* [5], ii. 481) has studied the same phenomenon with the following results: (1). The electro-motive force between two surfaces of mercury proceeds from the different degrees of oxidation of these surfaces. 2. The contraction or expansion consequent on the passage of a current between a drop of water and a surface of mercury is equal to the change of volume due to the formation of mercurous oxide. 3. The other best known phenomena of impulsion are to be attributed to this cause, and not to alteration of the capillarity-constants, which, contrary to Lippmann's view (*Pogg. Ann.* cxlix. 546), have but little to do with the electromotive force of the surface.

Detection of Mercury.—To detect the presence of mercury in urine, Mayençon and Bergeret (*J. Pharm. Chim.* [4], xvii. 148) acidulate the liquid with a few drops of sulphuric acid, and suspend within it, for about half an hour, an iron nail attached to a platinum wire; then, after washing and drying the mercury precipitated on the wire, they introduce it into an atmosphere of chlorine, whereby it is converted into mercuric chloride, and demonstrate the presence of this compound by rubbing the wire with a piece of paper moistened with aqueous potassium iodide, whereby a bright red streak is produced.

Estimation.—J. B. Hannay (*Chem. Soc. J.* xxvi. 565) has devised a method of estimating mercury volumetrically, depending on the fact that the precipitate formed by a few drops of ammonia in a solution of mercuric chloride, disappears completely on addition of a solution of potassium cyanide, whereby the mercuric chloride is converted into cyanide. The mercury must be in the form of mercuric chloride, into which, if previously precipitated as sulphide, it is easily converted by the action of nitromuriatic acid. A comparison of this method with the electrolytic estimation as

metallic mercury, showed that the reduction of mercury takes place most completely from the sulphate, less completely from the nitrate, in presence of free nitric acid, and least of all from the chloride, but that complete reduction may be obtained by previously converting the chloride into cyanide by the action of potassium cyanide.

Tuson a. Neison (*ibid.* xxxii. 679) modify this method by adding to the solution (either acid or neutral) a small quantity of ammonium chloride, then potassium carbonate, till a precipitate appears, and lastly the titrated solution of potassium cyanide, till the liquid becomes perfectly clear. By this modification the method is rendered applicable to the nitrate, sulphate, and other salts of mercury, as well as to the chloride.

Another method of estimating mercury volumetrically is described by J. Volhard (*Liebig's Annalen*, xc. 1), based upon the fact that mercuric salts decolorise the red solution of ferric thiocyanate, quickly in all cases, but completely only when they are added in slight excess. A similar effect is produced by silver, and the volumetric method founded upon it will be described in connection with that metal. In the case of mercury the solution must be slightly acid, and the results obtained with it are not quite exact, but sufficiently so for most purposes.

Compounds of Mercury.

Amalgams. Observations on the behaviour of amalgams at temperatures a little above the boiling point of mercury have been made by E. de Souza (*Deut. Chem. Ges. Ber.* viii. 1616). *Silver-amalgam* heated to the temperature of boiling sulphur till its weight became constant was found to contain 12.61 to 12.74 per cent. mercury, answering to the formula Ag^{13}Hg . *Gold-amalgam* similarly treated retained 10.02 to 10.5 per cent. Hg, answering to Au^2Hg .

By mixing 20 to 30 pts. of *copper* reduced by hydrogen with sulphuric acid and 79 pts. of mercury, a mass is obtained which, when freed from sulphuric acid by boiling water, forms after 10 to 12 hours a moderately solid amalgam having the lustre and polish of gold and becoming plastic when heated (*Moniteur Scientifique*, [3], vii. 312, 1877).

Chlorides. The resolution of *calomel* into mercuric chloride and metallic mercury is not complete at 440°. A gilt silver tube immersed in the vapour of calomel at this temperature, and kept cool by a stream of cold water running through it, becomes coated with a grey film of calomel mixed with only a small quantity of metallic mercury (Debray, *Compt. rend.* lxxxiii. 330).

Mercuric Chloride has been found native in a volcanic district on Ternate, one of the Molucca Islands (Frenzel, *Min. Mitth.* 1877, 305).

Mercuric chloride is reduced to mercurous chloride by the action of hypochlorites, the reaction being complete in boiling acid solutions (T. Fairley, *Rep. Br. Assoc.* 1875, [2], 42).

Amidochloride.—The action of the halogen-elements on white precipitate and other chlorine-compounds of metallic amides has been examined by V. Schwarzenbach (*Deut. Chem. Ges. Ber.* viii. 1231). It is well known that when a mixture of white precipitate and iodine (2 grams white precipitate and 5.04 iodine = 5 at. I to 2 mol. precip.) is drenched with alcohol, an explosion takes place after a while (about 35 minutes). If the alcohol be replaced by carbon sulphide, propyl alcohol, amyl alcohol, chloroform, or glycerin, no explosion takes place even after 24 hours; but if the quantity of iodine be increased to the proportion of 6 at. to 2 mol. white precipitate, the addition of chloroform or amyl alcohol produces a sharp detonation within the liquid, without, however, shattering the vessel. The gas evolved in the explosion produced by alcohol is nitrogen. *Chlorine* gas likewise acts very strongly on white precipitate. When this substance in powder is introduced into an open flask filled with chlorine, it becomes very hot in a few minutes, acquires a wavy motion, and either explodes immediately, or more frequently exhibits a bright glow and a green flame which lasts for some time. Similar effects are produced with bromine. The chlorides, bromides, and iodides of the alcohol-radicals do not act upon white precipitate, at least at ordinary temperatures and in open vessels; ethyl chloride not even at 30° and under increased pressure. *Acetyl chloride* produces acetamide, together with a red body which is soluble in alcohol, and contains mercury, nitrogen, and chlorine.

The action of iodine on white precipitate in presence of alcohol always produces nitrogen iodide; the addition of a small quantity of phenol prevents this reaction, however, but gives rise to the formation of a not inconsiderable quantity of iodoform. Phenol, iodine, and white precipitate without alcohol, do not produce iodoform.

Bromine acts like iodine, giving rise, with alcohol, phenol, and white precipitate, to the formation of bromoform, which may be separated by distillation from the mercuric bromide simultaneously formed (C. Rice, *Pharm. J. Trans.* [3], vi. 765).

Mercurous Iodide, Hg_2I_2 . The crystals of this compound have been examined by Des Cloizeaux (*Compt. rend.* lxxxiv. 1418). It is completely isomorphous with mercurous chloride. The crystals, which are yellow when recently prepared, but turn brown on exposure to the air, are quadratic, exhibiting the faces $\infty\text{P}\infty$, 0P and P , and are usually tabular from predominance of the two parallel prismatic faces; those of P appear also very unequally developed. Axes, $a:b=1:1.6726$. Observed angles, $\text{P}:0\text{P}=67.5^\circ$; $\text{P}:\text{P}=81^\circ 16'$; $\text{P}:\infty\text{P}\infty=49^\circ 22'$. The crystals usually cleave with moderate facility parallel to 0P , and exhibit strong positive double refraction.

Mercuric Cyanide. Double compounds of this salt with the chlorides of the rarer earth-metals have been prepared by J. E. Ahlén (*Bull. Soc. Chim.* [2], xxvii. 365). These compounds, which are represented by the general formula $\text{RCI}^3.3\text{Hg}(\text{CN})_2.8\text{H}_2\text{O}$, are very soluble, and crystallise from solutions containing excess of the chloride; they give off their water of crystallisation over sulphuric acid or at 100° .

Cerium double salt.	.	$\text{CeCl}^3.3\text{Hg}(\text{CN})_2.8\text{H}_2\text{O}$	Asbestos-like needles.
Lanthanum „	.	$\text{LaCl}^3.3\text{Hg}(\text{CN})_2.8\text{H}_2\text{O}$	Colourless silky needles.
Didymium „	.	$\text{DiCl}^3.3\text{Hg}(\text{CN})_2.8\text{H}_2\text{O}$	Reddish flexible needles.
Yttrium „	.	$\text{YCl}^3.3\text{Hg}(\text{CN})_2.8\text{H}_2\text{O}$	Colourless radiate prisms, giving off only $1\frac{1}{2}\text{H}_2\text{O}$ over sulphuric acid.
Erbium „	.	$\text{ErCl}^3.3\text{Hg}(\text{CN})_2.8\text{H}_2\text{O}$	Reddish prisms resembling the yttrium salt.

Iodate, $\text{Hg}(\text{IO}^3)_2$. This salt is precipitated in the amorphous state on adding iodic acid to a solution of mercuric oxycyanide:

The same precipitate is obtained from a solution of mercuric nitrate or acetate, but not from the chloride.

Mercuric iodate is a white amorphous powder, insoluble in water, and only slightly attacked by nitric acid, readily however by hydrochloric acid and the chlorides, bromides, iodides, cyanides, and cyanates of the alkali-metals, also by sodium thio-sulphate and by dilute solutions of the chlorides of manganese and zinc. It is insoluble in potash, soda, and ammonia, sodium sulphide, borax, sodium phosphate, alkaline iodates, bromates, and chlorates, and in acetic, hydrofluoric, and silico-fluoric acid. On evaporating a solution of the salt in an alkaline chloride, an iodate of the alkali-metal crystallises out first, then mercuric chloride, and when the solvent is in excess, a series of crystallised double salts is obtained. A solution of mercuric iodate in sodium thiosulphate yields, on addition of hydrochloric acid, a red precipitate which disappears in excess of the acid. The solution of the iodate in ammonium chloride gives with ammonia a white precipitate insoluble in excess (C. A. Cameron, *Chem. News*, xxxiii. 253).

Oxides. On the Heat of Formation of Mercurous and Mercuric Oxides, see *HEAT* (p. 955). On the Heat of Combination of Mercuric Oxide with Acids, see pp. 957, 998.

On the Decomposition of Mercuric Oxide by Heat, see p. 1010.

Mercuric Sulphide, HgS . *Preparation of Vermillion*.—This modification of mercuric sulphide may be prepared by the action of sodium thiosulphate on mercuric ammonium chloride. A solution of mercuric chloride is poured into an excess of dilute aqueous ammonia, and a strong solution of sodium thiosulphate is stirred into the liquid in quantity rather more than sufficient to dissolve the resulting precipitate. On warming the solution in a basin, the separation of vermilion immediately begins, and the heating must be continued till the whole acquires a pasty consistence. The ammonia and sal-ammoniac contained in the solution appear to exert an essential influence both on the formation and on the appearance of the product; its appearance is likewise affected by the temperature kept up during the evaporation. At 50° – 60° a lighter-coloured preparation is obtained than at 90° – 100° . The finest vermilion is produced at 70° – 80° (O. Hausmann, *Deut. Chem. Ges. Ber.* vii. 1746).

L. Raab (*N. Rep. Pharm.* xxiv. 39) heats sublimed and finely-triturated calomel with a solution of sodium thiosulphate, decants the resulting black mercury sulphide, and drenches it with a solution of liver of sulphur (prepared from pure potassium

carbonate). The solution is then evaporated, with stirring, to complete dryness, and the residue when cold is washed with warm water till all soluble matters are removed. On again drenching it with solution of liver of sulphur, and evaporating down, the black mercuric sulphide passes into the red modification.

Reactions.—1. Vermillion prepared in the wet way by digesting metallic mercury with ammonium pentasulphide is decomposed by light much more rapidly than sublimed vermilion, the depth and rapidity of the blackening varying according to the nature of the supernatant liquid, the change being especially rapid under alkaline liquids (K. Heumann, *Ber.* vii. 750).

2. Vermillion is rapidly decomposed by boiling with water and finely-divided copper, the products being metallic mercury, copper sulphide, and a dark-coloured powder insoluble in nitric acid, which is turned white by boiling with strong nitric acid, black again by contact with alkalis, and once more white by boiling with nitric acid. The white compound thus produced has the composition $2\text{HgS} \cdot \text{Hg}(\text{NO}_3)_2$, and is identical with the white precipitate formed by passing a small quantity of hydrogen sulphide into a solution of mercuric nitrate; it may also be produced by digesting mercuric sulphide with a strong solution of the nitrate. The blackening of this compound arises from separation of mercuric sulphide. When moistened with caustic soda, it first turns yellow, then brown, and finally black; if heat be applied, however, it turns black almost immediately. The black substance is an oxysulphide, $\text{HgO} \cdot 2\text{HgS}$. Dilute acids dissolve out the oxide, and when the compound is boiled with strong nitric acid, the resulting mercuric nitrate combines with the separated sulphide, reproducing the white compound. The statements of Palm (*Jahresb. f. Chem.* 1862, 223) respecting the formation of red addition-products of cinnabar and mercuric salts are erroneous, nothing but white compounds being thus obtained. The decomposition of mercuric sulphide by copper is the cause of the well-known deterioration of the colour of vermilion by contact with copper and brass: hence the means recommended by Karmarsch for preventing this deterioration, viz., exhausting the vermilion with a solution of pearlash, or bringing it in contact with water and slips of copper to remove admixed sulphur, are useless.

Zinc powder likewise decomposes mercuric sulphide even more rapidly than copper powder, vermilion prepared in the wet way being likewise in this case decomposed much more rapidly than sublimed vermilion; the products are zinc sulphide, zinc amalgam, and metallic mercury. On adding vermilion to zinc powder previously drenched with hydrochloric acid, hydrogen sulphide is immediately evolved, and the colour is destroyed. This shows that mercuric sulphide is likewise decomposed by nascent hydrogen (Heumann, *Deut. Chem. Ges. Ber.* vii. 752, 1388 and 1486).

Mercuric sulphide is insoluble in caustic soda-ley and in sodium monosulphide, but dissolves in a mixture of the two; with 2 pts. crystallised sodium sulphide, 2 pts. soda-ley of sp. gr. 1.33, and 1 pt. mercuric sulphide, an orange-red solution of mercury-sodium sulphide is obtained which filters readily. On heating this solution with water, black mercuric sulphide separates, and by adding a sufficient excess of water the whole of the mercury may be removed from the liquid; if, however, an excess of alkali is present, the complete precipitation of the mercury cannot be effected. Mineral acids, organic acids, and hydrogen sulphide produce an immediate precipitate of black amorphous sulphide. If the liquid be left to itself in a loosely closed vessel, it absorbs carbonic acid, gives off hydrogen sulphide, and deposits, first, crystals of sodium carbonate mixed with 5 per cent. mercury sulphide, afterwards red and red-brown crystals of mercury sulphide, which are finer and more regular the more slowly the absorption of carbonic acid takes place. These crystals are hexagonal prisms or plates which react chemically like cinnabar (Méhu, *Russ. Zeitschr. Pharm.* 1876, 321).

Compound of Mercuric Sulphide with Cuprous Chloride, $2\text{HgS} \cdot \text{Cu}_2\text{Cl}^2 = \text{Cl} \cdot \text{Cu} \cdot \text{S} \cdot \text{Hg} - \text{Hg} \cdot \text{S} \cdot \text{Cu} \cdot \text{Cl}$.—When red or black mercuric sulphide is boiled with a solution of cupric chloride, no reaction takes place at first; but, on adding strong hydrochloric acid, a brilliant orange-powder is immediately formed, whilst the liquid assumes a dark brown colour due to the formation of cuprous chloride, which dissolves with that colour in the excess of cupric chloride. The yellow precipitate contains a large quantity of admixed sulphur, which, however, may be easily removed by solution in carbon sulphide. The formation of this compound may be represented by the equation:

The formation of cuprous chloride is probably also partly due to another reaction represented by the equation $\text{HgS} + 2\text{CuCl}^2 = \text{HgCl}^2 + \text{Cu}_2\text{Cl}^2 + \text{S}$, partly to a secondary action of the excess of cupric chloride on the previously formed yellow body. Strong

hydrochloric acid, boiled with the compound $2\text{HgS} \cdot \text{Cu}^2\text{Cl}^2$, dissolves out cuprous chloride and mercuric chloride, with slight evolution of hydrogen sulphide. Dilute sulphuric acid exerts no action on the compound even at the boiling heat; but the boiling concentrated acid decomposes it, with elimination of hydrogen chloride and sulphur dioxide, forming a compound of mercuric sulphate and sulphide. Caustic soda colours the yellow compound deep black, removing all the chlorine, and replacing it by oxygen, whence there results a mixture of 2 mol. HgS and 1 mol. Cu^2O . Dilute hydrochloric acid heated with this mixture dissolves a large quantity of mercury but only a small quantity of copper, the reaction, as shown by direct experiment, taking place according to the equation:

Cuprous or cupric sulphide digested with mercuric chloride yields nothing but the white compound $2\text{HgS} \cdot \text{HgCl}^2$ (Heumann, *Deut. Chem. Ges. Ber.* vii. 1390).

Analysis.—For the quantitative analysis of native cinnabar, Fr. Gramp (*J. pr. Chem.* [2], xi. 77) oxidises it with nitric acid of sp. gr. 1.4 in a sealed tube at 120° , whereby complete solution is effected.

An analysis by C. W. Dabney of native cinnabar from Canyon City, Oregon, has been published by J. W. Mallet (*Chem. News*, xxxiv. 180). This cinnabar is remarkable for giving off hydrogen sulphide when treated with hydrochloric acid, then yielding a small quantity of sulphur when heated in a sealed tube, then again giving off hydrogen sulphide when heated with hydrochloric acid, which, at the same time, dissolves iron. The analysis of the mineral, which forms veins in calcespar, gave:

Hg	S ^(*)	S ^(*)	Fe	SiO ^a	O ^(*)
78.42	0.54	13.59	4.09	3.06	0.30 = 100.

(*) Given off as H^2S .

(*) In the residue.

(*) By difference.

The double reaction is explained on the supposition that the iron is present partly as magnetic pyrites, partly as iron pyrites. Supposing part of the sulphur to be combined with the mercury as HgS , then calculating the quantity given off in the form of H^2S as Fe^2S , the remaining sulphur as FeS^2 , and the rest of the iron as Fe^2O^3 , we have:

HgS	Fe^2S^2	FeS^2	Fe^2O^3	SiO ^a
90.97	1.37	1.95	3.36	3.06 = 100.71.

To the presence of similar mixtures of iron sulphides containing different proportions of sulphur, Mallet likewise attributes the differences in the analyses of cinnabar from other localities (*e.g.* from Japan, analysed by John), which have given, instead of 32 pts. sulphur, as much as 44.64 pts. to 200 of mercury.

MERCURY-ACETAMIDE, $\text{C}^4\text{H}^5\text{N}^2\text{O}^2\text{Hg} = (\text{CH}^3 \cdot \text{CO} \cdot \text{NH})^2\text{Hg}$. This compound, produced by saturating an aqueous solution of acetamide with mercuric oxide (i. 7), is decomposed by heating to 100° in sealed tubes with carbon disulphide, yielding mercuric sulphide, carbon oxysulphide, acetonitril, and acetamide:

and

Iodine (not in excess) and thiocarbanilide likewise separate large quantities of acetamide from its mercury-compound. Mercury-acetamide is completely decomposed by hydrogen sulphide in alcoholic solution, behaving, therefore, with various reagents in the same manner as mercury-benzamide. Both these compounds are also decomposed in a similar manner by dry distillation, yielding large quantities of the acid amide, together with water, ammonia, carbon, and metallic mercury; the benzamide-compound also yields benzonitril (Oppenheim a. Pfaff, *Deut. Chem. Ges. Ber.* vii. 623).

Phenyl-mercuracetamide or *Mercuracetanilide*, $(\text{CH}^3 \cdot \text{CO} \cdot \text{N} \cdot \text{C}^6\text{H}^5)^2\text{Hg}$, is formed by fusing acetanilide with mercuric oxide, and crystallises from alcoholic solution in small colourless needles which melt, with partial decomposition, at 215° , and are completely decomposed by hydrogen sulphide.

MERCURY-BENZAMIDE, $(\text{C}^6\text{H}^5 \cdot \text{CO} \cdot \text{NH})^2\text{Hg}$. See **BENZAMIDE** (p. 155).

MERCURY-DICMYL, $(\text{C}^{10}\text{H}^{13})^2\text{Hg}$, is formed by heating a mixture of bromocymene and xylene with sodium-amalgam, with addition of a little acetic ether. It forms long slender needles, which melt at 134° , and dissolve with moderate facility in boiling alcohol, very sparingly in cold alcohol, more readily in benzene and in xylene. It volatilises without decomposition.

MERCURY-PHENYLXANTHAMIDE. See **XANTHAMIDE**.

MERCURY THIOCYANATE. See THIOCYANATES.

MESACONIC ACID, $C^8H^6O^4$. See PYROCITRIC ACIDS, under CITRIC ACID (pp. 511, 518); also PYROTARTARIC ACID.

MESADIBROMOPYROTARTARIC ACID. See PYROTARTARIC ACID.

MESIDINE. See MESITYLENES (AMIDO-); also CUMIDINE (p. 592).

MESITOL, $C^9H^{12}O = C^9H^{11}.OH$ (Biedermann a. Ledoux, *Deut. Chem. Ges. Ber.* viii. 57). Mesidine nitrate, treated with nitrous acid, yields a solution of diazo-mesitylene nitrate, and on distilling this solution, a large quantity of gas is given off, and mesitol passes over with the aqueous vapour, solidifying partly in the condensing tube, partly in the receiver. Mesitol is also formed, together with another body, most probably oxymesitylenic acid, by fusing potassium mesitylenesulphonate with potassium hydroxide. On acidulating the melt with sulphuric acid, and distilling with water, the mesitol passes over with the steam at the beginning of the distillation.

Mesitol has a strong odour of phenol, dissolves very easily in alcohol, ether, and benzene, floats on water, volatilises very readily with aqueous vapour, and crystallises at the same time in very beautiful long white needles. It melts at 68° – 69° , and boils at 215° – 220° .* Mesitol dissolves very easily in the fixed alkalis, and is precipitated therefrom in the crystalline state by hydrochloric acid. It does not dissolve in ammonia or in alkaline carbonates. No nitro-derivatives of it have been obtained. Treated in acetic acid solution with bromine, it forms monobromomesitol, which is precipitated by water in white flocks, and crystallises from alcohol in slender needles having a silky lustre and melting at 80° .

MESITYL OXIDE, $C^6H^{10}O$. This compound is formed, together with other products, by the action of zinc-methyl or zinc-ethyl on acetone (Pawlow, *Deut. Chem. Ges. Ber.* ix. 1311); also in small quantity, together with ammonia and other bases, by the distillation of diacetanamine (Heintz, *Liebig's Annalen*, clxiv. 133; clxxxi. 70; *Ber.* viii. 768).

Mesityl oxide, as well as phorone, is converted by strong sulphuric acid, for the most part, into mesitylene (Claisen, *Ber.* vii. 1168). By prolonged boiling with dilute nitric acid, resinous products are formed at first, afterwards acetic and oxalic acids. Bromine acts violently on mesityl oxide, with evolution of hydrogen bromide; but a solution of mesityl oxide in carbon sulphide takes up bromine directly, forming the compound $C^6H^{10}O.Br^2$. As the solvent evaporates, this dibromide remains in the form of a dark-coloured oil which becomes yellowish on distillation with steam. It is, however, only comparatively permanent under water; in the dry state it assumes, after a few hours, a deep violet colour, and slowly gives off hydrogen bromide. It cannot be distilled even in a vacuum. An alcoholic solution of mesityl oxide is strongly attacked by sodium-amalgam; and if, after the odour of the mesityl oxide is no longer perceptible, the solution be precipitated with water, and the oil thereby thrown down be subjected, after drying, to distillation, the greater part ($\frac{3}{4}$ of it) passes over between 205° and 225° , and of this the principal fraction at 213° – 217° . This fraction has the composition $C^{12}H^{22}O$. Sometimes, also, there is formed a small quantity of a solid body which melts between 110° and 120° (Claisen, *Ber.* viii. 1256).

MESITYLENE, $C^6H^2(CH^3)^3$ [1 : 3 : 5], and **PSEUDOCUMENE**, $C^6H^2(CH^3)^3$ [1 : 2 : 4] (Jacobsen, *Liebig's Annalen*, clxxiv. 170; *Ber.* ix. 256; x. 855). These two modifications of trimethylbenzene occur together in coal-tar oil, and cannot be effectually separated by the usual methods of fractional distillation, or fractional crystallisation of the barium salts of their sulphonic acids. The separation may, however, be effected by converting them into the amides of their sulphonic acids. For this purpose, the portions of commercial cumene from coal-tar oil, boiling between 160° and 168° , and freed from phenol, are agitated with ordinary sulphuric acid, and the resulting sulphonic acids are converted into barium salts and then into sodium salts; the latter in the state of dry powder are triturated with an equal weight of phosphorus pentachloride; the product is freed from phosphorus oxychloride by heating; and the residual semifluid mass, when cold, is added to a large excess of concentrated aqueous ammonia. The resulting sulphamides, which harden after a few days to a crystalline mass, are washed with water, dissolved in alcohol, and separated from one another by distilling off the alcohol and leaving the residue to crystallise, whereupon the pseudocumenesulphamide crystallises out first, and then the mesitylenesulphamide.

To obtain the hydrocarbons from these sulphamides, the latter are heated in

* Fittig a. Hoogewerff (*Liebig's Annalen*, cl. 323), by heating potassium mesitylenesulphonate with potash, obtained a phenol to which they assigned the formula C^6H^2O (xyleneol, vi. 1128). It is described as melting at 70° – 73° , boiling at 216° – 217° , and yielding with bromine a dibromo-derivative which Biedermann a. Ledoux were not able to obtain.

sealed tubes with strong hydrochloric acid, the mesitylenesulphamide to about 160°, the pseudocumenesulphamide to about 170°. The hydrochloric acid must be used in considerable excess, as otherwise the products will consist of the corresponding dimesitylene- and dipseudocumene-sulphamides, especially if the temperature required for the decomposition be not continued long enough.

The mother-liquors of mesitylene and pseudocumene thus obtained, yielded, when treated as above described, sulphamides melting respectively at 130° and 100°–102°; and both of these sulphamides, when heated with hydrochloric acid, yielded one and the same hydrocarbon, boiling at 138°–140°, which is the boiling point of metaxylene. Crude coal-tar cumene contains, therefore, only two trimethylbenzenes, viz. mesitylene and pseudocumene; and the great difficulty of separating these two hydrocarbons arises from the fact that they obstinately retain, not, as might be expected, a third trimethylbenzene, but a dimethylbenzene, viz. metaxylene. That the separation of the two trimethylbenzenes cannot be effected through the medium of the barium salts of their sulphonic acids is due to the formation of a molecular compound of these two barium salts, which may, in fact, be directly obtained by crystallising the two together (p. 1285).

Mesitylene is also formed: α . By the action of strong sulphuric acid on mesityl oxide and on phorone (from acetone) (Claissen, *Ber.* vii. 1168). β . By polymerisation of allylene, $\text{CH}_2=\text{C}(\text{CH}_3)=\text{CH}_2$ (prepared by the action of alcoholic potash on propylene bromide, and purified by conversion into the copper compound) under the influence of strong sulphuric acid. The allylene is absorbed by the acid in large quantity, forming a brown-yellow solution, which when diluted with a little water and distilled, yields a distillate consisting of two layers, the upper of which is nearly pure mesitylene. The polymerisation of the allylene takes place, not during its absorption by the sulphuric acid, but in the subsequent distillation (Fittig a. Schroe, *Ber.* viii. 17; Jacobsen, *ibid.* x. 855).

Nitro- and Amido-mesitylenes (Ladenburg, *Ber.* vii. 1133; *Liebig's Annalen*, clxxix. 163).—Dinitromesitylene is converted by ammonium sulphide into the nitromesidine, $\text{C}_9\text{H}_7(\text{CH}_3)_3(\text{NO}_2)(\text{NH}_2)$, discovered by Maule (iii. 930), which melts at 72°–73°, and crystallises in large thick yellow prisms when left to cool slowly from the state of fusion. By the action of acetyl chloride it is converted into nitroacetyl-mesidine and hydrochloride of nitromesidine:

The quantity of nitroacetyl-mesidine is however greater, and that of nitromesidine hydrochloride less than that which corresponds with the preceding equation; the nitromesidine hydrochloride may be dissolved out of the crude product by warm water.

Nitroacetyl-mesidine forms nearly colourless needles having a silky lustre; it melts at 188°, and distils without decomposition; dissolves easily in warm alcohol even when dilute. By fuming nitric acid, or better by a mixture of nitric and sulphuric acids, it is converted into dinitro-acetyl-mesidine, $\text{C}_9\text{H}_7(\text{NH}(\text{C}_2\text{H}_3\text{O})(\text{NO}_2)_2)$, which crystallises from hot alcohol, in which it is but slightly soluble, in shining white needles melting at 275°. The dinitromesidine, $\text{C}_9\text{H}_7(\text{NH}_2)(\text{NO}_2)_2$, obtained by heating this acetyl-compound to 160° with hydrochloric acid, melts at 193°–195°, and is identical with that which Fittig obtained (vi. 300) by reduction of trinitromesitylene. On drenching it with alcohol saturated with nitrous acid, it becomes very hot, so that it is necessary to add the alcohol only gradually and to moderate the action by cooling. The resulting dinitromesitylene, $\text{C}_9\text{H}_7(\text{NO}_2)_2$, forms nearly colourless shining needles, melts at 86°, and is identical with the dinitromesitylene discovered by Hofmann (iii. 930).

Mononitromesitylene, $\text{C}_9\text{H}_7(\text{NO}_2) = \text{C}_9\text{H}_7(\text{NO}_2)(\text{CH}_3)_3$.—The mode of preparing this compound given by Fittig and Storer (vi. 299) yields it in small quantity only. Larger quantities are obtained by distilling with steam the oil which remains when the last mother-liquors of the preparation of dinitromesitylene are left to evaporate. The same nitromesitylene is obtained by converting dinitromesitylene into nitromesidine, and treating the latter with nitrous acid and alcohol. It melts at 42°, and boils at 255°. By tin and hydrochloric acid it is reduced to amidomesitylene, $\text{C}_9\text{H}_7(\text{NH}_2)$, boiling at 229°–230°, and remaining liquid at –15°. The *platinochloride* of this base, $(\text{C}_9\text{H}_7(\text{NH}_2).\text{HCl})_2\text{PtCl}_4$, is nearly insoluble in hot water, and crystallises from strong hydrochloric acid in needles having a golden-yellow shimmer.

Acetylamidomesitylene, $\text{C}_9\text{H}_7(\text{NH}(\text{C}_2\text{H}_3\text{O}))$, prepared from the preceding base by the action of acetyl chloride, or by heating with glacial acetic acid, melts at 216°–217°, and sublimes in needles without decomposition. It dissolves in nitric acid of sp. gr. 1.4, and is precipitated therefrom by water without alteration. If, however, it be

added to fuming nitric not too highly concentrated, and the liquid be gradually mixed with water, nitro-acetyl-mesidine gradually separates. The nitro-base thus produced crystallises from alcohol in white needles melting at 186° – 188° , and is identical with the nitro-acetyl-mesidine obtained, as above mentioned, by acetylation of nitro-mesidine. Like the latter it yields, when heated to 160° with hydrochloric acid, the nitromesidine which melts at 74° .

Mesitylene-acediamine, $C^9H^{10}(NH.C^2H^3O)^2$, is obtained by boiling mesitylene diamine, $C^9H^{10}(NH^2)^2$, with glacial acetic acid. It melts at a temperature above 300° , and is nearly insoluble in water and in dilute hydrochloric acid (Ladenburg, *Ber.*, viii. 677).

Mesitylenesulphonic acid, $C^9H^{11}(SO^2H) = C^9H^2(CH^3)^3(SO^2.OH)$, crystallises in prisms containing 2 mols. H^2O . *Barium Mesitylenesulphonate*, $(C^9H^{10}SO^2)^2Ba + 9H^2O$, is obtained, by slow evaporation of its solution, in large monoclinic tables; by more rapid crystallisation in long flat prisms acuminate on both sides, 5.53 parts of which dissolve in 100 pts. water at 11.5° . At the same temperature 4.19 pts. of the anhydrous salt dissolve in 100 pts. of water (Jacobsen).

Mesitylenesulphamide, $C^9H^{11}SO^2NH^2 = C^9H^2(CH^3)^3(SO^2.NH^2)$, crystallises from alcohol as a white, long-fibred, asbestos-like mass, from hot water in capillary needles. 1 part of it dissolves in 185 pts. boiling water, and in about 3000 pts. water at 0° , in 0.88 pt. boiling alcohol of 83 per cent., and in 18 pts. of the same alcohol at 0° . In ether it is less soluble than in alcohol; it dissolves also in strong sulphuric acid and in alkalis. Melting point 141° – 142° (Jacobsen). By oxidation with potassium dichromate and sulphuric acid it is converted into parasulphamine-mesitylenic acid, $C^9H^2(CH^3)^3(SO^2NH^2)(CO^2H)$. See MESITYLENIC ACID (p. 1285).

Dimesitylenesulphanide, $(C^9H^{11}SO^2)^2NH$, formed by heating the preceding compound with hydrochloric acid not in excess, and not long enough to effect its complete decomposition (p. 1283), is moderately soluble in hot water, and crystallises therefrom in needles which melt at 124° , and are partly decomposed on volatilisation (Jacobsen).

Pseudocumene or Unsymmetrical Trimethylbenzene,

$C^6.CH^3.CH^3.H.C^4.H.H$, is obtained: 1. From coal-tar cumene in the manner already described (p. 1282), or more simply by agitating the crude coal-tar cumene with strong sulphuric acid, mixing the acid mass with about five times its bulk of water, syphoning off the layer of dilute sulphuric acid which sinks to the bottom, diluting the remaining liquid with four times its bulk of water, and leaving the clear warmed solution to crystallise, whereupon it deposits cubes of pseudocumenesulphonic acid. These, when purified by crystallisation and heated, yield a distillate of pure pseudocumene (Jacobsen, *Ber.* ix. 258). 2. By dehydration of phorone with phosphoric anhydride,* $C^9H^{14}O - H^2O = C^9H^{12}$. 100 pts. phorone (from acetone) are heated in a sand-bath with 75 pts. phosphoric anhydride mixed with twice its weight of sand, the mixture being slowly distilled to dryness and the distillate fractionated. The greater part of it is found to consist of pseudocumene, identical in its properties with that obtained from coal-tar oil (Jacobsen, *Ber.* x. 855). 3. By the action of methyl iodide and sodium at 100° in a reflux apparatus on the dibromotoluene, $C^6.CH^3.Br.H.Br.H^2$, prepared by exposing a mixture of ortho- and para-bromotoluene to the action of bromine and iodine in sunshine (Fittig & Jannasch, *Liebig's Annalen*, cli. 283; Jannasch, *ibid.* clxxvi. 283). 4. As a bye-product, in the preparation of durenene (tetramethylbenzene) from dibromoxylene, methyl iodide, and sodium (Jannasch, *loc. cit.*)

Pseudocumene boils at 166° , and is oxidised by dilute nitric acid to paraxylic acid, $C^9H^3(CH^3)^2(CO^2H)$, and xylic acid, $C^9H^3(CH^3)(CO^2H)^2$ (vi. 1129).

Pseudocumenesulphonic acid, $C^6.CH^3.CH^3.H.C^4.H.SO^2H$.—The barium salt of this acid separates from solution at ordinary temperatures in anhydrous crystalline scales; but on leaving its solution to evaporate over sulphuric acid, at a temperature between 0° and 5° , the salt separates in limpid rhombic tables or rhombohedral crystals which contain 2 mol. water and effloresce very easily.

When the barium salts of pseudocumenesulphonic and mesitylenesulphonic acids, previously deprived of their water of crystallisation, are crystallised together in molecular proportions, there is obtained, whether the crystallisation takes place at the ordinary or at a lower temperature, an anhydrous double salt composed of pseudocumenesulphonate and mesitylenesulphonate of barium; this result confirms what has already been said (p. 1283) about the difficulty of separating the two hydrocarbons by means of their barium sulphonates. 100 pts. water at 11.5° dissolve 5.81 pts. of this double salt.

* Phorone dehydrated by sulphuric acid yields, as already observed, mesitylene instead of pseudocumene (p. 1285).

Pseudocumenesulphamide, $C^9H^{11}SO^2NH^2$, crystallises from alcohol in short hard prisms, from hot water in laminae, and melts between 175° and 176° . One part of it dissolves in 380 pts. of boiling water, in about 7000 pts. of water at 0° , and in 4.4 pts. of 83 per cent. alcohol at 0° . It is less soluble in ether than in alcohol, and behaves to strong sulphuric acid and alkalis like mesitylenesulphamide.

MESITYLENE, HOMOLOGUES OF (Jacobsen, *Ber.* vii. 1430). These bodies are derivatives of benzene containing three alcohol-radicles, C^9H^{2n+1} , in the symmetrical positions 1, 3, 5. The formation of a hydrocarbon having the composition $C^{10}H^{14}$ in the preparation of mesitylene was observed some years ago by Fittig a. Brückner (*Lieb. Ann.* cxlvii. 42), and by Jacobsen (*ibid.* cxlvi. 85), and the formation of a sulphonic acid yielding a sparingly soluble barium salt (like that of the sulpho-acid from the hydrocarbon $C^{10}H^{14}$ just mentioned) was noticed by H. Rose (*ibid.* cxliv. 53). It appeared probable that the source of this hydrocarbon was to be found in the methyl-ethyl ketone which Fittig had detected in crude acetone; and in fact Jacobsen found that pure acetone did not yield any homologues of mesitylene, but that when mixtures of pure acetone (b. p. 58° – 59.5°) with methyl-ethyl ketone were subjected to the process usually adopted for the preparation of mesitylene, large quantities of higher hydrocarbons (b. p. 170° – 230°) were obtained, from which, by fractionation and further methods of purification, three hydrocarbons were isolated, represented by the formulæ $C^{10}H^{14}$, $C^{11}H^{16}$, and $C^{12}H^{18}$.

Dimethylethylbenzene, $C^{10}H^{14} = C^6H^3(CH^3)^2(C^2H^3)$, boils at 180° – 182° , and yields on oxidation mesitylenic acid and a little uvitic acid. Its sulphonic acid crystallises in large needles, and yields a barium salt which crystallises in pearly scales. As it is but sparingly soluble in water, it is easily separated from barium mesitylene-sulphonate, and therefore well adapted for the preparation of the pure hydrocarbon. *Tribromodimethylethylbenzene* is sparingly soluble in alcohol, and crystallises from a hot solution in thin long needles melting at 218° ; it readily sublimes, and distils above 360° . *Trinitrodimethylethylbenzene* crystallises from hot alcohol in hard, long needles melting at 238° .

Methyldiethylbenzene, $C^{11}H^{16} = C^6H^3(CH^3)(C^2H^3)^2$, boils at 198° – 200° . On oxidation it yields chiefly uvitic acid, and its tribromo-compound crystallises from hot alcohol in needles melting at 206° .

Triethylbenzene, $C^{12}H^{18} = C^6H^3(C^2H^3)^3$, is obtained in small quantity only by the process above mentioned, much more abundantly (as also methyldiethylbenzene) from those fractions of crude acetone which pass over above 65° ; in very small quantity, on the other hand, by treating nearly pure methyl-ethyl ketone with sulphuric acid. It boils at 217° – 220° , and is oxidised by chromic acid to trimesic acid.

Methyl-dipropyl-benzene, $C^{13}H^{20} = C^6H^3(CH^3)(C^3H^7)^2$, is obtained, together with *Dimethyl-propyl-benzene*, $C^{11}H^{16} = C^6H^3(CH^3)^2(C^2H^3)$, and mesitylene, by carefully distilling 2 vols. methyl-propyl ketone (b. p. 104° – 110°), and 4 vols. acetone with 3 vols. sulphuric acid, and subjecting the portions of the product which boil between 190° and 260° to repeated fractional distillation over sodium. Dimethyl-propyl-benzene boils at 206° – 210° ; methyl-dipropyl-benzene at 243° – 248° . The former when boiled with dilute nitric acid (sp. gr. 1.1) yielded mesitylenic acid, with scarcely any secondary products; the latter gave nothing but uvitic acid, together with a very small quantity of an acid which volatilised with vapour of water.

The products of still higher boiling point did not yield any tripropyl-benzene; neither were higher homologues of mesitylene obtained by the action of sulphuric acid on methyl-propyl ketone, or methyl-isobutyl ketone, or methyl- α -naphthol (Jacobsen, *Ber.* viii. 1258).

MESITYLENIC ACID,

This acid is formed, together with a very small quantity of uvitic acid, $C^9H^8O^4$, by boiling symmetrical dimethylethylbenzene (p. 1285) with nitric acid of sp. gr. 1.1 (Jacobsen, *Ber.* vii. 1430; Wroblewsky, *ibid.* ix. 495).

Parasulphamine-mesitylenic acid,

is produced by boiling mesitylene-sulphamide for five hours with potassium dichromate (7 pts.) and sulphuric acid (10 pts. diluted with 3 vols. water). It crystallises from its aqueous solution in flat irregular prisms; melts at 247° ; dissolves easily in alcohol and ether, sparingly in boiling water, and is nearly insoluble in cold water. The barium salt is very soluble and difficult to crystallise. The copper salt,

$[\text{C}^6\text{H}^2(\text{CH}^3)_2(\text{SO}^2\text{NH}^2)\text{CO}^2]^2\text{Cu} + 4\text{H}^2\text{O}$, is precipitated from the solution of the barium salt by cupric sulphate in small blue needles, which, after drying in the air, give off water over sulphuric acid, and recover it on subsequent exposure to the air; at 200° the salt becomes light-green, loses all its water, and is afterwards not altered by contact with the air.

By heating with concentrated hydrochloric acid, parasulphamine-mesitylenic acid is partly converted into mesitylenic acid, which may be separated from the unaltered acid by sublimation (Hall a. Remsen, *Ber.* x. 1039).

MESOCAMPHORIC ACID, $\text{C}^{10}\text{H}^{16}\text{O}^4$. Jungfleisch (*Ber.* vi. 268), by heating dextrocamphoric acid with a little water to 170° – 180° , has obtained an inactive camphoric acid which he has not been able to separate into dextro- and lævo-acid. It crystallises in tufts of needles, and appears to be identical with mesocamphoric acid (vii. 235). Another modification, likewise inactive, and apparently identical with Chautard's paracamphoric acid (vi. 389), is formed by heating camphoric acid to 280° . F. Wreden (*Ber.* vi. 565) remarks that mesocamphoric acid, which he also regards as identical with Jungfleisch's acid, is, according to his own experiments, very easily converted into another inactive modification, probably identical with the second acid obtained by Jungfleisch.

METACINNAMENE or **METASTYROLENE**, C^8H^8 , is formed, together with cinnamene and other products, by heating phenylbromethyl with an alcoholic solution of potassium cyanide (Radziszewski, *Ber.* vii. 140).

METACROLEIN, $\text{nC}^3\text{H}^4\text{O}$. This polymeride of acrolein, which Geuther a. Cartmell obtained by heating acrolein hydrochloride with potassium hydrate, is likewise formed, together with ethoxyl-acrolein, $\text{C}^6\text{H}^8\text{O}^2 = \text{C}^3\text{H}^3(\text{OC}^2\text{H}^5)_2\text{O}$, and other products, by heating the same salt with sodium ethylate (Taubert, p. 42 of this volume).

$[\text{NH} : \text{CNH} = 1 : 3]$. This modification of cyananiline, which melts at 54° , is obtained by distilling uramido-benzoic acid with a fourth of its weight of phosphoric anhydride. Para-uramidobenzoic acid, similarly treated, yields paracyananiline melting at 86° (Griess, *Ber.* viii. 1114).

META-DERIVATIVES, AROMATIC (1 : 3). This article includes a number of meta-derivatives which have not been noticed under the respective primary compounds, and references to a few others, which otherwise might not easily be found.

See CARBAMIDES (p. 394).

Metabromaniline, $\text{C}^6\text{NH}^2\text{H.Br.H}^3$. See BENZENES (BROMAMIDO-), p. 193.

Metabromobenzyl Bromide, $\text{C}^6\text{H}^4\text{Br.CH}^2\text{Br} = \text{C}^6\text{CH}^2\text{Br.H.Br.H}^3$. See BENZYL, HALOID ETHERS OF (p. 314).

Metachlor-orthonitraniline, $\text{C}^6\text{NH}^2\text{NO}^2\text{H.H.Cl.H}$. See BENZENES (CHLORO-NITRAMIDO-), p. 202.

Metachlor-ortho-oxybenzoic or *Metachlorosalicylic acid*, $\text{C}^6\text{CO}^2\text{H.OH.H.H.Cl.H}$ (m. p. 172.5°). See BENZOIC ACIDS (OXY-), pp. 280, 300.

Meta-cresol, $\text{C}^6\text{OH.H.OH}^3\text{H}^3$. See PHENOLS.

Meta-cyaniline. See PHENYLAMINES.

Metadibromobenzidine, $\text{C}^{12}\text{H}^{10}\text{N}^2\text{Br}^2$. See METAZOXYDIBROMOBENZENE (p. 1287).

Metadicyanobenzene, $\text{C}^6\text{H}^4(\text{CN})^2$, obtained by distilling the potassium salt of benzene-metadisulphonic acid (p. 251) with potassium cyanide, crystallises in filiform needles, very soluble in water and melting at 156° (Körner a. Monselise, *Gazz. chim. ital.* 1876, 133); according to Limpricht (*Liebig's Annalen*, clxxx. 88) it forms nodular groups of needles melting at 150° .

Meta-hydrazodibromobenzene. See METAZOXYDIBROMOBENZENE (p. 1287).

Metanitrobenzoyl-carbamide, $\text{C}^6\text{NH}^2\text{H}[\text{CO.NH.CO.NH}^2]\text{H}^3$ (see the corresponding Amido-compound, *supra*).

Metanitrobenzyl Bromide, $\text{C}^6\text{H}^4(\text{NO}^2).\text{CH}^2\text{Br} = \text{C}^6\text{CH}^2(\text{NO}^2).\text{H.Br.H}^3$. See TOLUENES (NITRO-).

Metanitro-orthochloraniline, $\text{C}^6\text{NH}^2\text{H.NO}^2\text{H.H.Cl}$. See BENZENES (CHLORONITRAMIDO-), p. 203.

Meta-oxyphenyl-urethane, $\text{C}^2\text{H}^3\text{O.CO.NH}(\text{C}^6\text{H}^4)\text{OH}$. See URETHANES.

Meta-oxuvitic acid. See OXYUVITIC ACID.

Metaphenylene-diamine, $C^6H^4.NH^2.H.NH^2.H^3$. See BENZENES (DIAMIDO), (p. 210).

Metazocarbonylbenzene—*Metadimethylamidocarbonylbenzene*, or *Carboxylphenylmetazodimethylamidobenzoic acid*,

is formed by the action of metadiazobenzoic acid on metadimethylamidobenzoic acid. It is a reddish-brown precipitate, gradually becoming crystalline, and possessing great tinctorial power (Griess, *Ber.* 1877, 525).

Metazoxydibromobenzene, $C^{12}H^8Br^2N^2O$, is prepared by heating 13 pts. metabromonitrobenzene (m. p. 63°), with 50 pts. alcohol (of about 90 per cent.) and 8 pts. potassium hydroxide; boiling the product for half an hour after the reaction has ceased, then distilling off the alcohol, washing the residual brown-red crystalline mass with water or alcohol, to remove a red colouring matter, and recrystallising it from hot alcohol with addition of animal charcoal, or better from boiling crystallisable acetic acid containing nitric acid. It forms broad, light-yellow prisms, melting at 111° – 112° , soluble in ether, glacial acetic acid, carbon sulphide, benzene, and nitrobenzene; volatilises completely when heated; and forms with strong sulphuric acid a deep yellow solution, turning blood-red when warmed (S. Gabriel, *Ber.* ix. 1405).

Metahydrazodibromobenzene, $C^{12}H^{10}Br^2N^2$, obtained by boiling the preceding compound with ammonium sulphide, forms white or faintly reddish thick prisms, melting at 107° – 109° , easily soluble in ether, benzene, warm alcohol, carbon sulphide, and nitrobenzene. It volatilises without decomposition, and dissolves with yellow colour in strong sulphuric acid. The hydrazodibromobenzene which melts at 130° is a para-compound.

When metahydrazodibromobenzene is boiled with strong hydrochloric acid till complete solution takes place on addition of water, and the solution, after decolorisation with animal charcoal, is supersaturated with ammonia, *metadibromobenzenidine*, $C^{12}H^{10}N^2Br^2$, is obtained in white crystals of rhombic habit, melting at 151.5° to 152° , easily soluble in hot alcohol, also in ether, benzene, and nitrobenzene, sparingly in carbon sulphide. The crystals volatilise when heated, turning slightly brown. The *hydrochloride*, $C^{12}H^{10}N^2Br^2.2HCl$, forms white crystalline scales. The *platinchloride* has the formula $2(C^{12}H^{10}N^2Br^2.HCl).PtCl^4$.

Azodibromobenzene, $C^{12}H^8Br^2N^2$, prepared from metahydrazodibromobenzene by oxidation with ferric chloride, or by boiling the alcoholic solution of the same compound with animal charcoal, crystallises in slender needles with oblique end-faces; melts at 125.5° ; volatilises without decomposition; dissolves easily in carbon sulphide, ether, and nitrobenzene, sparingly in alcohol.

Metazoxydiiodobenzene, $C^{12}H^8I^2ON^2$, prepared by heating 10 pts. iodonitrobenzene (m. p. 56°) with 50 pts. alcohol and 8 pts. potassium hydroxide, forms flat yellow needles, which volatilise completely when heated; they are sparingly soluble in cold, easily in hot alcohol, easily also in the other ordinary solvents. Heated to 100° in a sealed tube with alcoholic ammonium sulphide, this compound is converted into *metahydrazodiiodobenzene*, $C^{12}H^{10}I^2N^2$, which melts at 89° – 90° , dissolves readily in the ordinary solvents, and is decomposed by hydrochloric acid, with separation of iodine. *Metazodiiodobenzene*, $C^{12}H^8I^2N^2$, prepared from the last by oxidation with ferric chloride, crystallises in orange-red needles with oblique end-faces; melts at 150° ; dissolves slightly in alcohol, easily in the other ordinary solvents; volatilises when heated (Gabriel, *loc. cit.*)

METADIABASE, METADOLERITE, and METAMELAPHYRE.
See MELAPHYRE (p. 1272).

METALS. *Formation in Veins.*—Experiments by St. Meunier (*Compt. rend.* lxxxiv. 638) on the reduction of the noble metals by metallic sulphides, tend to show that the presence of gold in iron pyrites, and more especially that of silver in galena, may be due to reactions of this kind. When sea-water acts on a vein of galena, the small amount of silver which the water contains may become concentrated in the galena. The separation of sulphur which accompanies this reaction may lead to the formation of silver sulphide or to the persulphuration of the lead sulphide. On the supposition that the same reaction may be exerted by sodium sulphide, Meunier suggests that sulphuretted mineral springs may play a certain part in the formation of mineral veins.

On the Electrodeposition of Metals on other Metals, see *Dingl. pol. J.* ccviii.

340, 466; *Jahresb. f. Chem.* 1873, 1007.—*Chem. Centr.* 1874, 1680; *Dingl. pol. J.* cexi. 74; cexii. 160, 440; cexiii. 170, 358; *Jahresb.* 1874, 1092–1095). On the Coating of Iron with Copper, see p. 1118 of this volume.

Casting of Metals under reduced Pressure.—To obviate the defects arising from the enclosure of air-bubbles between the metal and the surface of the mould, Cumin a. Martel (*Engineering*, Dec. 20, 1872; *Dingl. cexii.* 259) exhaust this enclosed gas at the moment of casting by means of an air-pump. The sides of the mould must, of course, be porous enough to give passage to the air. Such moulds may be formed of gypsum, mixtures of gypsum with graphite or alum, or of graphite alone.

Action of Water containing Soap, Albumin, Glycerin, or other Organic Substances, on Red-hot Metals.—Metals at a red heat are not suddenly cooled by immersion in water containing such substances. When, for example, a red-hot copper ball is plunged into soap-water, the rapid production of steam which would ensue on dipping the ball into pure water does not take place. The ball, in fact, continues to glow in the soap-solution, and is surrounded by a layer of vapour, the surface of which completely reflects the light which falls upon it, so that the copper looks as if it were coated with oxidised silver. On continued immersion, the envelope of vapour gradually diminishes, till finally the soapy water comes in contact with the metal, producing an extremely violent burst of vapour (Barrett, *Monit. scient.* [3], iv. 91).

Colouring of Metals.—This may be effected by means of a solution of 42.5 grams sodium thiosulphate in 450 grams water mixed with a solution of 45.5 lead acetate in 225 water. Such a solution, when heated, yields lead sulphide, which, when deposited on metals in a thin film, gives them a fine colour. Iron is thereby coloured steel-blue; zinc brown; brass and bronze gold-yellow; copper red, crimson, chestnut brown, light-blue, or reddish-white, according to the temperature of the bath and the time of immersion. If the lead acetate be replaced by an equal quantity of sulphuric acid, bronze acquires first a red, then a green, and finally a splendid green-red colour (*Iron*, Oct. 1874, 419; *Dingl. pol. J.* cexv. 93). A black colour may be produced on copper-alloys and on silver by means of deliquescent platonic chloride rubbed on the surface (Weiskopf, *Dingl. pol. J.* cexv. 470).

METANETHOL-CAMPHOR, $C^{10}H^{12}O$ (Perrenoud, *Liebig's Annalen*, clxxxvii. 63). This substance, discovered by Gerhardt, is most advantageously prepared as follows: An intimate mixture of anethol (210 pts.) and zinc chloride (750 pts.), is heated in a copper retort, and after a few minutes, when white fumes make their appearance in the receiver, a current of super-heated steam is passed over the mixture, the operation being continued till about 2 litres of water have been evaporated. The metanethol-camphor then condenses, together with the aqueous vapours, in the form of a dark-coloured crystalline mass, which must be freed from water, washed with alcohol containing ether, and recrystallised from hot glacial acetic acid or ether. The product amounts to between 5.5 and 10 per cent. of the anethol employed.

Pure metanethol-camphor forms thin silky needles, felted like asbestos or grouped in large tufts, and exhibiting a fine play of colours in polarised light. It melts at 132° , boils with partial decomposition at a temperature above 300° , but sublimes between 115° and 120° . It does not volatilise with vapour of water at 100° . It dissolves very easily in glacial acetic acid at the boiling heat, less easily in hot ether or alcohol, readily in chloroform, carbon sulphide, benzene, and strong sulphuric acid, sparingly in cold ether, still more sparingly in cold alcohol, and is insoluble in water and in soda-ley.

Metanetholcamphor-sulphonic acid, $C^{10}H^{11}O.SO_3H$, is formed when a solution of the camphor in 4 to 6 pts. of cold strong sulphuric acid is left to itself for some hours. Its *calcium salt*, prepared from the dilute solution of the acid, and purified by recrystallisation from alcohol, forms large fatty-lustrous retangular plates, often with rounded edges. They contain water of crystallisation, which they give off with efflorescence on exposure to the air. The salt has the composition $(C^{10}H^{11}SO_3)^2Ca + H_2O$ at 120° – 130° , and decomposes at a higher temperature; it dissolves easily in water and in aqueous alcohol, less easily in absolute alcohol. The *barium salt*, $(C^{10}H^{11}OSO_3)^2Ba + H_2O$ (at 126°),* crystallises in concentric groups of thick prisms 1 mm. long, having a strong lustre, and permanent in the air. It dissolves very sparingly in absolute alcohol, somewhat more freely in ordinary alcohol, easily in water. The *sodium salt* forms needle-shaped crystals. The *sulphochloride*, $C^{10}H^{11}O.SO_2Cl$, prepared from the sodium salt by the action of phosphorus pentachloride, crystallises in thick prisms, soluble in ether, glacial acetic acid, and chloroform, and melting at 182° – 183° .

* Deduced from the barium determination (mean 22.94 per cent.), which, however, agrees better with the formula of the anhydrous salt (calc. 23.18) than with that above given (calc. 22.49). The water was not determined directly.

METEORITES. The following article contains descriptions and analyses of a number of meteorites which have been recently examined, and in many cases have been actually seen to fall.

The Meteoric Irons of the Mexican Desert. Daubréelite. J. Lawrence Smith (*Sill. Am. J.* 1876, [3], xii. 107; 1878, [3], xvi. 270) draws attention to the newly discovered masses of meteoric iron occurring in the region of Mexico called the *Bolson de Mapini*, or the Mexican Desert, situated in Cohahuila and Chihuahua, two of the northern provinces of the Mexican Republic. In 1854, three masses were described, two of which were conveyed to the United States; in 1868, eight other masses were conveyed to the States; and in 1871 a still larger block was discovered, estimated to weigh 3500 kilog., near El Para. There is, moreover, some account of a mass yet vaster, to be seen in the very centre of this desolate region.

It was in one of these irons that Smith found the mineral to which he has given the name of *daubréelite*. It consists of shiny black particles, more or less scaly in structure, not altogether unlike fine particles of molybdenite. The fracture is uneven, except in one direction, where there appears to be a cleavage. It is brittle and easily pulverised, and is not magnetic. It undergoes but little alteration before the blow-pipe, but becomes slightly magnetic. It is not acted upon in the slightest degree by hydrochloric acid, either hot or cold, but dissolves slowly and completely in nitric acid, when heated on a water-bath, without any liberation of free sulphur. Its sp. gr. is 5·01. It consists of chromium sesquisulphide and iron monosulphide. The analyses gave the following numbers:

	Found	FeS + Cr ² S ³
Sulphur	43·26	44·29
Chromium	36·38	36·33
Iron	20·36	19·38
	<hr/> 100·00	<hr/> 100·00

Chantonay, Dép. de la Vendée, France. August 5, 1812.—Tschemmak (*Wien. Akad. Ber.* lxx. Nov. 1874) finds that the meteorites of Orvinio and Chantonay closely resemble each other in point of structure. Sections of the latter stone, of which representations are given in his paper, show it to be made up of chondritic fragments covered with a dark-coloured crust, and cemented together with a black and in places semivitreous material. The fragments are not very abundantly provided with spherules, although large ones are occasionally met with. The chondrite of this stone differs from that of the Orvinio meteorite in containing less iron; a section shows olivine, bronzite, a fibrous translucent material, as well as nickel-iron and magnetic pyrites; no chromite. Fine black veins of a mineral traverse the fragments here and there, and are connected with the cementing material. Similar veins are noticed in the meteorites of Sissa, Kakowa, Château Renard, Alessandria, and Pultusk; and in the Sissa and Kakowa stones they present the appearance as if the meteorite had originally come in contact with a molten material which had been injected into the clefts of its surface. Moreover, in the Chantonay stone, clefts are to be met with into which the black matter has penetrated to a depth of 6 mm. only, although the cleft remains partly open. The black semivitreous magma consists of an entirely opaque mass, enclosing flakes of the silicate which forms the fragment, as well as occasional spherules.

Although Rammelsberg, who analysed this stone, does not describe the physical character of the material he operated on, and did not examine the fragments and the cementing material separately, as Tschemmak has done in his examination of the Orvinio meteorite, Tschemmak points out that the two stones have much the same composition, and differ mainly in the proportion of iron. The characters observed in these two meteorites point to the conclusion that they did not originally possess their present constitution, but that they have attained their present appearance through the disintegration of a solid rock-mass and its subsequent cementation with a semivitreous magma. Though they resemble somewhat the eruptive breccias, they differ from them in that the meteoric cementing material is less homogeneous, and encloses compact flakes of the rock itself. The Chantonay stone exhibits the fine texture observed in some metamorphosed breccias. The two stones convey to us evidence of changes which must have occurred on the solid surface of some planet that was subsequently reduced to fragments (see the Orvinio Meteorite, p. 1293).

The Siderolite of Rittersgrün: found 1833 (*Nova Acta der k. Leop.-Carol. Deut. Akad. der Naturforscher.* xl. No. 8, 333, Halle, 1878). The examination by Winkler of the siderolite of Rittersgrün, Saxony, shows it to accord very closely in composition with the siderolite of Breitenbach in Bohemia, examined some years since in the Laboratory of the Mineral Department of the British Museum, and strengthens

the views expressed at the time that these bodies, as well as the meteorite of Steinbach in the Erzgebirge, were probably members of the same fall, possibly of the 'Eisenregen,' reported by Sarcotorius to have fallen 'im Meissnischen' at Whitsuntide 1164.

The Rittersgrün siderolite was found in 1833 by a workman employed in clearing the forest, and offered for sale as old iron to a smith, but without success; but in 1861 it came to the notice of Breithaupt, and was secured for the mineral collection of the Bergakademie of Freiberg. Its mean diameter is 0·43 meter, and its weight 86·5 kilog. It has recently been sawn through in Vienna, a troublesome and costly work extending over two months. An excellent chromolithograph of the surface thus exposed was prepared by Prof. Weisbach in 1876, and published with a few notes.

The meshwork of nickel-iron of the siderolite encloses the following minerals: troilite, asmanite, bronzite, and chromite. The metallic portion constitutes about 51·06 per cent., and the non-metallic ingredients about 48·94 per cent. of the stone. The nickel-iron contains:

Fe	Ni	Co	Cu	P	S	Si	C	Asmanite
89·990	9·740	0·230	0·035	0·150	0·011	0·066	trace	0·956 = 100·278

which constituents may be arranged as follows:

Nickel iron, Fe ⁸⁹ Ni	98·995
Iron nickel phosphide, (FeNi) ⁴ P	0·293
Iron phosphide, Fe ² P	0·539
Iron silicide, Fe ² Si	0·330
Iron sulphide	0·030
Iron carbide	trace
Copper	0·035
Asmanite	0·056

100·278

The iron sulphide, regarded as troilite or monosulphide, when in the form of pieces, is not acted upon by the magnet, and when in the state of powder, but slightly so. The ratios of iron to sulphur in troilite and in magnetic pyrites differ in so small a degree that the analytical results do not always set the question at rest. Moreover it is a question whether the meteoric sulphide, associated as it is with nickel-iron, does not contain some of that metal as an ingredient. The numbers obtained in these analyses are as follows:

	Calculated	I	Found II	III
Iron	63·63	65·87	63·58	63·00
Nickel	—	1·40	—	1·02
Sulphur	36·37	34·27	36·42	35·27
Silicic acid	—	—	—	0·67
	100·00	101·54	100·00	99·96

The asmanite appears to have the density of 2·274–2·278, and the following composition:

	I	II
Silica	95·77*	97·84
Ferric oxide	3·16	1·65
Lime and magnesia	trace	—
Loss on ignition	1·07	1·01
	100·00	100·50

As regards the crystalline form of this mineral, Weisbach considers that the recent researches of Schuster and of von Lasaulx have placed almost beyond doubt the identity of tridymite and asmanite. It occurred to Winkler that the relative solubility of tridymite and asmanite in potash-solution should be determined, and in as nearly possible parallel experiments as could be devised, and it was found that of tridymite from Siebenbürgen 49·63 parts, and of the asmanite of the siderolite from Rittersgrün 43·88 parts were dissolved.

The bronzite, the most important of the non-metallic minerals, was obtained in a pure state with comparative ease. It is but slightly affected by the blowpipe, and is not acted upon by acids, with the exception of hydrogen fluoride. Its sp. gr. is 3·310. It has the following composition:

* By difference.

	I	II	III
Silicic acid	57.27	56.56	56.56
Alumina	2.28	2.05	2.04
Ferrous oxide	10.99	10.74	10.09
Manganous oxide	0.41	0.42	0.55
Magnesia	24.78	25.13	25.59
Lime	1.77	2.52	1.66
Soda	not deter.	1.42	1.43
Chromite	0.94	0.98	0.98
	98.44	99.83	98.90

No trace of olivine was met with in this meteorite.

Heated in a vacuum, it lost 0.23 per cent. of its weight, and the gas evolved took fire, but was so small in quantity that it could not be further examined. The meteorite possesses the 'crust of fusion' in a well-developed form; it is of about the thickness of a piece of paper, and close under it are found the mixtures of the minerals troilite, asmanite, and bronzite of an unaltered light brown colour, although they turn deep black when raised to a temperature slightly above that at which lead melts.

Grosnaja, Banks of the Terek, Caucasus. June 28, 1861, 7 A.M. (*Mineralog. und Petrographischen Mittheilungen*, 1877, 153).—Some sixteen years ago Abich sent a description of this fall to G. Rose in Berlin. It appears that most of the stones fell into the Terek; one, however, which resembles a colossal hailstone, penetrated the ground to the depth of $1\frac{1}{2}$ feet, and was taken out while still warm. The crust was to a considerable extent removed; the density of the stone is 3.7. A report by the military authorities has recently been prepared, and it appears in Tschermak's paper, together with his notes on an examination of the stones.

The fall appears to have been attended with a great deal of noise, like the firing of cannon followed by a fusillade. The stone secured fell within 30 paces of the bank of the Terek. When taken out, it was found to weigh in all 10 lbs. Many heard a second sound, as though the meteorite burst twice in its descent through the atmosphere, and the noise attending the fall was heard 8 versts distant on the other side of the Terek. The water fizzed just as it would if brought in contact with a heated iron.

A system of cracks and fissures arrayed like the branches of a tree traverse the stone, giving the impression that they are the result of the blow which it received on its fall. The colour is blackish-grey with bright points. There are many enclosed mineral particles, some almost invisible, others 1 cm. across, the greater part having a diameter of less than 2 mm. The matrix is black and opaque, even when viewed in microscopic section, and many of the enclosed particles are opaque or only translucent in points. Most of these, however, are transparent, and the majority have a circular or rounded outline. Five distinct ingredients could be distinguished. The first is a clear greenish mineral, with incomplete cleavage along two directions, perpendicular to each other, and identified as olivine. A second in round tough spherules, brownish in hue, and not numerous, with a finely foliated or finely fibrous structure, was found to be bronzite. Enclosed particles are sometimes made up of these two minerals, sometimes, but not very frequently, of them together with a third silicate in long greenish prisms, which have the appearance and angles of augite. The meteorite also contains some magnetic pyrites (troilite?), a very little nickel-iron, and perhaps a little carbon, to which the dark hue of the matrix is due.

Two peculiarities observed in several chondritic meteorites are noticeable in this one. The first is the occurrence of a crust on the bronzite spherules possessing fibrous structure. This crust is thin, and is distinguished from the enclosed material by its paler colour; it has the same fibrous structure, doubly refractive power, and, in fact, is optically orientated like the enclosed silicate. It appears to have been produced by some agent acting from without, perhaps heat in conjunction with a reducing gas. The agent has not caused fusion, but a slight modification of the texture of the surface. The second peculiarity is the distribution in zones of the magnetic pyrites in many of the granular enclosed masses. When a section is examined by reflected light, it is found that many of these masses are apparently surrounded by a crust of the sulphide; in others it occupies the centre of the mass, in all cases apparently filling up interstices. It seems as if the sulphide had impregnated the rocky mass, and the absence of all magnetic pyrites in the very compact enclosed particles, and the tough fibrous bronzite chondra, confirms this view. It is believed that this impregnation took place after the enclosed mineral particles attained their present form, and the only explanation which can be suggested is that this must have happened while the whole tufaceous mass was strongly heated. The enclosed granules coming

in contact with fused magnetic pyrites must have drawn it into the fine fissures and interstices, in some instances into the cavities of the granules themselves. This implies the existence of two definite stages in the formation of these and similar chondritic structures: first, the production of the olivinous tuff by the splitting and attrition of the rock when the tougher particles are rolled and rubbed together till they have a roundish or spherular form; and secondly a subsequent application of heat to the tuff, accompanied not unfrequently by the reducing action of gases and vapours.

The stone consists of:

SiO ²	Al ² O ³	FeO	CaO	MgO	K ² O	Na ² O	C	H	Magnetic pyrites	
33.75	3.44	28.86	3.22	23.55	0.30	0.63	0.68	0.17	5.37	= 100

Olivine appears to be the prevailing silicate of the meteorite. In addition to bronzite there appears to be a little augite and felspar.

Roda, Province of Huesca, Spain. Spring of 1871 (*Compt. rend.* lxxix. 1507 and 1509).—This stone fell at a spot two kilometers from Roda; the exact date of its fall is not known. It is covered with a black crust; the interior is ashy-grey with greenish grains resembling peridot, some several mm. in diameter, scattered throughout the mass. The grey surface is, however, not of a uniform tint, but presents two irregularly-shaped areas, one grey, the other yellowish-grey. The stone is very friable. Before the blowpipe it is fusible, becoming black and feebly magnetic.

Only 14.75 per cent. of the stone is acted upon by acid, the portion unacted upon amounting to 85.97 per cent. Below are given, in addition to the composition of the constituents separated by acid, the results of an analysis of the minerals constituting the mass of the stone:

	SiO ²	Al ² O ³	Cr ² O ³	FeO	CaO	MgO	K ² O	Na ² O	S	
A. Soluble.	38.85	4.81	—	24.27	8.21	23.86	—	—	—	= 100.00
B. Insoluble.	52.93	1.95	0.39	16.29	1.92	26.52	—	—	—	= 100.00
C. Total.	51.51	2.30	0.34	17.04	2.31	26.61	0.80	0.40	—	= 101.31

The soluble portion appears to be an iron olivine, mixed probably with a little anorthite; the insoluble portion consists chiefly of bronzite, or, according to Pisani, probably hypersthene, with the specific gravity of which mineral that of the meteorite more closely accords. The sulphur and chromium are, it is presumed, present as magnetic pyrites and chromite; no nickel whatever was detected.

The yellowish grains are very slightly attacked by acid, only 6 per cent. being soluble in that reagent. Their composition proved to be:

Silica	51.10	27.3
Alumina	2.83	1.3
Ferrous oxide	27.70	11.1
Magnesia	17.20	3.8
						98.83	44.9

These numbers indicate, according to Pisani's view, the presence of a hypersthene rather than a bronzite, a hypersthene richer in iron than that of Farsund, Norway. The ratio of iron oxide to magnesia is the same as that of the bronzites of the Hainholz, Shalka, Borkut, and several other stones.

On some grains of the mineral a well-marked cleavage was distinguished along one direction; in others a disposition to cleave along a second direction was remarked; on examining such fragments in the polarising microscope, however, one of the optic axes was almost always seen, while the other is invisible. The angle of the optic axes, as measured in oil, was approximately determined, making $2H=104^\circ$. The bisectrix is negative; but whether it was the acute or obtuse bisectrix was not determined.

Daubrée's examination points to the chief constituent of this stone being bronzite rather than hypersthene. The absence of dichroism, the frequent occurrence of the right angle in the contour of the crystals, and the fineness of the striae peculiar to bronzite, were noticed. Magnified 800 diameters, most of the crystals are seen to enclose yellowish-brown rarely translucent matter with very varied contour, and occasionally with a crystalline form, that of a modified oblique prism, which is that of pyroxene. They are ranged in rectilinear series, which are not always orientated parallel to the axes of the crystal. The Roda meteorite, with the single exception that it contains no iron, bears a great likeness to the meteorite of Lodran (1868, October 1), and establishes a new link between cosmical rocks and those belonging to our planet. If, says Daubrée, we were to refuse to admit the testimony of those who affirm that they witnessed the fall of this fragment of rock, the characters of its crust would fully attest its cosmical origin.

Orvinio (formerly Canemorto), near Rome. 1872, August 31, 5.15 A.M. (*Compt. rend.* lxxv. 655; G. S. Ferrari, *Ricerche fisico-astronomiche intorno all' Uranolito caduto nell' agro Romano*, Rome, Tip. Bel. Arti. 1873; P. Keller, *Pogg. Ann.* cl. 171; *Min. Mitth.* 1874, 258; M. Le Chev. Michel-Etienne de Rossi and G. Bellucci, *Atti del' Acc. pontif. di Nuovi Lincei*, 1873; *Les Mondes*, Dec. 25; 1873; L. Sipőcz, *Min. Mitth.* 1874, 244; G. Tschermak, *Sitz. Ak. Wiss. Wien.* lxx. Novem. 1874). A meteor was seen at daybreak in the provinces of Rome, Umbria, Abruzzo, and Terra di Lavoro. It resembled a large red star, increasing in brilliancy as it travelled northwards, and leaving a white train. Two reports were heard, the second over Orvinio, where the greater part of the stone fell. Six fragments were found, weighing collectively 3.396 kilog. In September 1873 two more small fragments were heard of at Anticoli Corradi.

The mass of the stone is of a lead-grey colour; the ground-mass appears to be made up of two minerals, one clear and uniform, the other dull and less homogeneous. The stone acts powerfully on the magnet.

In the paper of M. le Chevalier Michel-Etienne de Rossi analyses of the stone are given, according to which it contains 16.84 per cent. of alumina and some arsenic. This is far in excess of that found in any other meteorite, and in the absence of a second and confirmatory analysis may be assumed to consist in part of magnesia thrown down with the alumina through the employment of insufficient ammonium chloride. The occurrence of arsenic is of extreme rarity; it is stated to be present in the iron of Braunau and the olivine of the Atacama meteorite.

Tschermak finds, on cutting this stone, that its structure is unusual and remarkable, consisting of light-coloured fragments (I) surrounded by a compact dark cementing material (II). The former are yellowish-grey, enclose spherules and particles of iron and magnetic pyrites, and are in fact normal chondrite, and resemble the mass of the stone which fell at Seres, Macedonia (June 1818). The latter enclose numerous particles of iron and magnetic pyrites, for the most part uniformly distributed; the portion nearest the enclosed fragments bears very distinct indications of having been at one time fluid, and conveys the impression that this cementing material was at one time in a plastic condition while in motion. Both parts have nearly the same density, and apparently the same chemical composition and mineral characteristics. The Orvinio stone resembles certain brecciated volcanic rocks, which consist of a ground-mass through which granular fragments of the same rock are distributed, as when older crystalline lavas are interpenetrated by others more compact and of a more recent date.

The meteoric rocks possessing chondritic structure are regarded by Tschermak as tufas which have undergone detritation, and their spherules as particles which, by their superior toughness, have acquired a rounded form during the trituration of the rock, instead of breaking up into splinters.

The dark-coloured cementing material contains two ingredients: an opaque semi-vitreous constituent, and particles in every way similar to the dark crust of the fragments from which they may probably have been detached; many of them can still be recognised as olivine and bronzite.

The two species of rock, the chondritic fragments with the sp. gr. 3.675 (I), and the darker cementing material, with the sp. gr. 3.600 (II), have the following composition:

	SiO ^a	Al ^a O ^a	Cr ^a O ^a	FeO	MgO	CaO	Na ^a O	K ^a O	Fe	Ni	S
I. 38.01	2.22	trace	6.55	24.11	2.33	1.46	0.31	22.34	2.15	1.94	= 101.42
II. 36.82	2.31	trace	9.41	21.69	2.31	0.96	0.26	22.11	3.04	2.04	= 100.95

These analyses establish the similarity in composition of the two portions.

Castralia, Nash County, N. Carolina (*Sill. Am. J.* [3], viii. 147). May 14, 1874, 2.30 P.M.—A dozen or more stones fell, and although the fall took place by day, a luminous meteor was observed. The area over which the fragments fell was ten miles long by three wide. Three stones weighing 7.3 kilog. were found. The colour of the interior is in many parts a dark grey, owing to the presence of a large amount of nickel-iron; in the lighter portions are seen some white spots of a mineral which is doubtless enstatite.

The metallic part, 15.21 per cent., consists of:

$$\text{Iron} = 92.12; \text{nickel} = 6.20; \text{cobalt} = 0.41 \quad = 98.73$$

and the siliceous portions:

	SiO ^a	Al ^a O ^a	FeO	MgO	Na ^a O	S
A. Soluble . . .	38.01	0.46	17.51	41.27	—	1.01 = 98.26
B. Insoluble . . .	52.61	4.80	13.21	27.31	1.38	— = 99.31

The soluble silicate is an olivine in which the ratio of MgO to FeO is about 4 : 1; the insoluble part is a bronzite; and in addition to the minerals already mentioned,

the presence in the Castralia stones of small amounts of iron sulphide and anorthite was recognised.

Iowa County, State of Iowa (*Sill. Am. J.* ix. 459; x. 44, 206, 357; xi. 253). February 12, 1875; 10.30 A.M. (Chicago time).—*An Account of the Detonating Meteor of February 12, 1875*, by C. W. Irish, Iowa City, 1875; Delafontaine, *Bibliothèque Universelle*, Oct. 1875, 188; G. A. Daubrée, *L'Institut*, 1875 (Nos. 105-122); C. W. Gumbel, *Münch. Akad. Ber.* 1875, v. 313. A great number of large stones fell on this occasion, weighing in all 700 lbs., the largest being 120 lbs. in weight. Some passed so near the earth's surface that they clipped off the branches of trees. Three separate explosions of the fire-ball were noticed while still in view, and about two or three minutes after it had disappeared, three reports, resembling the discharge of the blast of a quarry, were heard.

The stones have the usual black crust. A preliminary chemical examination showed them to contain :

Nickel-iron = 12.53; troïlite = 5.82; silicates = 81.64 = 100.00

The nickel-iron consists of :

Iron = 89.04; nickel = 10.35; cobalt = 0.54 = 99.93

with traces of copper, phosphorus, and sulphur. The silicate contains iron, ferrous oxide, alumina, magnesia, and soda, with traces of lithia and potash, and is very similar in composition to a large class of meteorites notably represented by the stones which fell at Vouille (May 31, 1831), and Aumale, Algeria (August 25, 1865).

A. W. Wright collected and analysed the gases contained in this meteorite and arrived at the following results :

	I	II	III	IV	V
	At 100°	At 250°	Below red-heat	At low red-heat	At full red-heat
Carbon dioxide . . .	95.46	92.32	42.27	35.82	5.56
Carbon monoxide . . .	0.00 (?)	1.82	5.11	0.49	0.00
Hydrogen . . .	4.54	5.86	48.06	58.61	87.63
Nitrogen (calculated) . .	0.00	0.00	4.56	5.18	6.91
	100.00	100.00	100.00	100.00	100.00

The reader is referred to the *Amer. Jour. Sc.* for the papers subsequently published by Mallet and Wright on the question of the conditions under which gases are occluded by meteorites.

Prof. Gumbel finds the crust of this meteorite to possess a deep bottle-green or brownish-red colour, and to exhibit in polarised light all the characters of an amorphous vitreous mass. The composition of the stone, according to his analysis, is :

Meteorite iron	12.32
Troïlite	5.25
Silicate, decomposed by acid	48.11
Silicate, not acted upon by acid	34.32

100.00

The silicate decomposed by acid is an olivine, having the formula $2(\frac{2}{3}\text{MgO} + \frac{1}{3}\text{FeO}) \cdot \text{SiO}_2$, and the insoluble silicate gave the oxygen ratios : Silicic acid = 29.68; bases = 10.92. It appears not improbable that the silicate in this case was not completely decomposed during fusion. A plate accompanying Gumbel's paper shows a microscopic section of the meteorite exhibiting olivine, augite, meteoric iron, chromite, troïlite, particles of a reddish hue which resemble garnet, but refracting light doubly, and possessing optical characters which will not allow of their being identified with nosean; also chondra showing fibrous, radiate, and granular structure, as well as others which evidently consist of olivine, and some which are opaque and finely granular. The meteoric iron has a hackly angular, structure, and such an appearance as it would present if reduced to the metallic state in the position which it at present occupies.

Zsadány, Temesvár, the Banat, Hungary. March 31, 1875 (*Egyetértés és Magyar Újság*, April and June, 1875; *Verhand. Naturwiss. Med. Vereins zu Heidelberg*, 1878, ii. Heft. 2).—No meteor was seen; a sound as of platoon-firing was heard; and a small shower of black stones fell, some of which were cold when picked up. Sixteen stones in all were found, having an aggregate weight of 400 grams.

The finely-grained light-grey matrix encloses granules of magnetic pyrites (troïlite?), granules and plates of nickel-iron, and numerous dark-grey crystalline spherules, averaging $\frac{1}{2}$ mm. in diameter; one little sphere had a breadth of $3\frac{1}{2}$ mm. They had an excentric-radiate or contorted-radiate structure. A freshly broken surface of the

stone is studded with these chondra, and they are easily removed from the matrix. As regards their mineralogical aspect, the spherules are found to be of two kinds. One consists of small prisms of a rhombic mineral which has all the appearance of a variety of enstatite; others are found to possess the characters of olivine. An accessory mineral, transparent, pure, and with well-defined edges, differs from the rhombic augite in exhibiting no cleavage fissures, from olivine by the smoothness of its polished exterior, and from both of them by exhibiting distinct pleochroism with absorption, one tone being colourless, the other pale-red with a faint tinge of brown. It appears to be rhombic, and shows a close resemblance to a variety of hypersthene found by Cohen in a gabbro from S. Africa. The Zsadány stone resembles those which fell on different occasions at Lancé, Gopalpur, and Pultusk.

The portions soluble and insoluble in acid have the following composition :

	Soluble portion	Insoluble portion
Silica	44.56	56.71
Alumina	trace	2.32
Iron oxide	17.54	13.21
Lime	trace	1.77
Magnesia	37.90	25.99
	<hr/> 100.00	<hr/> 100.00

The stones appear to consist to the extent of three-fourths of a bronzite, the remaining fourth being an olivine in which the equivalents of $\text{MgO} : \text{FeO}$ are as 3.89 : 1, or approximately that which is often met with in meteoric olivines.

Feid-Chair, Corde de la Calle, Constantine. August 16, 1875 (about noon) (*Compt. rend.* 1877, lxxxiv. 70).—This meteorite fell at a spot named Feid-Chair, about 30 kilometers from La Calle, the descent being attended with the customary luminous appearance. It weighs 380 grams; all search to discover other stones proved of no avail. The stone has a black crust and a grey interior, in which particles of nickel-iron and troilite are imbedded. Spherules are recognised, but the matrix likewise exhibits a brecciated structure; grains of a dull black hue are also distributed through the mass. The Feid-Chair meteorite closely resembles the stones which fell at La Baffe (Sept. 13, 1822), Heredia, Costa Rica (April 1, 1857), Canellas, near Barcelona (May 14, 1861), and Khetree, Rajpootana (Jan. 19, 1867).

Rowton, near Wellington, Shropshire. April 20, 1876; 3.40 P.M.—A block of meteoric iron, weighing $7\frac{1}{2}$ lbs., was seen to fall at this place. Rain was falling heavily at the time, when a strange rumbling noise was heard, followed by a startling explosion like a discharge of heavy artillery, audible over an area several miles in extent among the neighbouring villages of Shropshire. The iron was found about an hour later; the hole it had made was probed, and it was discovered about 18 inches below the surface. The hole was nearly perpendicular, the meteorite having entered the ground almost vertically in a N.W. to S.E. direction, and when found it was quite warm. The mass is irregularly angular, and except at the point where it struck the ground, it is covered with a thin pellicle of magnetic oxide of iron. It was presented by the Duke of Cleveland to the British Museum. It is only the seventh aërosiderite, or meteoric iron, the fall of which has been witnessed, although upwards of a hundred iron masses have been discovered in different parts of the globe, which are undoubtedly meteoric, and two such have been found in Great Britain.

No analysis of this iron has yet been published.

Vavilovka, Gov. Cherson, Russia. 1876, June 7th (*Mém. de la Soc. nation. des Sciences nat. de Cherbourg*, xxi. 205).—It appears that at this time a large number of stones fell, and a noise as of thunder was heard. A stone examined by R. Prendal had a black crust 0.6–1.0 mm. thick, and a number of irregular and prominent bands. A cut section showed under a glass a fine-grained grey mass through which numberless white spots with angular boundaries are distributed. This meteorite is so brittle that the preparation of sections was attended with great difficulty. The metallic constituents are particles of nickel-iron distributed throughout the mass of the stone, and grains of a sulphide which are not magnetic. The specific gravity of this meteorite is 3.51, and an analysis by R. Prendal shows it to contain :

SiO_2	FeO^*	Al_2O_3	CaO	MgO	Alkalies	Iron sulphide	Ni
53.81	9.41	8.75	2.07	18.54	1.14	5.26	0.70 = 99.68

These numbers throw but little light on the minute constitution of the stone. It is to be classed with the chondrites.

Stålldalen, near Kopparberg, Örebro län, Sweden. June 28, 1876; 11.50

A.M. (*Föredrag i Mineralogi vid Akademiens årshögtid den 3 Aprill, 1877; Aftonbladets Artiebologs Tryckeri, Stockholm, 1877; Nature, July 19, 1877; Öfversigt af Kongl. Vetenskaps Akad. Förhandl. 1877, No. 4, p. 35*). A meteor traversed the greater part of Central Sweden in a W.N.W direction, and was plainly visible in very bright sunshine. A loud whistling noise was heard, followed by two sharp reports and others less loud resembling thunder. The fall of the meteorites was witnessed by eight or ten persons. The largest weighs $4\frac{1}{2}$ skulpund (1 lb. av. = 1.068 ltt. or skulpund). Ståldalen is a station on the Swedish Central Railway. Some of the meteorites which fell into the water were lost. The total number of stones found is eleven, and they weigh collectively 34 kilog. Lindström finds the total composition of one of these stones to be:

Silica	35.71	Soda	0.62
Phosphoric acid	0.30	Potash	0.15
Alumina	2.11	Iron	21.10
Chromium oxide	0.40	Nickel	1.61
Ferrous oxide	10.29	Cobalt	0.17
Manganous oxide	0.25	Phosphorus	0.01
Nickel monoxide	0.20	Sulphur	2.27
Lime	1.61	Chlorine	0.04
Magnesia	23.16		
			100.00

Of these ingredients, 4.51 per cent. constitute magnetic pyrites (?), and 14.65 per cent. nickel-iron, the composition of which appears to be:

Fe	Ni	Co	P
90.78	8.29	0.88	0.05 = 100.00

The portions (I) gelatinisable with and (II) unacted upon by acid have the following composition:

	SiO ²	P ² O ⁵	Al ² O ³	FeO	NiO	MnO	CaO	MgO	Na ² O	K ² O	Cl
I. 36.76	0.83	0.13	20.35	0.60	—	0.64	40.47	0.18	0.16	9.13 = 100.25	
II. 57.37	0.07	5.07	8.03	—	0.63	3.41	23.54	1.38	0.23	— = 99.73	

In the soluble portion the oxygen-ratio of acids to bases is 20.08 : 21.16, and in the insoluble part 30.64 : 15.08. In addition to olivine and bronzite, this meteorite appears to contain an insoluble felspar and a little apatite.

Rochester, Indiana. 1876, December 21, 9 P.M. (*Sill. Am. J.* [3], xiv. 219).—The course of this meteor was studied by Professor Kirkwood of Bloomington, Indiana, who considers the length of its observed track to be from 1000 to 1100 miles, one of the longest on record. Its height is supposed to have been 38 miles above the place where the fragment preserved fell from it. In various parts of its track it threw off fragments, accompanied with the usual rumbling noise. 'The pyrotechnic display is said to have been transcendently beautiful, hardly equalled or surpassed by any previous occurrence of the kind.' The only fragment preserved fell at Rochester and rebounded, falling finally on the surface without penetrating it. 'It is of the pisolitic variety, very friable, of a grey colour, easily crushed under the fingers into light powder and small globules, some of them *perfectly spherical*, of which the writer has some specimens 2 mm. in diameter.' It resembles the Ausun stone. The crust is dull black and quite rough. The composition of the stone appears to be approximately:

Bronzite and pyroxene minerals	46.00
Olivine minerals	41.00
Nickel-iron	10.00
Troilite	3.00
Chromite	0.15

and that of the portion soluble (I) 47.80 per cent., and insoluble in acid (II) 52.20 per cent.:

	SiO ²	FeO	Al ² O ³	CaO	MgO	Cr ² O ³	Na ² O
I. 34.55	27.75	—	—	36.38	—	0.46 = 99.14	
II. 57.81	11.04	0.23	5.31	24.97	0.10	0.84 = 100.30	

The spherules were isolated and examined; they contained 46.80 per cent. soluble silicate, and 53.20 insoluble silicate, the magnesia in the soluble part amounting to 34.48 per cent.; they are consequently merely concretions of the matrix of the stone. The nickel-iron contained:

Iron = 94.49; Nickel = 4.12; Cobalt = 0.51	= 99.12
--	---------

Warrenton, Missouri. 1877, January 3 (about sunrise) (*Sill. Am. J.* [3],

xiv. 222).—A sound was heard like the whistle of a locomotive, or like the passage of a cannon-ball through the air; it came from the north-west, and became louder and louder to four observers stationed at Warrenton. On looking up they saw a falling object strike a tree, breaking off the limbs and then coming to the ground with a crash. The stone was broken in pieces. It was supposed to have had a conical form and a length of 18 inches; the weight was estimated at 100 lbs., but only 10 to 15 lbs. weight of the fragments have been saved. No explosion or luminous phenomena were observed. It most closely resembles the Ormans stone (July 11, 1868). Its crust has an unusual thickness, being in places $2\frac{1}{2}$ to $3\frac{1}{2}$ mm. thick. The interior of the stone has a very dark uniform ash colour; it is soft and easily crushed, and has a specific gravity of 3.47.

The ratio of the constituent minerals is:

Olivine minerals	76.00
Bronzite and pyroxene minerals	18.00
Nickel-iron	2.00
Troilite	3.50
Chromite	0.50

80.40 per cent. of silicate is soluble in acid and has the composition under I; 19.60 per cent. of silicate, being insoluble in acid; it is given under II.

	SiO ²	FeO ²	Al ² O ³	CaO	MgO	Na ² O	NiO	CoO	Cr ² O ³	
I. Soluble.	33.02	37.57	0.12	trace	28.41	0.07	1.54	0.31	—	= 101.04
II. Insoluble.	56.90	10.20	0.20	7.62	22.41	1.00	—	—	0.33	= 97.66

The nickel-iron contains:

$$\text{Iron} = 88.51; \text{Nickel} = 10.21; \text{Cobalt} = 0.60 \quad = 99.32$$

Cynthiana, Kentucky. 1877, January 23, 4 P.M. (*Sill. Am. J.* [3], xiv. 224). A brilliant meteor was seen traversing Monroe County, Indiana, in a south-easterly direction; it was also observed at Decatur County, of the same state. The meteorite fell about sixty miles distant from these places, and appeared to descend almost vertically, accompanied with the usual noises. One mass was seen to fall, and was dug out of a hole thirteen inches deep. This stone is wedge-shaped, with one portion of it very extensively and regularly pitted, the rest being smooth. The crust is dull-black and perfect as when it fell. The stone weighs six kilograms; it is of the harder brecciated variety, and when broken presents a mottled surface identical with that of the Parnallee stone, which it resembles in every respect, even in density, which in both cases is 3.41. The constituent minerals of the meteorite appear to be:

Olivine minerals	50.00
Bronzite and pyroxene minerals	30.00
Nickel-iron	6.00
Troilite	5.50
Chromite	0.52

The silicates soluble in acid form 56.50 per cent. of the total silicates, and possess the composition given under I; those insoluble in acid amount to 43.50 per cent., and are given under II:

	SiO ²	FeO	Al ² O ³	CaO	MgO	Na ² O	Cr ² O ³	
I. Soluble.	33.65	30.83	0.11	trace	34.61	—	—	= 99.20
II. Insoluble.	57.60	11.42	0.43	5.70	23.97	1.24	0.38	= 100.74

The nickel-iron forming 5.93 per cent. of the meteorite consists of:

$$\text{Iron} = 90.64; \text{Nickel} = 8.35; \text{Cobalt} = 0.73 \quad = 99.72$$

Hungen, between Steinheim and Borsdorf, Province Oberhessen. 1877, May 17, 7 A.M. (*Min. Mitth.* 1877, 313).—An eyewitness of the fall of one of these meteorites states that, as he was passing through a wood, he heard a noise as of thunder, followed by a humming, hissing, whistling sound, such as would be caused by a number of stones quickly rushing among trees. One struck a pine tree close to him, severed a branch about the thickness of the finger, and fell at his feet. Buchner visited the spot five months later, and found a second stone weighing 26 grams. The first weighed 86 grams. The descent of the meteorite took place in the direction from north-west to south-east. The crust of this stone is dull black and thin; the fractured surface displays a grey, occasionally brown matrix, traversed by a very thin but very conspicuous brilliant black band of material; it runs obliquely to the flattened side of the stone, and is also found in the smaller mass picked up five months

later, which evidently never formed part of the larger meteorite. On part of the fractured surface of the larger stone a second black line, parallel to the first but less brilliant, is seen. Abundant particles of nickel-iron and troilite are met with; the crust appears to consist, to the extent of one half, of the metallic alloy. The ground-mass appears to be olivine; some olivine spherules are conspicuous, surrounded by the black material or by nickel-iron; other chondra have a banded or radiated structure, as in the stones of Shergotty or Gopalpur, and appear to be bronzite; and lastly there are spherules of a homogeneous grey translucent substance, devoid of or rarely traversed by fissures.

According to Tschermak's examination of the smaller stone, it approaches closely in its character to the Pultusk meteorites. The black crust has the unusual thickness of 1·5 mm., and encloses nickel-iron, magnetic pyrites (troilite?), and even lustreless chondra which may consist of chromite or picotite. Tschermak also determined the presence of granules of olivine, bronzite, and diallage, for such he believes to be the brown mineral, forming angular fragments, which are found not to be rhombic and to resemble an augite.

Cronstadt, Orange River Free State, South Africa. 1877, June.—A shower of stones fell near Cronstadt in June 1877, in a wooded district, so that few could be collected. One of them is preserved in the British Museum.
